Abstract

This paper applies conformal prediction to derive predictive distributions that are valid under a nonparametric assumption. Namely, we introduce and explore predictive distribution functions that always satisfy a natural property of validity in terms of guaranteed coverage for IID observations. The focus is on a prediction algorithm that we call the Least Squares Prediction Machine (LSPM). The LSPM generalizes the classical Dempster-Hill predictive distributions to regression problems. If the standard parametric assumptions for Least Squares linear regression hold, the LSPM is as efficient as the Dempster-Hill procedure, in a natural sense. And if those parametric assumptions fail, the LSPM is still valid, provided the observations are IID.

Keywords: Conformal prediction, Least Squares, predictive distributions, regression.

Let me conclude by observing that $A_{(n)}$ is supported by all of the serious approaches to statistical inference. It is Bayesian, fiducial, and even a confidence/tolerance procedure. It is simple, coherent, and plausible. It can even be argued, I believe, that $A_{(n)}$, along with $H_{(n)}$, constitutes the fundamental solution to the problem of induction.

Bruce M. Hill, 1988

To be truly useful, however, the methods need extension to regression models with unknown regression parameters.

Christian Genest and Jack Kalbfleisch, 1988

1. Introduction

This paper applies conformal prediction to derive predictive distribution functions that are valid under a nonparametric assumption. In our definition of predictive distribution func-
tions and their property of validity we follow Shen et al. (2017, Section 1), whose terminology we adopt, and Schweder and Hjort (2016, Chapter 12), who use the term “prediction confidence distributions”. The theory of predictive distributions as developed by Schweder and Hjort (2016) and Shen et al. (2017) assumes that the observations are generated from a parametric statistical model. We extend the theory to the case of regression under the general IID model (the observations are generated independently from the same distribution), where the distribution form does not need to be specified; however, our exposition is self-contained. Our predictive distributions generalize the classical Dempster–Hill procedure (to be formally defined in Section 5), which these authors referred to as direct probabilities (Dempster) and $A_{(n)}/H_{(n)}$ (Hill). For a relatively recent review of predictive distributions, see Lawless and Fredette (2005).

We start our formal exposition from defining conformal predictive distributions (CPDs), nonparametric predictive distributions based on conformal prediction, and algorithms producing CPDs (conformal predictive systems, CPSs) in Section 2; we are only interested in regression problems in this paper. An unusual feature of CPDs is that they are randomized, although they are typically affected by randomness very little. The starting point for conformal prediction is the choice of a conformity measure; not all conformity measures produce CPDs, but we give simple sufficient conditions. In Section 3 we apply the method to the classical Least Squares procedure obtaining what we call the Least Squares Prediction Machine (LSPM). The LSPM is defined in terms of regression residuals; accordingly, it has three main versions: ordinary, deleted, and studentized. The most useful version appears to be studentized, which does not require any assumptions on how influential any of the individual observations is. We state the studentized version (and, more briefly, the ordinary version) as an explicit algorithm. The next two sections, 4 and 5, are devoted to the validity and efficiency of the LSPM. Whereas the LSPM, as any CPS, is valid under the general IID model, for investigating its efficiency we assume a parametric model, namely the standard Gaussian linear model. The question that we try to answer in Section 5 is how much we should pay (in terms of efficiency) for the validity under the general IID model enjoyed by the LSPM. We compare the LSPM with three kinds of oracles under the parametric model; the oracles are adapted to the parametric model and are only required to be valid under it. The weakest oracle (Oracle I) only knows the parametric model, and the strongest one (Oracle III) also knows the parameters of the model. In important cases the LSPM turns out to be as efficient as the Dempster–Hill procedure. Section 6 is devoted to experimental results demonstrating the validity and, to some degree, efficiency of our methods.

2. Randomized and conformal predictive distributions

We consider the regression problem with $p$ attributes. Correspondingly, the observation space is defined to be $\mathbb{R}^{p+1} = \mathbb{R}^p \times \mathbb{R}$; its element $z = (x, y)$, where $x \in \mathbb{R}^p$ and $y \in \mathbb{R}$, is interpreted as an observation consisting of an object $x \in \mathbb{R}^p$ and its label $y \in \mathbb{R}$. Our task is, given a training sequence of observations $z_i = (z_i, y_i)$, $i = 1, \ldots, n$, and a new test object $x_{n+1} \in \mathbb{R}^p$, to predict the label $y_{n+1}$ of the $(n + 1)$th observation. Our statistical model is the general IID model: the observations $z_1, z_2, \ldots$, where $z_i = (x_i, y_i)$, are generated independently from the same unknown probability measure $P$ on $\mathbb{R}^{p+1}$.
We start from defining predictive distribution functions following Shen et al. (2017, Definition 1), except that we relax the definition of a distribution function and allow randomization. Let $U$ be the uniform probability measure on the interval $[0, 1]$.

**Definition 1** A function $Q : (\mathbb{R}^{p+1})^{n+1} \times [0, 1] \to [0, 1]$ is called a randomized predictive system (RPS) if it satisfies the following three requirements:

$R1a$ For each training sequence $(z_1, \ldots, z_n) \in (\mathbb{R}^{p+1})^n$ and each test object $x_{n+1} \in \mathbb{R}^p$, the function $Q(z_1, \ldots, z_n, (x_{n+1}, y), \tau)$ is monotonically increasing both in $y$ and in $\tau$ (where “monotonically increasing” is understood in the wide sense allowing intervals of constancy). In other words, for each $\tau \in [0, 1]$, the function

$$y \in \mathbb{R} \mapsto Q(z_1, \ldots, z_n, (x_{n+1}, y), \tau)$$

is monotonically increasing, and for each $y \in \mathbb{R}$, the function

$$\tau \in [0, 1] \mapsto Q(z_1, \ldots, z_n, (x_{n+1}, y), \tau)$$

is monotonically increasing.

$R1b$ For each training sequence $(z_1, \ldots, z_n) \in (\mathbb{R}^{p+1})^n$ and each test object $x_{n+1} \in \mathbb{R}^p$,

$$\lim_{y \to -\infty} Q(z_1, \ldots, z_n, (x_{n+1}, y), 0) = 0$$

and

$$\lim_{y \to \infty} Q(z_1, \ldots, z_n, (x_{n+1}, y), 1) = 1.$$

$R2$ As function of random training observations $z_1 \sim P, \ldots, z_n \sim P$, a random test observation $z_{n+1} \sim P$, and a random number $\tau \sim U$, all assumed independent, the distribution of $Q$ is uniform:

$$\forall \alpha \in [0, 1] : \mathbb{P}\{Q(z_1, \ldots, z_n, z_{n+1}, \tau) \leq \alpha\} = \alpha.$$

The output of the randomized predictive system $Q$ on a training sequence $z_1, \ldots, z_n$ and a test object $x_{n+1}$ is the function

$$Q_n : (y, \tau) \in \mathbb{R} \times [0, 1] \mapsto Q(z_1, \ldots, z_n, (x_{n+1}, y), \tau),$$

which will be called the randomized predictive distribution (function) (RPD) output by $Q$. The thickness of an RPD $Q_n$ is the smallest number $\epsilon \geq 0$ such that the diameter

$$Q_n(y, 1) - Q_n(y, 0)$$

of the set

$$\{Q_n(y, \tau) \mid \tau \in [0, 1]\}$$

is at most $\epsilon$ for all $y \in \mathbb{R}$ except for finitely many values. The exception size of $Q_n$ is the cardinality of the set of $y$ for which the diameter (2) exceeds the thickness of $Q$. Notice that a priori the exception size can be infinite.
In this paper we will be interested in RPDs of thickness \( \frac{1}{n+1} \) with exception size at most \( n \), for typical training sequences of length \( n \) (cf. (16) below). In all our examples, \( Q(z_1, \ldots, z_n, z_{n+1}, \tau) \) will be a continuous function of \( \tau \). Therefore, the set (3) will be a closed interval in \([0, 1]\). However, we do not include these requirements in our official definition.

Four examples of predictive distributions are shown in Figure 5 below as shaded areas; let us concentrate, for concreteness, on the top left one. The length of the training sequence for that plot (and the other three plots) is \( n = 10 \); see Section 6 for details. Therefore, we are discussing an instance of \( Q_{10} \), of width 1/11 with exception size 10. The shaded area is \( \{(y, Q_{10}(y, \tau)) \mid y \in \mathbb{R}, \tau \in [0, 1]\} \). We can regard \((y, \tau)\) as a coordinate system for the shaded area. The cut of the shaded area by the vertical line passing through a point \( y \) of the horizontal axis is the closed interval \([Q(y, 0), Q(y, 1)]\), where \( Q := Q_{10} \). The notation \( Q(y) \) for the vertical axis is slightly informal.

Next we give basic definitions of conformal prediction adapted to producing predictive distributions (there are several equivalent definitions; the one we give here is closer to Vovk et al. 2005, Section 2.2, than to Balasubramanian et al. 2014, Section 1.3). A conformity measure is a measurable function \( A : (\mathbb{R}^{p+1})^{n+1} \rightarrow \mathbb{R} \) that is invariant with respect to permutations of the first \( n \) observations: for any sequence \((z_1, \ldots, z_n) \in (\mathbb{R}^{p+1})^n\), any \( z_{n+1} \in \mathbb{R}^{p+1} \), and any permutation \( \pi \) of \( \{1, \ldots, n\} \),

\[
A(z_1, \ldots, z_n, z_{n+1}) = A(z_{\pi(1)}, \ldots, z_{\pi(n)}, z_{n+1}).
\]

Intuitively, \( A \) measures how large the label \( y_{n+1} \) in \( z_{n+1} \) is, based on seeing the observations \( z_1, \ldots, z_n \) and the object \( x_{n+1} \) of \( z_{n+1} \). A simple example is

\[
A(z_1, \ldots, z_n) := y_{n+1} - \hat{y}_{n+1},
\]

\( \hat{y}_{n+1} \) being the prediction for \( y_{n+1} \) computed from \( x_{n+1} \) and \( z_1, \ldots, z_n \) as training sequence (more generally, we could use the whole of \( z_1, \ldots, z_{n+1} \) as the training sequence).

The conformal transducer determined by a conformity measure \( A \) is defined as

\[
Q(z_1, \ldots, z_n, (x_{n+1}, y), \tau) := \frac{1}{n+1} \left\{ \left( i = 1, \ldots, n+1 \mid \alpha^y_i < \alpha^y_{n+1} \right) \right\} + \frac{\tau}{n+1} \left\{ \left( i = 1, \ldots, n+1 \mid \alpha^y_i = \alpha^y_{n+1} \right) \right\},
\]

where \((z_1, \ldots, z_n) \in (\mathbb{R}^{p+1})^n\) is a training sequence, \( x_{n+1} \in \mathbb{R}^p \) is a test object, and for each \( y \in \mathbb{R} \) the corresponding conformity score \( \alpha^y_i \) is defined by

\[
\alpha^y_i := A(z_1, \ldots, z_{i-1}, z_{i+1}, \ldots, z_n, (x_{n+1}, y), z_i), \quad i = 1, \ldots, n,
\]

\[
\alpha^y_{n+1} := A(z_1, \ldots, z_n, (x_{n+1}, y)).
\]

A function is a conformal transducer if it is the conformal transducer determined by some conformity measure. A conformal predictive system (CPS) is a function which is both a conformal transducer and a randomized predictive system. A conformal predictive distribution (CPD) is a function \( Q_n \) defined by (1) for a conformal predictive system \( Q \).

Any conformal transducer \( Q \) and Borel set \( A \subseteq [0, 1] \) define the conformal predictor

\[
\Gamma^A(z_1, \ldots, z_n, x_{n+1}, \tau) := \{ y \in \mathbb{R} \mid Q(z_1, \ldots, z_n, (x_{n+1}, y), \tau) \in A \}.
\]
Nonparametric predictive distributions based on conformal prediction

The standard property of validity for conformal transducers is that the values (also called p-values) $Q(z_1, \ldots, z_{n+1}, \tau)$ are distributed uniformly on $[0, 1]$ when $z_1, \ldots, z_{n+1}$ are IID and $\tau$ is generated independently of $z_1, \ldots, z_{n+1}$ from the uniform probability distribution $U$ on $[0, 1]$ (see, e.g., Vovk et al. 2005, Proposition 2.8). This property coincides with requirement R2 in the definition of an RPS and implies that the coverage probability, i.e., the probability of $y_{n+1} \in \Gamma^A(z_1, \ldots, z_n, x_{n+1})$, for the conformal predictor (8) is $U(A)$.

**Remark 2** The usual interpretation of (6) is that it is a randomized p-value for testing the null hypothesis of the observations being IID. In the case of CPDs, the informal alternative hypothesis is that $y_{n+1}$ is too small. Then (5) can be interpreted as a degree of conformity of the observation $(x_{n+1}, y_{n+1})$ to the remaining observations. Notice the one-sided nature of this notion of conformity: a label can only be strange (non-conforming) if it is too small; large is never strange.

**Defining properties of distribution functions**

Next we discuss why Definition 1 (essentially taken from Shen et al. 2017) is natural. The key elements of this definition are that (1) the distribution function $Q$ is monotonically increasing, and (2) its value is uniformly distributed. The following two lemmas show that these are defining properties of distribution functions of probability measures on the real line.

First we consider the case of a continuous distribution function; the justification for this case, given in the next lemma, is simpler.

**Lemma 3** Suppose $F$ is a continuous distribution function on $\mathbb{R}$ and $Y$ is a random variable distributed as $F$. If $Q : \mathbb{R} \to \mathbb{R}$ is a monotonically increasing function such that the distribution of $Q(Y)$ is uniform on $[0, 1]$, then $Q = F$.

In the general case we need randomization. Remember the definition of the lexicographic order on $\mathbb{R} \times [0, 1]$: $(y, \tau) \leq (y', \tau')$ is defined to mean that $y < y'$ or both $y = y'$ and $\tau \leq \tau'$.

**Lemma 4** Let $P$ be a probability measure on $\mathbb{R}$, $F$ be its distribution function, and $Y$ be a random variable distributed as $P$. If $Q : \mathbb{R} \times [0, 1] \to \mathbb{R}$ is a function that is monotonically increasing (in the lexicographic order on its domain) and such that the image $(P \times U)Q^{-1}$ of the product $P \times U$, where $U$ is the uniform distribution on $[0, 1]$, under the mapping $Q$ is uniform on $[0, 1]$, then, for all $y$ and $\tau$,

$$Q(y, \tau) = (1 - \tau)F(y-) + \tau F(y).$$  \hspace{1cm} (9)

Equality (9) says that $Q$ is essentially $F$; in particular, $Q(y, \tau) = F(y)$ at each point $y$ of $F$’s continuity. It is a known fact that if we define $Q$ by (9) for the distribution function $F$ of a probability measure $P$, the distribution of $Q$ will be uniform when its domain $\mathbb{R} \times [0, 1]$ is equipped with the probability measure $P \times U$.

The previous two lemmas suggest that properties R1a and R2 in the definition of RPSs are the important ones. However, property R1b is formally independent of R1a and R2 in our case of the general IID model (rather than a single probability measure on $\mathbb{R}$): consider, e.g., a conformity measure $A$ that depends only on the objects $x_i$ but does not depend on the labels $y_i$.  

5
Simplest example: monotonic conformity measures

We start from a simple but very restrictive condition on a conformity measure making the corresponding conformal transducer satisfy R1a. A conformity measure $A(z_1, \ldots, z_n)$ is monotonic if

- monotonically increasing in $y_{n+1}$,

$$y_{n+1} \leq y_{n+1}' \implies A(z_1, \ldots, z_n, (x_{n+1}, y_{n+1})) \leq A(z_1, \ldots, z_n, (x_{n+1}, y_{n+1}'));$$

- monotonically decreasing in $y_1$,

$$y_1 \leq y_1' \implies A((x_1, y_1), z_2, \ldots, z_n, z_{n+1}) \geq A((x_1, y_1'), z_2, \ldots, z_n, z_{n+1}).$$

(Because of the requirement of invariance (4), being decreasing in $y_1$ is equivalent to being decreasing in $y_i$ for any $i = 2, \ldots, n$.)

This condition implies that the corresponding conformal transducer (6) satisfies R1a by Lemma 5 below.

An example of a monotonic conformity measure is (5), where $\hat{y}$ is produced by the $K$-nearest neighbours regression algorithm:

$$\hat{y}_{n+1} := \frac{1}{K} \sum_{k=1}^{K} y(k)$$

is the average label of the $K$ nearest neighbours of $x_{n+1}$, where $y(1), \ldots, y(n)$ is the sequence $y_1, \ldots, y_n$ sorted in the order of increasing distances between $x_i$ and $x_{n+1}$ (we assume $n \geq K$ and in the case of ties replace each $y(i)$ by the average of $y_j$ over all $j$ such that the distance between $x_j$ and $x_{n+1}$ is equal to the distance between $x_i$ and $x_{n+1}$). This conformity measure satisfies, additionally,

$$\lim_{y \to \pm \infty} A(z_1, \ldots, z_n, (x_n, y)) = \pm \infty$$

and, therefore, the corresponding conformal transducer also satisfies R1b and so is an RPS and CPS.

Criterion of being a CPS

Unfortunately, many important conformity measures are not monotonic, and the next lemma introduces a weaker sufficient condition for a conformal transducer to be an RPS.

**Lemma 5** The conformal transducer determined by a conformity measure $A$ satisfies condition R1a if, for each $i \in \{1, \ldots, n\}$, each training sequence $(z_1, \ldots, z_n) \in (\mathbb{R}^{p+1})^n$, and each test object $x_{n+1} \in \mathbb{R}^p$, $\alpha_{n+1}^y - \alpha_i^y$ is a monotonically increasing function of $y \in \mathbb{R}$ (in the notation of (7)).

Of course, we can fix $i$ to, say, $i := 1$ in Lemma 5. We can strengthen the conclusion of the lemma to the conformal transducer determined by $A$ being an RPS (and, therefore, a CPS) if, e.g.,

$$\lim_{y \to \pm \infty} (\alpha_{n+1}^y - \alpha_i^y) = \pm \infty.$$
3. Least Squares Prediction Machine

In this section we will introduce three versions of what we call the Least Squares Prediction Machine (LSPM). They are analogous to the Ridge Regression Confidence Machine (RRCM), as described in Vovk et al. (2005, Section 2.3) (and called the IID predictor in Vovk et al. 2009), but produce (at least usually) distribution functions rather than prediction intervals.

The ordinary LSPM is defined to be the conformal transducer determined by the conformity measure

\[ A(z_1, \ldots, z_{n+1}) := y_{n+1} - \hat{y}_{n+1} \tag{10} \]

(cf. (5)), where \(y_{n+1}\) is the label in \(z_{n+1}\) and \(\hat{y}_{n+1}\) is the prediction for \(y_{n+1}\) computed using Least Squares from \(x_{n+1}\) (the object in \(z_{n+1}\)) and \(z_1, \ldots, z_n\) (including \(z_{n+1}\)) as training sequence. The right-hand side of (10) is the ordinary residual. However, two more kinds of residuals are common in statistics, and so overall we will discuss three kinds of LSPM. The deleted LSPM is determined by the conformity measure

\[ A(z_1, \ldots, z_{n+1}) := y_{n+1} - \hat{y}_{n+1}, \tag{11} \]

whose difference from (10) is that \(\hat{y}_{n+1}\) is replaced by the prediction \(\hat{y}_{n+1}\) for \(y_{n+1}\) computed using Least Squares from \(x_{n+1}\) and \(z_1, \ldots, z_n\) as training sequence (so that the training sequence does not include \(z_{n+1}\)). The version that will be most useful in this paper will be the "studentized LSPM", which is midway between ordinary and deleted LSPM; we will define it formally later.

Unfortunately, the ordinary and deleted LSPM are not RPS, because their output \(Q_n\) (see (1)) is not necessarily monotonically increasing in \(y\) (remember that, for conformal transducers, \(Q_n(y, \tau)\) is monotonically increasing in \(\tau\) automatically). However, we will see that this can happen only in the presence of high-leverage points.

Let \(\bar{X}\) stand for the \((n+1) \times p\) data matrix, whose \(i\)th row is the transpose \(x'_i\) to the \(i\)th object (training object for \(i = 1, \ldots, n\) and test object for \(i = n+1\)). The hat matrix for the \(n+1\) observations \(z_1, \ldots, z_{n+1}\) is

\[ \bar{H} = \bar{X}(\bar{X}'\bar{X})^{-1}\bar{X}'. \tag{12} \]

Our notation for the elements of this matrix will be \(\bar{h}_{i,j}\), \(i\) standing for the row and \(j\) for the column. For the diagonal elements \(\bar{h}_{i,i}\) we will use the shorthand \(\bar{h}_i\).

The following proposition can be deduced from Lemma 5 and the explicit form (analogous to Algorithm 1 below but using (21)) of the ordinary LSPM.

**Proposition 6** The function \(Q_n\) output by the ordinary LSPM (see (1)) is monotonically increasing in \(y\) provided \(\bar{h}_{n+1} < 0.5\).

The condition needed for \(Q_n\) to be monotonically increasing, \(\bar{h}_{n+1} < 0.5\), means that the test object \(x_{n+1}\) is not a very influential point. An overview of high-leverage points is given by Chatterjee and Hadi (1988, Section 4.2.3.1), where they start from Huber’s 1981 proposal to regard points \(x_i\) with \(\bar{h}_i > 0.2\) as influential.

The assumption \(\bar{h}_{n+1} < 0.5\) in Proposition 6 is essential:

**Proposition 7** Proposition 6 ceases to be true if the constant 0.5 in it is replaced by a larger constant.
The next two propositions show that for the deleted LSPM, determined by (11), the situation is even worse than for the ordinary LSPM: we have to require $\bar{h}_i < 0.5$ for all $i = 1, \ldots, n$.

**Proposition 8** The function $Q_n$ output by the deleted LSPM according to (1) is monotonically increasing in $y$ provided $\max_{i=1,\ldots,n} \bar{h}_i < 0.5$.

We have the following analogue of Proposition 7 for the deleted LSPM.

**Proposition 9** Proposition 8 ceases to be true if the constant 0.5 in it is replaced by a larger constant.

The best choice, from the point of view of predictive distributions, seems to be the studentized LSPM determined by the conformity measure

$$A(z_1, \ldots, z_{n+1}) := \frac{y_{n+1} - \hat{y}_{n+1}}{\sqrt{1 - \bar{h}_{n+1}}}$$

(intermediate between those for the ordinary and deleted LSPM: a standard representation for the deleted residuals is $(y_i - \hat{y}_i)/(1 - \bar{h}_i)$, $i = 1, \ldots, n + 1$; we ignore a factor independent of $i$ in the definition of internally studentized residuals in, e.g., Seber and Lee 2003, Section 10.2).

An important advantage of studentized LSPM is that to get predictive distributions we do not need any assumptions of low leverage.

**Proposition 10** The studentized LSPM is an RPS and, therefore, a CPS.

The studentized LSPM in an explicit form

We will give two explicit forms for the studentized LSPM (Algorithms 1 and 2); the versions for the ordinary and deleted LSPM are similar (we will give an explicit form only for the former, which is particularly intuitive). Predictive distributions (1) will be represented in the form

$$Q_n(y) := [Q_n(y, 0), Q_n(y, 1)]$$

(in the spirit of abstract randomized p-values of Geyer and Meeden 2005); the function $Q_n$ maps each potential label $y \in \mathbb{R}$ to a closed interval of $\mathbb{R}$. It is clear that in the case of conformal transducers this interval-valued version of $Q_n$ carries the same information as the original one: each original value $Q_n(y, \tau)$ can be restored as a convex mixture of the end-points of $Q_n(y)$; namely, $Q_n(y, \tau) = (1 - \tau)a + \tau b$ if $Q_n(y) = [a, b]$.

For the studentized residuals (13), we can easily obtain

$$\alpha_{n+1}^y - \hat{\alpha}_i^y = B_i y - A_i, \quad i = 1, \ldots, n,$$

in the notation of (7), where $y$ is the label of the $(n + 1)$th object $x_{n+1}$ and

$$B_i := \sqrt{1 - \bar{h}_{n+1} + \frac{\bar{h}_{i,n+1}}{\sqrt{1 - \bar{h}_i}}}.$$
Algorithm 1: Least Squares Prediction Machine

Data: a training sequence \((x_i, y_i) \in \mathbb{R}^p \times \mathbb{R}, i = 1, \ldots, n\), and a test object \(x_{n+1} \in \mathbb{R}^p\).

Set \(\bar{X}\) to the data matrix for the given \(n + 1\) objects \(x_1, \ldots, x_{n+1}\);

define the hat matrix \(\hat{H}\) by (12);

for \(i \in \{1, 2, \ldots, n\}\) do

- define \(A_i\) and \(B_i\) by (15) and (14), respectively;
- set \(C_i := A_i / B_i\);

end

sort \(C_1, \ldots, C_n\) in the increasing order obtaining \(C^{(1)} \leq \cdots \leq C^{(n)}\);

return the predictive distribution (16) for \(y_{n+1}\)

\[
A_i = \frac{\sum_{j=1}^{n} \hat{h}_{j,n+1} y_j}{\sqrt{1 - \hat{h}_{i,n+1}}} + \frac{y_i - \sum_{j=1}^{n} \hat{h}_{i,j} y_j}{\sqrt{1 - \hat{h}_i}}. \tag{15}
\]

We will assume that all \(B_i\) are defined and positive; this assumption will be discussed further at the end of this subsection.

Set \(C_i := A_i / B_i\) for all \(i = 1, \ldots, n\). Sort all \(C_i\) in the increasing order and let the resulting sequence be \(C^{(1)} \leq \cdots \leq C^{(n)}\). Set \(C^{(0)} := -\infty\) and \(C^{(n+1)} := \infty\). The predictive distribution is:

\[
Q_n(y) := \begin{cases} \left[ \frac{i}{n+1}, \frac{i+1}{n+1} \right] & \text{if } y \in (C^{(i)}, C^{(i+1)}) \text{ for } i \in \{0, 1, \ldots, n\} \\ \left[ \frac{i-1}{n+1}, \frac{i''+1}{n+1} \right] & \text{if } y = C^{(i)} \text{ for } i \in \{1, \ldots, n\}, \end{cases} \tag{16}
\]

where \(i' := \min\{j \mid C^{(j)} = C^{(0)}\}\) and \(i'' := \max\{j \mid C^{(j)} = C^{(i)}\}\). We can see that the thickness of this CPD is \(\frac{1}{n+1}\) with the exception size equal to the number of distinct \(C_i\), at most \(n\).

The overall algorithm is summarized as Algorithm 1. Remember that the data matrix \(\bar{X}\) has \(x_i', i = 1, \ldots, n + 1\), as its \(i\)th row; its size is \((n + 1) \times p\).

Finally, let us discuss the condition that all \(B_i\) are defined and positive, \(i = 1, \ldots, n\). By Chatterjee and Hadi (1988, Property 2.6(b)), \(\hat{h}_{i,n+1} = 1\) implies \(\hat{h}_{i,n+1} = 0\) for \(i = 1, \ldots, n\); therefore, the condition is equivalent to \(\hat{h}_i < 1\) for all \(i = 1, \ldots, n + 1\). By Mohammadi (2016, Lemma 2.1(iii)), this means that the rank of the extended data matrix \(\bar{X}\) is \(p\) and it remains \(p\) after removal of any one of its \(n + 1\) rows. If this condition is not satisfied, we define \(Q_n(y) := [0, 1]\) for all \(y\). This ensures that the studentized LSPM is a CPS.

The batch version of the studentized LSPM

There is a much more efficient implementation of the LSPM in situations where we have a large test sequence of objects \(x_{n+1}, \ldots, x_{n+m}\) instead of just one test object \(x_{n+1}\). In this case we can precompute the hat matrix for the training objects \(x_1, \ldots, x_n\), and then, when processing each test object \(x_{n+j}\), use the standard updating formulas based on the Sherman–Morrison–Woodbury theorem: see, e.g., Chatterjee and Hadi (1988, p. 23, (2.18)–(2.18c)). For the reader’s convenience we will spell out the formulas. Let \(X\) be the \(n \times p\) data matrix for the first \(n\) observations; its \(i\)th row is \(x_i'\), \(i = 1, \ldots, n\). Set

\[
g_i := x_i'(X'X)^{-1}x_{n+1}, \quad i = 1, \ldots, n + 1. \tag{17}
\]
Algorithm 2: Least Squares Prediction Machine (batch version)

Data: a training sequence \((x_i, y_i) \in \mathbb{R}^p \times \mathbb{R}, i = 1, \ldots, n\), and a test sequence \(x_{n+j} \in \mathbb{R}^p, j = 1, \ldots, m\).

Set \(X\) to the data matrix for the \(n\) training objects; set \(H = (h_{i,j})\) to the hat matrix (18);

\[
\text{for } j \in \{1, 2, \ldots, m\} \text{ do }
\]
set \(x_{n+1} := x_{n+j}\);

\[
\text{define an } (n + 1) \times (n + 1) \text{ matrix } \bar{H} = (\bar{h}_{i,j}) \text{ by (19) and (20)};
\]

\[
\text{for } i \in \{1, 2, \ldots, n\} \text{ do }
\]
define \(A_i\) and \(B_i\) by (15) and (14), respectively;

\[
\text{set } C_i := A_i/B_i
\]

\[
\text{end}
\]
sort \(C_1, \ldots, C_n\) in the increasing order obtaining \(C_1 \leq \cdots \leq C_n\);

\[
\text{return the predictive distribution (16) for the label of } x_{n+j}
\]

\[
\text{end}
\]

Finally, let \(H\) be the \(n \times n\) hat matrix

\[
H := X(X'X)^{-1}X'
\]

for the first \(n\) objects; its entries will be denoted \(h_{i,j}\), with \(h_{i,i}\) sometimes abbreviated to \(h_i\).

The full hat matrix \(\bar{H}\) is larger than \(H\), with the extra entries

\[
\bar{h}_{i,n+1} = \bar{h}_{n+1,i} = \frac{g_i}{1 + g_{n+1}}, \quad i = 1, \ldots, n + 1.
\]

(19)

The other entries of \(\bar{H}\) are

\[
\bar{h}_{i,j} = h_{i,j} - \frac{g_i g_j}{1 + g_{n+1}}, \quad i, j = 1, \ldots, n.
\]

(20)

The overall algorithm is summarized as Algorithm 2. The two steps before the for loop are preprocessing; they do not depend on the test sequence.

The ordinary LSPM

A straightforward calculation shows that the ordinary LSPM has a particularly efficient and intuitive representation (Burnaev and Vovk, 2014, Appendix A):

\[
C_i = \frac{A_i}{B_i} =  \hat{y}_{n+1} + (y_i - \hat{y}_i) \frac{1 + g_{n+1}}{1 + g_i},
\]

(21)

where \(\hat{y}_{n+1}\) and \(\hat{y}_i\) are the Least Squares predictions for \(y_{n+1}\) and \(y_i\), respectively, computed from the test objects \(x_{n+1}\) and \(x_i\), respectively, and the observations \(z_1, \ldots, z_n\) as the training sequence. The predictive distribution is defined by (16). The fraction \(\frac{1 + g_{n+1}}{1 + g_i}\) in (21) is typically and asymptotically (at least under the assumptions A1–A4 stated in the next section) close to 1, and can usually be ignored. The two other versions of the LSPM also typically have

\[
C_i \approx \hat{y}_{n+1} + (y_i - \hat{y}_i).
\]

(22)
4. A property of validity of the LSPM in the online mode

In the previous section (cf. Algorithm 1) we defined a procedure producing a “fuzzy” distribution function $Q_n$ given a training sequence $z_i = (x_i, y_i)$, $i = 1, \ldots, n$, and a test object $x_{n+1}$. In this and following sections we will use both notation $Q_n(y)$ (for an interval) and $Q_n(y, \tau)$ (for a point inside that interval, as above). Remember that $U$ is the uniform distribution on $[0, 1]$.

Prediction in the online mode proceeds as follows:

**Protocol 1** Online mode of prediction

Nature generates an observation $z_1 = (x_1, y_1)$ from a probability distribution $P$; 
for $n = 1, 2, \ldots$ do

- Nature independently generates a new observation $z_{n+1} = (x_{n+1}, y_{n+1})$ from $P$;
- Forecaster announces $Q_n$, a predictive distribution based on $(z_1, \ldots, z_n)$ and $x_{n+1}$;
- set $p_n := Q_n(y_{n+1}, \tau_n)$, where $\tau_n \sim U$ independently

end for

Of course, Forecaster does not know $P$ and $y_{n+1}$ when computing $Q_n$.

In the online mode we can strengthen condition R2 as follows:

**Theorem 11** In the online mode of prediction (in which $(z_i, \tau_i) \sim P \times U$ are IID), the sequence $(p_1, p_2, \ldots)$ is IID and $(p_1, p_2, \ldots) \sim U^\infty$, provided that Forecaster uses the studentized LSPM (or any other conformal transducer).

The property of validity asserted in Theorem 11 is marginal, in that we do not assert that the distribution of $p_n$ is uniform conditionally on $x_{n+1}$. Conditional validity is attained by the LSPM only asymptotically and under additional assumptions, as we will see in the next section.

5. Asymptotic efficiency

In this section we obtain some basic results about the LSPM’s efficiency. The LSPM has a property of validity under the general IID model, but a natural question is how much we should pay for it in terms of efficiency in situations where narrow parametric or even Bayesian assumptions are also satisfied. This question was asked independently by Evgeny Burnaev (in September 2013) and Larry Wasserman. It has an analogue in nonparametric hypothesis testing: e.g., a major impetus for the wide-spread use of the Wilcoxon rank-sum test was Pitman’s discovery in 1949 that even in the situation where the Gaussian assumptions of Student’s $t$-test are satisfied the efficiency (“Pitman’s efficiency”) of the Wilcoxon test is still 0.95.

In fact the assumptions that we use in our theoretical study of efficiency are not comparable with the general IID model used so far: we will add strong parametric assumptions on the way labels $y_i$ are generated given the corresponding objects $x_i$ but will remove the assumption that the objects are generated randomly in the IID fashion; in this section $x_1, x_2, \ldots$ are fixed vectors. (The reason being that the two main results of this section, Theorems 12 and 13, do not require the assumption that the objects are random and IID.) Suppose that, given the objects $x_1, x_2, \ldots$, the labels $y_1, y_2, \ldots$ are generated by the rule

$$y_i = w^T x_i + \xi_i, \quad (23)$$
where \( w \) is a vector in \( \mathbb{R}^p \) and \( \xi_i \) are independent random variables distributed as \( N(0, \sigma^2) \) (the Gaussian distribution being parameterized by its mean and variance). There are two parameters: vector \( w \) and positive number \( \sigma \). We assume an infinite sequence of observations \((x_1, y_1), (x_2, y_2), \ldots \) but take only the first \( n \) of them as our training sequence and let \( n \to \infty \). These are all the assumptions used in our efficiency results:

**A1** As \( i \to \infty, \|x_i\| = o(i^{1/4}) \).

**A2** The first component of each vector \( x_i \) is 1.

**A3** The empirical second-moment matrix has its smallest eigenvalue eventually bounded away from 0:

\[
\lim \inf_{n \to \infty} \lambda_{\min} \left( \frac{1}{n} \sum_{i=1}^{n} x_i x_i' \right) > 0,
\]

where \( \lambda_{\min} \) stands for the smallest eigenvalue.

**A4** The labels \( y_1, y_2, \ldots \) are generated according to (23): \( y_i = w' x_i + \xi_i \), where \( \xi_i \) are independent Gaussian noise random variables distributed as \( N(0, \sigma^2) \).

Alongside the three versions of the LSPM, we will consider three “oracles” (at first concentrating on the first two). Intuitively, all three oracles know that the data is generated from the model (23). Oracle I knows neither \( w \) nor \( \sigma \) (and has to estimate them from the data or somehow manage without them). Oracle II does not know \( w \) but knows \( \sigma \). Finally, Oracle III knows both \( w \) and \( \sigma \).

Formally, **proper Oracle I** outputs the standard predictive distribution for the label \( y_{n+1} \) of the test object \( x_{n+1} \) given the training sequence of the first \( n \) observations and \( x_{n+1} \), namely it predicts with

\[
\hat{y}_{n+1} + \sqrt{1 + g_{n+1} \hat{\sigma}_n} t_{n-p},
\]

where \( g_{n+1} \) is defined in (17),

\[
\hat{y}_{n+1} := x'_{n+1} (X'X)^{-1} X'Y, \quad \hat{\sigma}_n := \sqrt{\frac{1}{n-p} \sum_{i=1}^{n} (y_i - \hat{y})^2}, \quad \hat{y}_i := x'_i (X'X)^{-1} X'Y,
\]

\( X \) is the data matrix for the training sequence (the \( n \times p \) matrix whose \( i \)th row is \( x_i' \), \( i = 1, \ldots, n \)), \( Y \) is the vector \((y_1, \ldots, y_n)'\) of the training labels, and \( t_{n-p} \) is Student’s \( t \)-distribution with \( n - p \) degrees of freedom; see, e.g., Seber and Lee (2003, Section 5.3.1) or Wang et al. (2012, Example 3.3). The version that is more popular in the literature on empirical processes for residuals is **simplified Oracle I** outputting

\[
N\left( \hat{y}_{n+1}, \hat{\sigma}_n^2 \right).
\]

The difference between the two versions, however, is asymptotically negligible (Pinelis, 2015), and the results stated below will be applicable to both versions.

**Proper Oracle II** outputs the predictive distribution

\[
N\left( \hat{y}_{n+1}, (1 + g_{n+1}) \sigma^2 \right).
\]
Correspondingly, simplified Oracle II outputs the predictive distribution

\[ N\left(\hat{y}_{n+1}, \sigma^{2}\right); \tag{27} \]

the difference between the two versions of Oracle II is again asymptotically negligible under our assumptions. For future reference, Oracle III outputs the predictive distribution

\[ N\left(w'x_{n+1}, \sigma^{2}\right). \]

Our notation is \( Q_n \) for the conformal predictive distribution (1), as before, \( Q_n^I \) for simplified or proper Oracle I’s predictive distribution, (25) or (24) (Theorem 12 will hold for both), and \( Q_n^{III} \) for simplified or proper Oracle II’s predictive distribution, (27) or (26) (Theorem 13 will hold for both). Theorems 12 and 13 are applicable to all three versions of the LSPM.

**Theorem 12** The random functions \( G_n : \mathbb{R} \rightarrow \mathbb{R} \) defined by

\[ G_n(t) := \sqrt{n} \left( Q_n(\hat{y}_{n+1} + \hat{\sigma}_n t, \tau) - Q_n^I(\hat{y}_{n+1} + \hat{\sigma}_n t) \right) \]

weakly converge to a Gaussian process \( Z \) with mean zero and covariance function

\[ \text{cov}(Z(s), Z(t)) = \Phi(s) (1 - \Phi(t)) - \phi(s) \phi(t) - \frac{1}{2} st \phi(s) \phi(t), \quad s \leq t. \]

**Theorem 13** The random functions \( G_n : \mathbb{R} \rightarrow \mathbb{R} \) defined by

\[ G_n(t) := \sqrt{n} \left( Q_n(\hat{y}_{n+1} + \sigma t, \tau) - Q_n^{III}(\hat{y}_{n+1} + \sigma t) \right) \]

weakly converge to a Gaussian process \( Z \) with mean zero and covariance function

\[ \text{cov}(Z(s), Z(t)) = \Phi(s) (1 - \Phi(t)) - \phi(s) \phi(t), \quad s \leq t. \]

In Theorems 12 and 13, we have \( \tau \sim U \); alternatively, they will remain true if we fix \( \tau \) to any value in \([0, 1]\). For simplified oracles, we have \( Q_n^I(\hat{y}_{n+1} + \hat{\sigma}_n t) = \Phi(t) \) in Theorem 12 and \( Q_n^{III}(\hat{y}_{n+1} + \sigma t) = \Phi(t) \) in Theorem 13. Our proofs of these theorems (omitted in this version of the paper) are based on the representation (21) and the results of Mugantseva (1977) (see also Chen 1991, Chapter 2).

Applying Theorems 12 and 13 to a fixed argument \( t \), we obtain (dropping \( \tau \) altogether):

**Corollary 14** For a fixed \( t \in \mathbb{R} \),

\[ \sqrt{n} \left( Q_n(\hat{y}_{n+1} + \hat{\sigma}_n t) - Q_n^I(\hat{y}_{n+1} + \hat{\sigma}_n t) \right) \Rightarrow \mathcal{N}\left(0, \Phi(t)(1 - \Phi(t)) - \phi(t)^2 - \frac{1}{2} t^2 \phi(t)^2\right), \]

\[ \sqrt{n} \left( Q_n(\hat{y}_{n+1} + \sigma t) - Q_n^{III}(\hat{y}_{n+1} + \sigma t) \right) \Rightarrow \mathcal{N}\left(0, \Phi(t)(1 - \Phi(t)) - \phi(t)^2\right). \]

Figure 1 presents plots for the asymptotic variances, given in Corollary 14, for the two oracular predictive distributions: black for Oracle I (\( \Phi(t)(1 - \Phi(t)) - \phi(t)^2 - \frac{1}{2} t^2 \phi(t)^2 \) vs \( t \)) and blue for Oracle II (\( \Phi(t)(1 - \Phi(t)) - \phi(t)^2 \) vs \( t \)); the red plot will be discussed later in this section. The two asymptotic variances coincide at \( t = 0 \), where they attain their maximum of between 0.0908 and 0.0909.

We can see that under the Gaussian model (23) complemented by other natural assumptions, the LSPM is asymptotically close to the oracular predictive distributions for Oracles I and II, and therefore is approximately conditionally valid and efficient. On the other hand, Theorem 11 guarantees the marginal validity of the LSPM under the general IID model, regardless of whether (23) holds.
Comparison with the Dempster–Hill procedure

In this subsection we discuss a classical procedure that was most clearly articulated by Dempster (1963, p. 110) and Hill (1968, 1988); therefore, in this paper we refer to it as the Dempster–Hill procedure. Both Dempster and Hill trace their ideas to Fisher’s (1939, 1948) nonparametric version of his fiducial method, but Fisher was interested in confidence distributions for quantiles rather than predictive distributions. Hill (1988) also referred to his procedure as Bayesian nonparametric predictive inference, which was abbreviated to nonparametric predictive inference (NPI) by Frank Coolen (Augustin and Coolen, 2004). We are not using the last term since it seems that all of this paper falls under the rubric of “nonparametric predictive inference”. An important predecessor of Dempster and Hill was Jeffreys (1932), who postulated what Hill later denoted as $A_{(2)}$ (see Lane 1980 and Seidenfeld 1995 for discussions of Jeffreys’s paper and Fisher’s reaction).

The Dempster–Hill procedure is the conformal predictive system determined by the conformity measure

$$A(z_1, \ldots, z_{n+1}) = A(y_1, \ldots, y_{n+1}) = y_{n+1}$$

(28)

that ignores the objects $x_i$. It can be regarded as the special case of the LSPM for the number of attributes $p = 0$; alternatively, we can take $p = 1$ but assume that all objects are $x_i = 0$. The predictions $\hat{y}$ are always 0 and the hat matrices are $\hat{H} = 0$ and $H = 0$ (although the expressions (12) and (18) are not formally applicable), which means that (10), (11), and (13) all reduce to (28). It is easy to see that the predictive distribution becomes,
in the absence of ties (Dempster’s and Hill’s usual assumption),

\[ Q_n(y) := \begin{cases} 
\left[ \frac{i}{n+1}, \frac{i+1}{n+1} \right] & \text{if } y \in (y(i), y(i+1)) \text{ for } i \in \{0, 1, \ldots, n\} \\
\left[ \frac{i-1}{n+1}, \frac{i+1}{n+1} \right] & \text{if } y = y(i) \text{ for } i \in \{1, \ldots, n\}
\end{cases} \quad (29) \]

(cf. (16)), where \( y(1) \leq \cdots \leq y(n) \) are the \( y_i \) sorted in the increasing order, \( y(0) := -\infty \), and \( y(n+1) := \infty \). This is essentially Hill’s assumption \( A_n \) (which he also denoted \( A_{(n)} \)); in his words: “\( A_n \) asserts that conditional upon the observations \( X_1, \ldots, X_n \), the next observation \( X_{n+1} \) is equally likely to fall in any of the open intervals between successive order statistics of the given sample” (Hill, 1968, Section 1). The set of all continuous distribution functions \( F \) compatible with Hill’s \( A_{(n)} \) coincides with the set of all continuous distribution functions \( F \) satisfying \( F(y) \in Q_n(y) \) for all \( y \in \mathbb{R} \), where \( Q_n \) is defined by (29).

Notice that the LSPM, as presented in (22), is a very natural adaptation of \( A_{(n)} \) to the Least Squares regression.

Since (29) is a conformal transducer (provided a point from an interval in (29) is chosen randomly from the uniform distribution on that interval), we have the same guarantees of validity as those given above: the distribution of (29) is uniform over the interval \([0, 1]\).

As for efficiency, it is interesting that, in the most standard case of IID Gaussian observations, our predictive distributions for linear regression are as precise as the Dempster–Hill ones asymptotically when compared with Oracles I and II. Let us apply the Dempster–Hill procedure to the location/scale model \( y_i = w + \xi_i, i = 1, 2, \ldots \), where \( \xi_i \sim N(0, \sigma^2) \) are independent. As in the case of the LSPM, we can compare the Dempster–Hill procedure with three oracles (we consider only simplified versions): Oracle I knows neither \( w \) nor \( \sigma \), Oracle II knows \( \sigma \), and Oracle III knows both \( w \) and \( \sigma \).

It is interesting that Theorems 12 and 13 (and therefore the blue and black plots in Figure 1) are applicable to both the LSPM and Dempster–Hill predictive distributions. (The fact that the analogous asymptotic variances for standard linear regression are as good as those for the location/scale model was emphasized in the pioneering paper by Pierce and Kopecky 1979.) The situation with Oracle III is different. Donsker’s (1952) classical result implies the following simplification of Theorems 12 and 13, where \( Q_{(n)}^{III} \) stands for Oracle III’s predictive distribution (independent of \( n \)).

**Theorem 15** In the case of the Dempster–Hill procedure, the random function \( G_n : \mathbb{R} \to \mathbb{R} \) defined by

\[ G_n(t) := \sqrt{n} \left( Q_n(w + \sigma t, \tau) - Q_{(n)}^{III}(w + \sigma t) \right) = \sqrt{n} \left( Q_n(w + \sigma t, \tau) - \Phi(t) \right) \]

weakly converges to a Brownian bridge, i.e., a Gaussian process \( Z \) with mean zero and covariance function

\[ \text{cov}(Z(s), Z(t)) = \Phi(s)(1 - \Phi(t)), \quad s \leq t. \]

The variance \( \Phi(t)(1 - \Phi(t)) \) of the Brownian bridge is shown as the red line in Figure 1. However, the analogue of the process (30) does not converge in general for the LSPM (under this section’s assumption of fixed objects).

### 6. Experimental results

In this section we explore experimentally the validity and efficiency of the studentized LSPM.
Online validity

First we check experimentally the validity of our methods in the online mode of prediction. It is guaranteed by our theoretical results but provides an opportunity to test the correctness of our implementation.
We generate \( N := 1000 \) of IID observations \( z_1, \ldots, z_N \) and the corresponding p-values \( p_n := Q_n(y_{n+1}, \tau_n), n = 1, \ldots, N \), in the online mode. In our experiments, \( x_n \sim N(0, 1) \), \( y_n \sim 2x_n + N(0, 1) \), and, as usual, \( \tau_n \sim U \), all independent. Figure 2 plots \( S_n := \sum_{i=1}^n p_i \) vs \( n = 1, \ldots, N \); as expected, it is an approximately straight line with slope 0.5. Figure 3 presents three plots: the cumulative sums \( S_n^\alpha := \sum_{i=1}^n 1_{\{p_i \leq \alpha\}} \), where 1 is the indicator function, vs \( n = 1, \ldots, N \), for three values of \( \alpha \), \( \alpha \in \{0.25, 0.5, 0.75\} \). For each of the three \( \alpha \)s the result is an approximately straight line with slope \( \alpha \). Finally, Figure 4 plots \( A_N^\alpha \) against \( \alpha \in [0, 1] \), where \( A_N^\alpha := \frac{1}{N} \sum_{i=1}^N 1_{\{p_i \leq \alpha\}} \). The result is, approximately, the main diagonal of the square \([0, 1]^2\), as it should be.

Efficiency

Next we explore empirically the efficiency of the studentized LSPM. Figure 5 compares the conformal predictive distribution with the true (Oracle III’s) distribution for four randomly generated test objects and a randomly generated training sequence of length 10 with 2 attributes. The first attribute is a dummy all-1 attribute; remember that Theorems 12 and 13 depend on the assumption that one of the attributes is an identical 1 (without it, the plots become qualitatively different: cf. Chen 1991, Corollary 2.4.1). The second attribute is generated from the standard Gaussian distribution, and the labels are generated as \( y_n \sim 2x_{n,2} + N(0, 1) \), \( x_{n,2} \) being the second attribute. We also show (with thinner lines) the output of Oracle I and Oracle II, but only for the simplified versions, in order not to clutter the plots. Instead, in the left-hand plot of Figure 6 we show the first plot of Figure 5 that is normalized by subtracting the true distribution function; this time, we show the output of both simplified and proper Oracles I and II; the difference is not large but noticeable. The right-hand plot of Figure 6 is similar except that the training sequence is of length 100 and
Figure 5: Examples of true predictive distribution functions (black), their conformal estimates (represented by the shaded areas), and the distribution functions output by simplified Oracle I (red) and Oracle II (blue) for a tiny training sequence (of length 10 with two attributes, the first one being the dummy all-1 attribute); in black and white, the true predictive distribution functions are the thick lines, and Oracle I is always farther from them in the uniform metric than Oracle II is.

there are 20 attributes generated independently from the standard Gaussian distribution except for the first one, which is the dummy all-1 attribute; the labels are generated as before, $y_n \sim 2x_{n,2} + N(0, 1)$.

Since Oracle III is more powerful than Oracles I and II (it knows the true data-generating distribution), it is more difficult to compete with; therefore, the black line is farther from the shaded area than the blue and red line for all four plots in Figure 5. The estimated distribution functions being to the left of the true distribution functions is a coincidence: the four plots correspond to the values 0–3 of the seed for the R pseudorandom number generator, and for other seeds the estimated distribution functions are often to the right.
7. Conclusion

This paper introduces conformal predictive distributions in regression problems. Their advantage over the usual conformal prediction intervals is that a conformal predictive distribution $Q_n$ contains more information and can produce a plethora of prediction intervals: e.g., for each $\epsilon > 0$, \( \{ y \in \mathbb{R} \mid \epsilon / 2 \leq Q_n(y, \tau) \leq 1 - \epsilon / 2 \} \) is a conformal prediction interval at confidence level $1 - \epsilon$.

Acknowledgments

We are grateful to Teddy Seidenfeld for useful historical information. We also thank the anonymous referees of the conference version of this paper for helpful comments. This work has been supported by the EPSRC (grant EP/K033344/1), EU Horizon 2020 Research and Innovation programme (grant 671555), US NSF (grant DMS1513483), and Leverhulme Magna Carta Doctoral Centre.
