Abstract

Adhesive arachnoiditis (AA) is a chronic inflammation inside the dura and remains one of the most challenging diseases. We describe a case of treatment-resistant extensive AA that offers insight into surgical treatment selection. The patient had a 2-year history of progressive spastic gait and was diagnosed with syringomyelia caused by extensive AA. Although syringe-subarachnoid and subarachnoid-subarachnoid shunting resulted in recurrence within a short period, syringo-peritoneal shunting improved the symptoms and there was no recurrence. This case suggests that syringo-peritoneal cerebrospinal fluid (CSF) shunt drainage, which has previously been considered a further step, may be a first-surgery option for extensive AA.

Keywords: adhesive, arachnoiditis, shunt, syringomyelia

Introduction

Adhesive arachnoiditis (AA) is a chronic inflammation inside the dura that affects the meninges and results in fibrosis. It is caused by various factors, including previous spinal surgery, trauma, infection, and spinal injection of substances such as anesthetics or oil-based myelographic contrast materials.¹ Disturbance of cerebrospinal fluid (CSF) flow caused by AA leads to syringomyelia or tethering.²,³

It is recommended that cases of syringomyelia with progressive symptoms undergo surgical treatment to reduce the syrinx and to stabilize the neurological status.² Various surgical methods have been reported, and shunt placement is one of the options.²,⁴,⁵ There are various shunt procedures, such as subarachnoid–subarachnoid shunt, syringo-subarachnoid shunt, and syringo-peritoneal shunt. However, no criteria have been established governing which shunt procedures are appropriate for which situations.

We present a case of huge syringomyelia due to extensive AA in which syringo-peritoneal shunt was more effective than intrathecal shunt. This case suggests that syringo-peritoneal CSF shunt drainage, which was previously considered a further step, is worth consideration as the first-choice treatment for extensive AA.

Case Report

An 11-year-old girl presented to our department with a 2-year history of progressive spastic gait. She had a history of congenital hydrocephalus and had been treated with external drainage. During this external drainage treatment period, she suffered from severe bacterial meningitis. The hydrocephalus and meningitis were eventually well controlled and she had been living at home independently.

Magnetic resonance imaging (MRI) showed a huge syrinx formation extending from the C7 to L2 level (Figs. 1A–1C). No evidence of hindbrain herniation was detected. Contrast-enhanced computed tomography and MRI did not indicate any abnormalities that could cause a syrinx. The subarachnoid space disappeared from C7 to the conus medullaris level and appeared to be unaffected from the rostral of the C7 level and the caudal of the conus medullaris (Figs. 1D and 1E).
Based on these findings and her episode of meningitis, she was diagnosed with syringomyelia caused by extensive AA. We speculated that CSF would be managed by drainage from the affected lesion to the normal subarachnoid space, which was the rostral side of the C7 level and the caudal side of the conus medullaris. Accordingly, a syringe-subarachnoid shunt from the syrinx to the lower cervical level (for draining CSF to the intact region) and a subarachnoid–subarachnoid shunt from the lower cervical level to the cauda equina level (for sharing drained CSF within intact regions) were placed. During this operation, the thickened arachnoid, which was consistent with our diagnosis, was detected (Fig. 2A). Pia, arachnoid, and CSF looked normal at the C5/6 and L2 levels which were speculated to be unaffected regions. Postoperative MRI showed a reduction of the syrinx (Figs. 2B–2D), and the spasticity of the bilateral lower extremities was gradually improved. Weakness of the bilateral quadriceps muscle and the tibialis anterior muscle, which seemed to be masked by spasticity preoperatively, appeared. Rehabilitation improved the weakness, and she was able to walk with a cane.

Weakness of the bilateral quadriceps muscle and the tibialis anterior muscle gradually worsened 1 year after the surgery. MRI revealed that the syrinx had enlarged (Figs. 3A and 3B). Additionally, CSF retention was found at the dorsal area of the cauda equina where the tip of the shunt tube was located (Figs. 3B–3D).

The shunt tubes were not clogged because CSF retention was found at the dorsal area of the cauda equina where no CSF retention was identified before the first surgery. Therefore, it was speculated that CSF was not well managed within the intra-arachnoid space, and drainage to the extradural space appeared necessary. Thus, syringe-peritoneal shunt placement was planned for the second operation. The proximal end of the shunt was inserted through the small myelotomy at the T9 level and the distal end was connected to a medium-pressure valve (Medtronic, Goleta, CA, USA) and a peritoneal catheter. Postoperative MRI showed the diminished

size of the syrinx (Figs. 4A–4C) and her symptoms improved again. After rehabilitation, she was discharged and able to live at home independently. At 2 years post-surgery, she could walk with a cane and MRI showed that the syrinx had not grown larger.

**Discussion**

We reported a case of huge syringomyelia due to AA in which a syringo-peritoneal shunt was more effective than an intrathecal shunt. Although selection of the type of shunt procedure has often been discussed,\(^6-10\) it remains unsolved question. The experience from this case may provide us with some insight on this point.

Despite advances in surgical skills, treatment of syringomyelia due to AA remains a major challenge.\(^2,11\) Various surgical treatments have been reported and the ideal treatment remains controversial.\(^2,12-15\) Restoration of the spinal subarachnoid space and CSF flow with arachnoidolysis and

duraplasty can be curative and one of the best treatments because it resolves the main pathogenic factors responsible for syrinx formation and propagation.\textsuperscript{2,4,16,17} Although several authors have reported good results,\textsuperscript{2,3,11,17–19} its indication is limited to patients with focal arachnopathies since broad arachnoid dissection is technically difficult.\textsuperscript{14,17} It is also restricted by the risk of spinal cord damage and the postoperative recurrence of adhesion\textsuperscript{12,13} (Table 1). In this case, AA was too extensive to attempt arachnoidysis.

Shunt placement is another one of the most common treatments as a CSF diversion procedure.\textsuperscript{4,20} Shunt placement is selected when other causative treatments have failed or when arachnoidysis is impossible due to extensive adhesion. Syringomyelia with extensive AA is mainly treated with this procedure.\textsuperscript{2,3} Various shunt procedures, such as subarachnoid–subarachnoid, syringe-subarachnoid, syringe-pleural, and syringe-peritoneal, have been reported.\textsuperscript{2,5,13,14,17,21} Shunt surgery can be categorized into intrathecal shunt and extrathecal shunt. Intrathecal shunt includes subarachnoid–subarachnoid and syringe-subarachnoid shunting, with the intent of restoring CSF flow in the dural sac. Extrathecal shunt includes syringe-pleural and syringe-peritoneal shunting and can achieve CSF drainage (Table 1). The type of shunt procedure is selected based on patient findings. There are few articles in which these various shunt surgeries have been compared directly, however,\textsuperscript{6} and the criteria for the selection of the type of shunt procedure have not been well studied.

Although the patient’s symptoms improved temporarily, they recurred within a relatively short period. As there were no obvious intraoperative events such as blood contamination, the reason for recurrence within a short period was speculated to be an insufficiency of non-affected subarachnoid space. A syringe-subarachnoid shunt and a subarachnoid–subarachnoid shunt were placed in the first operation to allow CSF to communicate freely in the intrathecal intact subarachnoid spaces and syrinx. Although drained CSF needed to be well managed by the intact subarachnoid space for our first surgery to be successful, it is quite difficult to predict whether or not this will occur. On the other hand, a syringe-peritoneal shunt which was emplaced in the second surgery can achieved the restoration of CSF drainage outside the dural sac. Its effect may be easier to predict than that of an intrathecal shunt in extensive AA (Table 1). Scarring from surgery for AA can result in additional AA and make the syrinx firm. Therefore, multiple surgeries contribute to the perpetuation of a syrinx cavity\textsuperscript{22} and should be avoided if possible. Although syringo-peritoneal shunt drainage may have a relatively high risk of shunt dysfunction or infection\textsuperscript{4} and be considered a further step in the treatment of syringomyelia,\textsuperscript{21} a syringe-peritoneal shunt may be a first-surgery option of the first surgery for syringomyelia due to extensive AA, as was seen in this case.

To date, no established definition of extensive AA exists. MRI findings, such as central clumping of the nerve roots in the dural sac, peripheral adhesions and tethering of nerve roots, pial and dural enhancement, an enlarged central canal, and altered CSF and spinal cord signal, indicate AA.\textsuperscript{23} AA with such MRI findings that exceeds two spinal segments has been termed as “extensive” AA because it is related to a worse long-term postoperative outcome.\textsuperscript{23} This definition is a reasonable one. In this study, shunt surgery was selected only in 1 out of 92 cases.\textsuperscript{2} Although the long-term outcome of shunt surgery has yet to be reported, a syringe-peritoneal shunt may be worth considering for the first surgery if AA exceeds two spinal segments.

It is of note that these considerations are based on only a single case and the follow-up period may not be sufficient. A further study would be helpful to establish criteria for shunt procedure selection. Nevertheless, considering that syringomyelia due

Table 1 Pons and cons of treatment for syringomyelia due to extensive adhesive arachnoiditis

| Surgery | Pros | Cons |
|---------|------|------|
| Restoration of the spinal subarachnoid space and CSF flow | Curative | Technically difficult |
| Shunt placement | Intrathecal shunt | Restoration of CSF flow inside the dural sac | Risk of spinal cord damage |
| | Extrathecal shunt | Restoration of CSF flow outside the dural sac | Risk of further adhesion |

CSF: cerebrospinal fluid
to AA is a rare disease and that each case is quite unique, we believe that insight from a case report is also valuable.

In the second operation, a shunt valve was placed because it may be helpful to adjust the amount of CSF drainage to check if the tubes are clogged. Although there are several case reports in which shunt valves have been used for syringomyelia, limited research has been carried out to evaluate their usefulness. In addition, the valves are not designed for this purpose. Nevertheless, we think that valve implantation is worth considering in syringo-peritoneal shunt surgery as over-drainage has been reported to result in serious complications.

Conclusion

We reported a case of syringomyelia due to extensive AA. It is difficult to determine whether the intrathecal shunt is effective because it is impossible to know whether or not drained CSF can be managed within the intrathecal region. Syringo-peritoneal shunt may be a viable first-surgery option for syringomyelia due to extensive AA.

Patient Consent

The parents of the patient have consented to the submission of the case report for submission to the journal.
