Intestinal monocytes and macrophages are required for T cell polarization in response to *Citrobacter rodentium*

Heidi A. Schreiber,1 Jakob Loschko,1 Roos A. Karssemeijer,2 Amelia Escolano,1 Matthew M. Meredith,1 Daniel Mucida,2 Pierre Guermonprez,1,4 and Michel C. Nussenzweig1,3

Inducing specific immunity and maintaining tolerance requires cells of the mononuclear phagocyte lineage. This lineage is comprised of three closely related cell types: DCs, monocytes, and macrophages (Shortman and Naik, 2007; Geissmann et al., 2010a,b; Liu and Nussenzweig, 2010; Yona and Jung, 2010; Chow et al., 2011). DCs are essential to both immunity and tolerance (Steinman et al., 2003); however, the role monocytes and macrophages play in these processes is not as well defined (Geissmann et al., 2008).

In mice, DCs and monocytes arise from the same hematopoietic progenitor, known as the macrophage–DC progenitor (MDP; Fogg et al., 2006). Their development diverges when MDPs become either common DC progenitors (CDPs) that are Flt3L-dependent, or monocytes, which are dependent on CSF1 (M-CSF; Witmer-Pack et al., 1993; McKenna et al., 2000; Fogg et al., 2006; Waskow et al., 2008). CDPs develop into either plasmacytoid DCs or preDCs that leave the bone marrow to seed lymphoid and nonlymphoid tissues, where they further differentiate into conventional DCs (cDCs; Liu et al., 2009). In contrast, monocytes circulate in the blood and through tissues, where they can become activated and develop into several different cell types, including some but not all tissue macrophages (Schulz et al., 2012; Serbina et al., 2008; Yona et al., 2013).

Abbreviations used: CDC, conventional DC; CDP, common DC progenitor; LysM, lysozyme; MDP, macrophage–DC progenitor; mLN, mesenteric LN.

Dendritic cells (DCs), monocytes, and macrophages are closely related phagocytes that share many phenotypic features and, in some cases, a common developmental origin. Although the requirement for DCs in initiating adaptive immune responses is well appreciated, the role of monocytes and macrophages remains largely undefined, in part because of the lack of genetic tools enabling their specific depletion. Here, we describe a two-gene approach that requires overlapping expression of *LysM* and *Csf1r* to define and deplete monocytes and macrophages. The role of monocytes and macrophages in immunity to pathogens was tested by their selective depletion during infection with *Citrobacter rodentium*. Although neither cell type was required to initiate immunity, monocytes and macrophages contributed to the adaptive immune response by secreting IL-12, which induced Th1 polarization and IFN–γ secretion. Thus, whereas DCs are indispensable for priming naive CD4+ T cells, monocytes and macrophages participate in intestinal immunity by producing mediators that direct T cell polarization.

tissues, like the intestine or lung, or during inflammation when monocytes begin to express many features of DCs including high levels of MHCII and CD11c (Serbina et al., 2003; León et al., 2007; Hashimoto et al., 2011).

The function of cDCs in immunity and tolerance has been explored extensively using a series of different mutant mice to ablate all or only some subsets of cDCs (Jung et al., 2002; Liu and Nussenzweig, 2010; Chow et al., 2011). In contrast, the methods that are currently available to study the function of monocytes and macrophages in vivo are far more restricted and less specific (Witko-Sjoderzczak et al., 1990; Dai et al., 2002; MacDonald et al., 2010; Chow et al., 2011). For example, Ccr2−/− and Cre2DTR mice (Boring et al., 1997; Kuziel et al., 1997; Serbina and Pamer, 2006; Tsou et al., 2007) have been used to study monocytes (Boring et al., 1997; Peters et al., 2004; Hohl et al., 2009; Nakano et al., 2009). However, CCR2 is also expressed on some subsets of cDCs, activated CD4+ T cells, and NK cells (Kim et al., 2001; Hohl et al., 2009; Egan et al., 2009; Zhang et al., 2010). Thus, it is challenging to dissect the precise role of monocytes as opposed to other cell types in immune responses in Ccr2−/− or Cre2DTR mice. Inducible DTR expression in CD11cLysmCre mice (hereafter MMDTR mice) is far more specific (Diehl et al., 2013), but restricted to a small subset of mononuclear phagocytes.

Here, we describe a genetic approach to targeting monocytes and macrophages that spares cDCs and lymphocytes, and we compare the effects of monocyte and macrophage ablation to cDC depletion on the adaptive immune response to intestinal infection with Citrobacter rodentium.

RESULTS

**LysmCre × Csf1rLysmCre**

To target monocytes and macrophages in vivo, we combined two genes, the macrophage colony-stimulating factor receptor (M-CSF-R; Csf1r; CD115) and lysozyme (Ly6c; LysM), neither of which alone is entirely specific for these cells. Transgenic mice that carry a BAC encoding a human diphtheria toxin receptor-mCherry fusion protein (DTR-mCherry) preceded by a loxP-flanked transcriptional Stop element under the control of the Csf1r promoter (Csf1rLysmCre; Fig. 1 A) were crossed with mice that express CRE recombinase under the control of LysM (LysmCre; Clausen et al., 1999). LysM-expressing cells in LysmCre × Csf1rLysmCre mice (hereafter MMDDTR mice, for monocyte and macrophage) delete the Stop element, which permits transcription of DTR-mCherry specifically in LysM/Csf1r double-positive cells. To verify DTR-mCherry expression in monocytes but not cDCs in MMDDTR mice, we examined spleen cells by flow cytometry (Fig. 1 B). We found that Ly6ChighCD115+ spleen monocytes uniformly expressed mCherry, whereas MHCIIhighCD11chigh cDCs did not (Fig. 1 B). Thus, DTR-mCherry is expressed in monocytes but not cDCs in the spleen of MMDDTR mice.

To test for deletion, we injected MMDDTR mice with 4 ng of diphtheria toxin (DT) per gram of body weight (~100 ng per mouse). A single DT injection resulted in the complete loss of peripheral blood and bone marrow monocytes after 24 h (Ly6Chigh and Ly6Clow; Fig. 1 C). Peripheral blood Ly6Chigh monocytes returned to normal levels after 3 d and were present at super-physiological levels in blood on days 4 and 5 before returning to baseline after 6 d (Fig. 1 D). Consistent with their proposed precursor product relationship (Yona et al., 2013), Ly6Clow monocyte reconstitution lagged behind that of the Ly6Chigh population (Fig. 1 D). The increase in peripheral blood monocytes was associated with an 18-fold increase in the serum concentration of M-CSF 24 h after DT injection (Fig. 1 E). In contrast, serum concentrations of GM-CSF and Flt3L remained unchanged (unpublished data). We conclude that DT injection into MMDDTR mice results in efficient ablation of peripheral blood monocytes.

**Macrophages and inflammatory monocytes**

To examine the specificity of ablation in MMDDTR mice, we compared these mice with zDCDDTR (Meredith et al., 2012) and CD11cDTR mice (Jung et al., 2002). Because DT injection is fatal for zDCDDTR and CD11cDTR mice, we produced bone marrow chimeras for all three strains, as well as B6 controls. As expected, DT injection did not affect cDCs (CD11cMHCIIhigh) in MMDDTR or B6 controls, but ablated these cells in both zDCDDTR and CD11cDTR chimeras (Fig. 2 A). In contrast, all spleen monocytes (CD115+Ly6Chigh) were ablated in MMDDTR mice (Fig. 2 A), but not in zDCDDTR mice. Finally, steady-state T and B lymphocytes were unaffected by DT injection in MMDDTR mice (Fig. 2 B). We conclude that DT injection depletes monocytes, but not cDCs or lymphoid cells, in MMDDTR mice.

Monocytes can develop many of the features of cDCs under inflammatory conditions (Serbina et al., 2003; León et al., 2007; Hohl et al., 2009). For example, during infection with Listeria monocytogenes, monocytes develop into Tip DCs that express high levels of CD11c and MHCII and produce both TNF and iNOS (Serbina et al., 2003). However, despite their phenotypic resemblance to cDCs, these activated monocytes are depleted by DT injection in MMDDTR but not in zDCDDTR mice (Fig. 2 C; Meredith et al., 2012).

In addition to monocytes, tissue macrophages also express both LysM and Csf1r. To determine if splenic macrophages are deleted by DT injection in MMDDTR mice, we examined spleen sections by immunofluorescence (Hashimoto et al., 2011) using antibodies to identify red pulp (F4/80high), marginal zone (SIGNR1+), and marginal zone metallophilic (CD169+) macrophages. All three macrophage populations were entirely ablated by 24 h after DT injection (Fig. 2 D). Red pulp, peritoneal, lung alveolar and interstitial macrophages, and Kupffer cells were also depleted 24 h after DT injection in MMDDTR mice (Fig. 2 E).

We conclude that a two-gene approach that relies on both LysM and Csf1r gene expression results in specific ablation of monocytes, macrophages, and inflammatory monocytes, and does not affect conventional splenic DCs or lymphocytes.

**DCs, monocytes, and macrophages in the intestine**

The phenotype of immune cells in the intestine is altered in the intestine. The presence of these cells is maintained in the intestine. As a result,
Figure 1. MM\textsuperscript{DTR} mice. (A) Diagrammatic representation of Lysm\textsuperscript{Cre} (top) Csf1r\textsuperscript{Cre}\textsuperscript{-DTR} (middle) and MM\textsuperscript{DTR} (bottom) mice. Expression of Cre recombinase is under the control of LysM. Expression of a DTR–mCherry protein in BAC transgenic mice is under the control of CSF1R, but is inhibited by a loxp site-flanked Stop element. In MM\textsuperscript{DTR} mice, CSF1R-expressing cells that had expressed LysM express the DTR–mCherry fusion protein and can be deleted by DT.

(B) Flow cytometric analysis of mCherry expression on splenic monocytes (Lin\textsuperscript{neg}CD11b\textsuperscript{high}Ly6C\textsuperscript{high}CD115\textsuperscript{+}) and cDCs (Lin\textsuperscript{neg}CD11c\textsuperscript{high}MHCII\textsuperscript{high}). Lineage gating includes NK1.1, B220, CD19, Ly6G, and TCR\beta. (C) Flow cytometry plots of bone marrow (top) and peripheral blood (bottom) without (left) and 24 h after (right) DT injection. Cells gated on Lin\textsuperscript{neg}CD11b\textsuperscript{high}Ly6G\textsuperscript{neg}. (D) Monocyte abundance in peripheral blood at multiple time points after DT injection in B6 and MM\textsuperscript{DTR} mice. Percentage of the two major monocyte populations, Lin\textsuperscript{neg}CD11b\textsuperscript{high}Ly6G\textsuperscript{neg} (left) and Lin\textsuperscript{neg}CD11b\textsuperscript{high}CD115\textsuperscript{+}Ly6C\textsuperscript{high} (right) in the blood. (E) M-CSF concentrations in sera of DT-treated MM\textsuperscript{DTR} mice determined by ELISA at multiple time points after DT injection. Results represent two to three experiments with two to five mice per group and experiment. Error bars indicate SEM. *, P < 0.05; **, P < 0.01; ***, P < 0.001.
Figure 2. Depletion of monocytes, macrophages, and cDCs in CD11c<sup>DTI</sup>, zDC<sup>DTI</sup>, and MM<sup>DTI</sup> mice. (A) Flow cytometry plots of spleen cDCs (Gate 1, CD11<sup>hi</sup>C<sup>hi</sup>, gated on Lin<sup>-</sup>) and monocytes (Gate 2, Ly6C<sup>hi</sup>CD115<sup>+</sup>, gated on Lin<sup>-</sup>C<sup>lo</sup>C<sup>lo</sup>CD11b<sup>+</sup>). Bar graphs show percentage of cDCs and monocytes among total spleen cells 24 h after DT injection. Each data point corresponds to an individual mouse. (B) Bar graphs show percentage of CD4<sup+</sup> and CD8<sup+</sup> T and B lymphocytes among total spleen cells 24 h after DT injection. Results represent three mice per group. (C) Intracellular staining for TNF and iNOS in splenic monocytes from DT-injected B6 and MM<sup>DTI</sup> mice infected with <i>L. monocytogenes</i>. Gated on Lin<sup>-</sup>CD11b<sup>hi</sup>MHCII<sup>lo</sup>CD11c<sup>lo</sup> cells. Cells were stimulated ex vivo with heat-killed <i>L. monocytogenes</i>. Results represent two to three experiments with two to five mice per group and experiment. (D) Spleens from B6 and MM<sup>DTI</sup> mice 24 h after DT injection. Sections were stained with B220 (green) to visualize B cell zones and macrophage markers (red) to reveal metallophilic (CD169), marginal zone (SIGNR1), and red pulp (F4/80) macrophages. Bars, 100 µm. (E) Tissue macrophage depletion in B6 and MM<sup>DTI</sup> mice 24 h after DT injection. Results from one representative experiment with four mice per group. Error bars indicate SEM. *, P < 0.05; **, P < 0.01; ***, P < 0.001.
monocytes and macrophages acquire some of the features of cDCs including high levels of MHCII and CD11c expression, making it difficult to distinguish the two cell types (Bogunovic et al., 2012; Varol et al., 2010). To examine the origin of DC-like cells in the small intestine lamina propria and serosa, we compared bone marrow chimera of B6 control, MM<sup>DTR</sup>, zDC<sup>DTR</sup>, and CD11c<sup>DTR</sup> mice injected with DT. 18–24 h after injection, single-cell suspensions from the small intestine lamina propria or serosa/muscularis were analyzed by flow cytometry (Fig. 3 A). Cells that resembled DCs, due to their high-level expression of CD11c and MHCII, were further fractionated by CD103 (integrin αE) and CD11b expression (Bogunovic et al., 2009; Varol et al., 2010).

CD103<sup>+</sup>CD11b<sup>+</sup> lamina propria cells, which originate from preDCs (Bogunovic et al., 2009; Varol et al., 2009), were depleted in zDC<sup>DTR</sup> and CD11c<sup>DTR</sup>, but not in MM<sup>DTR</sup> mice (Fig. 3, A and B). Conversely, CD103<sup>−</sup>CD11b<sup>+</sup> cells, which are largely derived from peripheral blood Ly6<sup>C</sup><sup>high</sup> monocytes in the steady-state and during inflammation (Varol et al., 2007, 2009; Bogunovic et al., 2009; Yona et al., 2013), were significantly depleted in MM<sup>DTR</sup> and CD11c<sup>DTR</sup>, but minimally depleted in zDC<sup>DTR</sup> mice. This F4/80<sup>+</sup> population remains partially depleted for 4 d after DT injection in MM<sup>DTR</sup> mice, but returns to a steady-state frequency by 1 wk (Fig. 3 C). Thus, CD103<sup>+</sup>CD11b<sup>+</sup> and CD103<sup>−</sup>CD11b<sup>+</sup> cells in the lamina propria are preDC and monocyte-derived, respectively. In contrast, the CD103<sup>+</sup>CD11b<sup>−</sup> population was partially depleted in both zDC<sup>DTR</sup> and MM<sup>DTR</sup> mice (Fig. 3, A and B). We conclude that CD103<sup>+</sup>CD11b<sup>+</sup> lamina propria cells are a heterogeneous population containing cDCs as well as monocyte/macrophages.

In the serosa/muscularis, a layer of the gut distant from the lumen, MHCII<sup>−</sup>CD11c<sup>+</sup> cells were homogeneously CD103<sup>−</sup> CD11b<sup>+</sup>, and these cells were depleted in MM<sup>DTR</sup> and CD11c<sup>DTR</sup> but not zDC<sup>DTR</sup> mice (Fig. 3, D and E).

**Cells migrating from the lamina propria are preDC derived**

Lamina propria CD103<sup>+</sup>CD11b<sup>+</sup> cells migrate to LNs in a CCR7-dependent fashion and facilitate antigen transport during infection (Bogunovic et al., 2009). To determine the origin of the migrating CD103<sup>+</sup>CD11b<sup>+</sup> cells, we examined steady-state migratory populations of mesenteric lymph node DCs after DT injection (Fig. 4, A and B). In contrast to the lamina propria, all CD103<sup>−</sup>CD11b<sup>−</sup> and CD103<sup>−</sup>CD11b<sup>+</sup> cells were depleted in the mesenteric lymph node after DT injection in zDC<sup>DTR</sup> and CD11c<sup>DTR</sup> mice, but these cells were not altered in MM<sup>DTR</sup> mice. In accordance with this finding, CD103<sup>+</sup>CD11b<sup>−</sup> cells remaining in the lamina propria of MM<sup>DTR</sup> mice after DT injection expressed high levels of CCR7 mRNA, whereas those in zDC<sup>DTR</sup> mice showed reduced low levels of CCR7 mRNA (Fig. 4 C). We conclude that in steady state, only preDC-derived CD103<sup>+</sup>CD11b<sup>+</sup> cells migrate from the lamina propria to the mesenteric lymph node.

To determine whether infection-induced inflammation altered the composition of these migratory populations, we examined mesenteric lymph node DCs 3 d after oral infection with *C. rodentium*, an enteric pathogen that resembles enteropathogenic and enterohemorrhagic *E. coli* (Mundy et al., 2005). Again, both CD103<sup>+</sup>CD11b<sup>−</sup> and CD103<sup>+</sup>CD11b<sup>+</sup> migratory DCs in the mesenteric LN (mLN) were entirely depleted in zDC<sup>DTR</sup>, but not altered in MM<sup>DTR</sup> mice depleted of monocytes and macrophages (Fig. 4, D and E). Furthermore, when the number of living bacteria in the draining mLN was determined, a strong, albeit not statistically significant decrease in CFU was observed, indicating that the transport of *C. rodentium* from the intestinal lumen to the mLN is not as efficient in zDC<sup>DTR</sup> mice as it is in control animals. This trend was, however, not observed in MM<sup>DTR</sup> mice (Fig. 4 F).

To test whether the impaired antigen transport observed in zDC<sup>DTR</sup> mice had an effect on T cell priming, we measured OT-II CD4<sup>+</sup> T cell proliferation and CD62L down-regulation after infection with OVA-expressing *C. rodentium*. We observed significantly less T cell proliferation and CD62L down-regulation in zDC<sup>DTR</sup> mice compared with B6 mice (Fig. 4, G–I). Furthermore, the observation that T cell priming (proliferation and down-regulation of CD62L) still occurred in MM<sup>DTR</sup> mice correlates with CFU data suggesting that monocytes and macrophages are not involved in antigen transport and their absence has no influence on priming naive T cells in the draining LN.

We conclude that in the steady state and during infection, only preDC-derived CD103<sup>+</sup>CD11b<sup>−</sup> and CD103<sup>+</sup>CD11b<sup>+</sup> cells migrate from the lamina propria to the mesenteric lymph node. Furthermore, priming of T cells is only impaired in the absence of preDC-derived migratory DCs, and therefore, monocyte-derived cells are not involved in antigen transport or priming of naive T cells.

**Monocytes and macrophages in intestinal infection**

To examine the role of monocytes and macrophages in adaptive immune responses in the intestine, we repeatedly injected DT starting 1 d before *C. rodentium* infection and every other day thereafter. Monocyte- and macrophage-depleted MM<sup>DTR</sup> and cDC-depleted zDC<sup>DTR</sup> mice experienced significant weight loss when compared with B6 controls (Fig. 5 A). Consistent with the weight loss, all zDC<sup>DTR</sup> mice succumbed to infection, with a mean survival of 11 d (Fig. 5 B). In contrast, although monocyte- and macrophage-depleted mice were more susceptible than controls, the difference was not statistically significant (Fig. 5 B). Thus, whereas loss of cDCs led to weight loss and a fatal infection, monocyte- and macrophage-depleted mice lost weight initially, but infection was only fatal in 50% of all MM<sup>DTR</sup> mice infected with *C. rodentium*. The number of fecal and invasive liver colony-forming units of *C. rodentium* in DT-treated mice at day 9 mirrored survival in that zDC<sup>DTR</sup> mice showed the highest levels, followed by MM<sup>DTR</sup> mice (Fig. 5, C and D). We conclude that cDCs are essential to the immune response against *C. rodentium* and for controlling bacterial dissemination.

**Monocytes and macrophages in adaptive immunity to an intestinal pathogen**

Infection with *C. rodentium* is associated with both an IL-22–driven innate response (Satoh-Takayama et al., 2008; Zheng et al., 2005; Mundy et al., 2009). Again, both CD103<sup>+</sup>CD11b<sup>−</sup> and CD103<sup>+</sup>CD11b<sup>+</sup> migratory DCs in the mesenteric LN (mLN) were entirely depleted in zDC<sup>DTR</sup>, but not altered in MM<sup>DTR</sup> mice depleted of monocytes and macrophages (Fig. 4, D and E). Furthermore, when the number of living bacteria in the draining mLN was determined, a strong, albeit not statistically significant decrease in CFU was observed, indicating that the transport of *C. rodentium* from the intestinal lumen to the mLN is not as efficient in zDC<sup>DTR</sup> mice as it is in control animals. This trend was, however, not observed in MM<sup>DTR</sup> mice (Fig. 4 F). To test whether the impaired antigen transport observed in zDC<sup>DTR</sup> mice had an effect on T cell priming, we measured OT-II CD4<sup>+</sup> T cell proliferation and CD62L down-regulation after infection with OVA-expressing *C. rodentium*. We observed significantly less T cell proliferation and CD62L down-regulation in zDC<sup>DTR</sup> mice compared with B6 mice (Fig. 4, G–I). Furthermore, the observation that T cell priming (proliferation and down-regulation of CD62L) still occurred in MM<sup>DTR</sup> mice correlates with CFU data suggesting that monocytes and macrophages are not involved in antigen transport and their absence has no influence on priming naive T cells in the draining LN.

We conclude that in the steady state and during infection, only preDC-derived CD103<sup>+</sup>CD11b<sup>−</sup> and CD103<sup>+</sup>CD11b<sup>+</sup> cells migrate from the lamina propria to the mesenteric lymph node. Furthermore, priming of T cells is only impaired in the absence of preDC-derived migratory DCs, and therefore, monocyte-derived cells are not involved in antigen transport or priming of naive T cells.
et al., 2008; Ota et al., 2011; Sonnenberg et al., 2011; Tumanov et al., 2011; Basu et al., 2012) and the induction of Th17 and Th1 CD4+ adaptive immune responses (Higgins et al., 1999; Bry and Brenner, 2004; Bry et al., 2006; Simmons et al., 2002; Mundy et al., 2005; Mangan et al., 2006). To measure the CD4+ T cell response during infection, lamina propria cells

Figure 3. Depletion of mononuclear phagocytes in the intestine of MM^DTR, zDC^DTR, and CD11c^DTR mice. (A) Flow cytometry plots of small intestine lamina propria mononuclear phagocyte populations 24 h after DT injection in chimeric B6, MM^DTR, zDC^DTR, and CD11c^DTR mice. Gating on Lin^negCD45+MHCII^high (left) and CD103 versus CD11b plots on gated population for each genotype (right). (B) Bar graphs show absolute numbers of CD103^−CD11b^+ , CD103^+CD11b^- , and CD103^-CD11b^+ cells in the small intestine lamina propria. Data pooled from >3 experiments with 3–17 mice per group. Each time point consists of three mice per group. (D) Flow cytometry plots of isolated serosa/muscularis cells 24 h after DT injection in chimeric B6, MM^DTR, zDC^DTR, and CD11c^DTR. Gating on CD11c^lowCD11b^- (left) and CD103 versus CD11b on gated population (right). (E) Bar graphs show absolute numbers of CD103^-CD11b^- cells in the serosa/muscularis. Results represent two experiments with 2–5 mice per group and experiment. Error bars indicate SEM. *, P < 0.05; **, P < 0.01.
were restimulated ex vivo and stained for IFN-\(\gamma\) and IL-17. Compared with B6 controls, cDC-depleted zDC\textsuperscript{DTR} mice displayed an overall decrease in activated T cells and a lower frequency of IFN-\(\gamma\)- or IL-17-producing cells (Fig. 5, E and F).

The frequency of IFN\(\gamma\)- and IL-17-producing CD4\textsuperscript{+} cells observed in depleted zDC\textsuperscript{DTR} mice was similar to that in naive mice (unpublished data). This reflects our finding, that there is little or no CD4\textsuperscript{+} T cell priming in the absence...
Figure 5. Response to *C. rodentium* infection in MM<sup>DTR</sup> and zDC<sup>DTR</sup> mice. (A) Weight loss after infection with *C. rodentium*. B6, MM<sup>DTR</sup>, and zDC<sup>DTR</sup> mice received DT 1 d before infection and then every other day for 9 d. Each group contains 24–32 mice. (B) Percent of mice surviving *C. rodentium* infection. As in A, but mice were observed for survival for 23 d. Mean survival (%; mean survival ± SEM) for each group is indicated. Each group contains 6–10 mice. (C) CFU per gram of homogenized feces at day 9 after infection. (D) CFU per gram of homogenized liver at day 9 after infection. (E) Frequency of TCR<sup>β</sup><sup>+</sup>CD4<sup>+</sup>CD44<sup>+</sup> cells (obtained from Lin<sup>−</sup>CD45<sup>+</sup> gate) among total colonic lamina propria cells. (F) Flow cytometry plots from colonic lamina propria cells isolated 9 d after *C. rodentium* infection. Cells were stimulated ex vivo with PMA/Ionomycin and stained for IFN-γ and IL-17. Representative plots show Lin<sup>−</sup>CD45<sup>−</sup>TCR<sup>β</sup><sup>+</sup>CD4<sup>+</sup>CD44<sup>high</sup> cells. Bar graphs show frequency of IFN-γ<sup>+</sup>IL-17<sup>−</sup>, IFN-γ<sup>+</sup>IL-17<sup>+</sup>, and IFN-γ<sup>−</sup>IL-17<sup>+</sup> subsets among CD4<sup>+</sup>CD44<sup>high</sup> colonic lamina propria cells. Data pooled from >3 experiments, 10–18 mice per group. *, P < 0.05; **, P < 0.01; ***, P < 0.001. Error bars indicate SEM.
of cDCs in DT-treated, C. rodentium–infected zDC<sup>DTR</sup> mice (Fig. 4, G–I).

In contrast, MM<sup>DTR</sup> mice showed normal frequencies of activated T cells in the lamina propria, but fewer cells producing IFN-γ or the combination of IFN-γ and IL-17, whereas the frequency of cells producing IL-17 alone were not affected (Fig. 5, E and F). Thus, intestinal monocytes and macrophages contribute to the IFN-γ–CD4<sup>T</sup> cell response after infection with C. rodentium. Similarly, monocyte and macrophage depletion after Listeria monocytogenes infection led to decreased survival and less IFN-γ production in antigen-specific CD4<sup>T</sup> cells, despite equal T cell activation compared with B6 controls (Fig. 6, A–C). We conclude that monocytes and macrophages shape the adaptive immune response to C. rodentium and L. monocytogenes by supporting the development of IFN-γ–producing Th1 cells.

Complete Th1 differentiation during intestinal bacterial infection requires high-level expression of IL-12 and IFN-γ (Higgins et al., 1999; Simmons et al., 2002). Because monocyte and macrophage depletion altered Th1 immunity, we tested whether their depletion plays a direct role in the induction of Th1 immunity by IL-12 production. On a per cell basis, cDCs produce far higher amounts of IL-12 during inflammation than monocytes and macrophages (Heufler et al., 1996; Gorak et al., 1998; Fig. 7 A); however, the latter are a more abundant population in the intestines (Lee et al., 1985; Fig. 3 A). IL12p70 cytokine production in colonic tissue was measured 3 d after C. rodentium infection in DT-treated B6 control and MM<sup>DTR</sup> mice (Fig. 7 B). Consistent with their tissue distribution, we found a large decrease in the overall intestinal IL12p70 protein level in C. rodentium infected mice depleted of monocytes and macrophages (Fig. 7 B). IL-12–induced differentiation of Th1 cells requires activation and phosphorylation of the transcription factor Stat4 (Hsieh et al., 1993; Murphy et al., 2000; Athie-Morales et al., 2004). To determine whether the monocyte and macrophage-induced reduction in local IL-12 was responsible for the observed decrease in IFN-γ production, we measured phosphorylation of Stat4 on tyrosine 693 in activated CD4<sup>T</sup> T cells within the lamina propria at day 9 of infection (Fig. 7 C). Compared with controls, DT injection in C. rodentium–infected, MM<sup>DTR</sup>–treated mice resulted in significantly less Stat4 phosphorylation. We conclude that intestinal monocytes and macrophages contribute to the production of the IL-12 that is required for Th1 cell polarization in the intestinal lamina propria during infection.

**DISCUSSION**

Although it is well established that cells of the mononuclear phagocyte lineage are essential for both innate and adaptive immunity (Steinman et al., 2003; Liu and Nussenzweig, 2010; Yona and Jung, 2010; Chow et al., 2011), understanding their individual contributions to immunity has been difficult because of overlapping phenotypic features and a lack of specific genetic tools (Lewis et al., 2011; Langlet et al., 2012; Miller et al., 2012; Tamoutounour et al., 2012). Here, we describe a two-gene approach to target monocytes and macrophages but not cDCs.

**Figure 6.** Monocytes and macrophage depletion during L. monocytogenes infection. (A–C) C57Bl/6 and MM<sup>DTR</sup> bone marrow chimeric mice received one DT injection 1 d before i.v. injection with (A) 5 × 10<sup>5</sup> virulent Lm or (B and C) 10<sup>8</sup> ActA Lm and every other day thereafter. Mice were sacrificed at day 7 after infection. (A) Percent of DT-injected C57Bl/6 and MM<sup>DTR</sup> mice surviving virulent Lm infection. Mean survival (ms) for MM<sup>DTR</sup> group is 4.5 d. ***, P < 0.000, as compared with B6 control receiving continuous DT. Each group contains eight individual mice. (B) Frequency of CD4<sup>+</sup> cells among total spleen CD4<sup>T</sup> cells. No statistical significance among C57Bl/6 and MM<sup>DTR</sup> groups. (C) Flow cytometry plots from splenocytes isolated 7 d after Lm infection. Cells were stimulated ex vivo with LLO<sub>90-201</sub> peptide in the presence of BFA, and stained for IFN-γ. Representative plots show Lm<sup>mTCR<sup>B</sup></sup>–CD4<sup>+</sup>CD44<sup>+</sup> cells. Bar graph shows frequency of IFN-γ–producing cells among CD4<sup>+</sup>CD44<sup>+</sup> cells. Data pooled from >3 experiments, 7–11 mice per group. ***, P < 0.001. Error bars indicate SEM.
Figure 7. Localized IL-12 reduction after monocyte and macrophage depletion during C. rodentium infection. (A) IL12p35 transcript levels from FACS-sorted lamina propria CD11c<sup>+</sup> and CD11b<sup>+</sup> cells 3 d after C. rodentium infection in B6 mice. (B) IL12p70 protein levels in the supernatant of colonic tissue, taken 3 d after C. rodentium infection, and cultured for 24 h. (C) Median Fluorescent Intensity (MFI) of Stat4 (pY693) of Lin<sup>−</sup>CD45<sup>+</sup>CD103<sup>+</sup>CD44<sup>+</sup>CD11b<sup>+</sup> cells. Results represent two experiments with three mice per group per experiment: *P < 0.05; ***P < 0.001. Error bars indicate SEM.

2007). Subsets of monocytes and macrophages can be depleted using clodronate liposomes or antibodies to CSF1R, but neither is specific for these cells (MacDonald et al., 2010; Chow et al., 2011). Genetic deletion of Csf1r or Csf1 also results in loss of monocytes and tissue macrophages, but experiments in these mice are difficult to interpret because of additional severe pleiotropic effects, including infertility, osteoporosis, neural development, low body weight, and severe skeletal abnormalities (Wiktore-Jedrzejczak et al., 1990; Dai et al., 2002). The most frequently used mouse model to study monocyte function is the Ccr2<sup>−/−</sup> mouse (Boring et al., 1997; Kuziel et al., 1997), wherein monocytes accumulate in the bone marrow due to a defect in migration (Boring et al., 1997; Peters et al., 2004; Serbina and Pamer, 2006; Tsou et al., 2007; Hohlf et al., 2009; Nakano et al., 2009). Most importantly, however, CCR2 is also expressed on CD103<sup>+</sup> DCs, NK cells, mature T cells, and activated Th1 cells (Kim et al., 2001; Egan et al., 2009; Hohlf et al., 2009; Zhang et al., 2010), and therefore the precise role of monocytes in Ccr2<sup>−/−</sup> and Ccr<sup>2DTR</sup> mice is difficult to discern with confidence. The Cx3cr1 gene has also been used to study monocyte and macrophage function, but it is also expressed on NK cells and CD11b<sup>+</sup> cells (Jung et al., 2000). Cx3cr1<sup>−/−</sup> mice have been useful because they show impaired trafficking of monocytes and other CX3CR1-expressing cells, but they show normal monocyte development (Auffray et al., 2009). Finally, the combination of conditional expression of DTR under the control of CX3CR1 (CX3CR1<sup>ILI-<sub>DTR</sub></sup>) and CD11c<sup>+</sup> leads to selective depletion of CX3CR1<sup>high</sup> macrophage-like cells in the gut, leaving CX3CR1<sup>low</sup> and monocytes unaffected (Diehl et al., 2013). In contrast, DT injection in MM<sup>DTR</sup> mice depletes all monocytes and macrophage populations examined, and does not alter cDC or lymphocytes, and therefore, these mice help to clarify the role of monocytes and macrophages in inflammation and immunity.

Comparison of zDC<sup>DTR</sup> and MM<sup>DTR</sup> mice allows for analysis of the origins of complex mixtures of mononuclear phagocytes in tissues (Ginhoux et al., 2009; Hashimoto et al., 2011). The intestinal lamina propria contains a particularly diverse group of these cells, all of which express relatively high levels of CD11c and MHCIId (Varol et al., 2010; Bogunovic et al., 2012; Tamoutounour et al., 2012). As expected, the CD103<sup>+</sup>CD11b<sup>+</sup> (cDCs) and CD103<sup>−</sup>CD11b<sup>+</sup> (majority monocytes/macrophages) in this mixture were significantly depleted in zDC<sup>DTR</sup> and MM<sup>DTR</sup> mice, respectively (Varol et al., 2007, 2009; Bogunovic et al., 2009; Yona et al., 2013). In contrast, the origin of CD103<sup>−</sup>CD11b<sup>+</sup> cDCs has been debated. These cells express intermediate levels of F4/80 and CD11b and show a gene expression signature that does not cluster entirely with either cDCs or macrophages (Uematsu et al., 2008; Bogunovic et al., 2009; Miller et al., 2012). They are deleted in CD11c<sup>+</sup> x Notch2<sup>−/−</sup> mice, and they are in part Flt3-dependent for their development, suggesting a preDC origin (Bogunovic et al., 2009; Lewis et al., 2011). However, CD11c<sup>+</sup> and Notch2 are also expressed in some monocytes (Jönsson et al., 2001), and this population is heterogeneous for CD64, further suggesting that a portion are derived from monocytes (Gautier et al., 2012; Langlet et al., 2012; Tamoutounour et al., 2012). Our experiments comparing zDC<sup>DTR</sup> and MM<sup>DTR</sup> clarify these apparently contradictory results and reveal that CD103<sup>−</sup>CD11b<sup>+</sup> cDCs are a heterogeneous group of cells, some of which originate from preDCs and others from monocytes.

Although CD103<sup>−</sup>CD11b<sup>+</sup> cDCs originating from preDCs cannot be distinguished from their monotypic counterparts by surface marker expression, our results show that the two cell types differ functionally in that only preDC-derived CD103<sup>−</sup>CD11b<sup>+</sup> migrate to the local lymph nodes after C. rodentium infection. Antigenic transport, induction of oral tolerance and mucosal immunity require CCR7-dependent migration of CD103<sup>−</sup> cells to the mesenteric lymph nodes (Johansson-Lindbom et al., 2005; Worbs et al., 2006; Jaensson et al., 2008; Bogunovic et al., 2009; Cerovic et al., 2013; Diehl et al., 2013; Farache et al., 2013; Schulz et al., 2009; Zigmond et al., 2012). We found that these CD103<sup>+</sup> migratory cells predominantly belong to the preDC-derived lineage. Other cells, such as monocyte-derived CD103<sup>−</sup>CD11b<sup>+</sup> and CD103<sup>−</sup>CD11b<sup>+</sup> cells (depleted in lamina propria of DT-treated MM<sup>DTR</sup>) do not appear to contribute to the transport of C. rodentium to the MLNs or the priming of naive T cells. In contrast, Diehl et al. (2013) have described a small subset of CX3CR1<sup>high</sup> mononuclear phagocytes that appear to migrate after depletion of intestinal microbiota by quadruple antibiotic therapy before infection with a nonpathogenic strain of Salmonella enterica. Thus, signals provided by microbiota depletion and noninvasive S. enterica infection, but absent during C. rodentium or invasive S. enterica infection, might mobilize these cells for migration (Diehl et al., 2013;
Farache et al., 2013). In conclusion, zDC\textsuperscript{DTR} and MM\textsuperscript{DTR} mice can be used to distinguish the origins and functions of complex mixtures of mononuclear cells in tissues, despite their phenotypic similarities.

Our experiments are consistent with the work of others showing that cDCs are essential to initiating adaptive T cell immunity in the gut after infection with \textit{C. rodentium} (Hirata et al., 2010). Furthermore, purified lamina propria CD103\textsuperscript+ CD11b\textsuperscript+ cells promote Th17 T cell differentiation in vitro (Denning et al., 2007, 2011; Denning et al., 2007; Rivollier et al., 2012; Uematsu et al., 2008). Moreover, CD11c\textsuperscript{cre} x Notch2\textsuperscript{fl/fl} mice that lack CD103\textsuperscript+CD11b\textsuperscript+ cells showed reduced numbers of IL-17-producing Th17 cells (Lewis et al., 2011). Whether this effect was caused by preDC- or monocyte-derived cells could not be determined. Our finding that the IL-17 response is not altered by monocyte and macrophage depletion, but is significantly reduced in zDC\textsuperscript{DTR} mice, suggests that it is the migratory preDC-derived subset within the CD103\textsuperscript+CD11b\textsuperscript+ population that is necessary for Th17 mucosal immunity.

The role of monocytes and macrophages in the adaptive immune response has been difficult to define, in part because of their ability to produce a variety of cytokines under different physiological and pathological conditions (Gordon and Taylor, 2005). For example, CD103\textsuperscript−CD11b\textsuperscript+F4/80\textsuperscript+ macrophages located in the lamina propria and the serosa normally express IL10 and other antiinflammatory cytokines (Denning et al., 2007; Hadis et al., 2011; Rivollier et al., 2012), but can produce proinflammatory cytokines such as IL-12 in response to infection (Dunay et al., 2008; Kim et al., 2011; Goldszmid et al., 2012; Rivollier et al., 2012), but can produce proinflammatory cytokines such as IL-12 in response to infection. In conclusion, monocytes and macrophages contribute to adaptive immune responses in the gut and do so by producing cytokines that are essential for optimal Th1 polarization during infection.

MATERIALS AND METHODS

\textbf{Mice.} \textit{Csf1r}\textsuperscript{LsL-DTR transgenic mice were generated by DNA microinjection into mouse oocytes. Founder lines were bred to C57BL/6 mice. Three different founder strains were maintained and compared, but no differences were observed. Expression of a DTR-mCherry fusion protein is under the control of the \textit{Csf1r} gene in \textit{Csf1r}\textsuperscript{LsL-DTR} mice, but is inhibited by a loxP-flanked Stop element. Expression of Cre recombinase excises the Stop element and allows transcription and translation of DTR-mCherry in cells expressing \textit{Csf1r}.

zDC\textsuperscript{DTR} mice (Meredith et al., 2012) were bred and housed at The Rockefeller University. C57BL/6, C57BL/6.SJL, and CD11c-DTR mice were purchased from The Jackson Laboratory. Bone marrow chimera recipients were irradiated with 2 doses of 525 rad 3 h apart, and injected with of 5–10 \times 10\textsuperscript{6} bone marrow cells. Bone marrow chimeras were reconstituted for a minimum of 8 wk after irradiation. All mice were housed in The Rockefeller University Comparative Bioscience Center under specific pathogen-free conditions. All experiments were performed in accordance with the National Institutes of Health guidelines and approved by The Rockefeller University Animal Care and Use Committee.

\textbf{Infections.} For \textit{C. rodentium} infection, mice were orally infected with 2 \times 10\textsuperscript{5} CFU. Successful infection was confirmed by plating feces and determination of the pathogen burden on day 4 after infection. Weight loss and appearance of infected mice was monitored daily. Mice that lost >20% of their initial body weight or that appeared moribund were sacrificed. Survival experiments were monitored up to day 22 after infection. At this time point, mice had either succumbed to the infection or cleared the infection (as determined by fecal CFU). For \textit{L. monocytogenes} infection, mice were i.v. infected with 5 \times 10\textsuperscript{5} or 10\textsuperscript{6} CFU of virulent or \textit{ΔActA} mutant \textit{Lm} (S. Way, University of Minnesota, Minneapolis, MN), respectively.

\textbf{DT injections.} DT was purchased from Sigma-Aldrich, and was titrated and tested to determine the lowest effective dose. For transient DT ablation, zDC\textsuperscript{DTR} bone marrow chimeras were injected i.p. with 20 ng DT per gram of body weight (~500 ng per mouse) on the first day of DC depletion and with 4 ng DT per gram body weight (~100 ng per mouse) on all subsequent days. B6, CD11c\textsuperscript{DTR}, and MM\textsuperscript{DTR} bone marrow chimeras received 4 ng DT per gram body weight (~100 ng per mouse) at any time. To analyze cell depletion, mice were euthanized 18–24 h after DT injection. For prolonged cell depletion, DT was injected every 48 h.

\textbf{Flow cytometry and cell sorting.} For FACS analysis, cells were stained using antibodies against F4/80-FITC (BM8), CD103-PE (2E7), CD11c-PerCP-Cy5.5 (M1/70), CD11c-PE-Cy7 (N418), CD11b-APC (AF598), MHCIIC-ef780 (M5/114.15.2), CD45-eF605NC (30-F110), B220-eF450 (PK136), and CD8-PE-Cy7 (1M7), and CD4-ef780 (RM4-5; eBioscience), and Ly6C-eF780 (M5/114.15.2), IL-17A-647 (TC11-18H10), and STAT4-647 (pY693; and BD). DAPI was added to exclude dead cells from analysis. For intracellular cytokine staining, cells were stimulated for 4 h using Leukocyte Activation Cocktail with GolgiPlug (BD). Surface-stained cells were fixed with Cytofix/Cytoperm (BD) and washed with Perm/Wash buffer (BD). Cells were analyzed on a LSR Fortessa flow cytometer (BD). Analysis was performed using FlowJo software (Tree Star). Cell sorting was performed on a FACSariaIII cell sorter (BD). Prism 4 (GraphPad Software) was used for statistical analyses.

\textbf{Spleen and LN cell isolation.} Spleen and lymph nodes were isolated, mechanically disrupted, and incubated with HBSS + 5% FBS + 0.5 mg/ml Collagenase (Roche) at 37°C for 30 min. Cells were filtered through 100-µM cell strainers and washed. For spleen cells, erythrocytes were lysed with ACK Lysing buffer (Gibco). Cells were counted, and up to 10\textsuperscript{6} cells were stained for FACS analysis.

\textbf{Intestinal cell isolation.} Small bowel (jejunum and ileum) and large bowel (cecum and colon) were carefully excised, and mesentery and fat were removed. Feces were removed, and Peyer’s patches were excised from the small intestine. Both small and large bowel were opened longitudinally and rinsed in HBSS (Gibco), followed by HBSS + 1 mM DTT (Sigma-Aldrich). Small and large bowel were cut into 1-cm pieces and incubated with 25 ml of HBSS + 5% FBS + 5 mM EDTA for 15 min at 37°C at 230 rpm. Tissues were briefly vortexed, and supernatant containing intraepithelial lymphocytes was decanted. Bowel was washed with 10 ml of HBSS + 5% FBS for 15 min at 37°C at 230 rpm. The gut tissues were then finely chopped and digested in

\textbf{Article}
Peritoneal macrophages were isolated with 5% FBS. Bowels were then incubated with HBBS + 1 mM DTT for 20 min at 37°C to 230 rpm and subsequently washed with HBBS to remove DTT. Gut tissues were incubated with PBS + 1.3 mM EDTA for 60 min at 37°C to 230 rpm. After that, the serosa/muscularis was separated from the lamina propria using dissection microscope. The separated tissues were processed as described above. The tissue was then homogenized with an 18-gauge needle and filtered through a 70-µm cell strainer.

Isolation of tissue macrophages. Peritoneal macrophages were isolated from peritoneal lavages. Lungs and livers were isolated after perfusion of sacrificed mice. Tissue was cut into small pieces and incubated with HBBS + 5% FBS + 0.5 mg/ml Collagenase + 50 µg/ml DNase at 37°C for 60 min. After passing the tissue through a 100 µm cell strainer, cells were separated by discontinuous Percoll gradient (70%/35%) centrifugation. Mononuclear cells were isolated from the interphase.

Fluorescent microscopy. Tissues were fixed in 3% PFA and 25% sucrose overnight, frozen in C.C.T Compound (Tissue-Tek; Sakura) and stored at −80°C. Frozen tissue was cut into 20-µm thick sections, fixed for 10 min in ice-cold acetone, and rehydrated in PBS for 30 min. Tissue sections were outlined with a Pari pen and stained for 2 h at room temperature in 1% FCS in PBS. Antibody cocktail contained anti-CD16/CD32 blocking Ab (2.4G2, 1:100; BD), FITC anti-CD45R/B220 (RA3-6B2, 1:200; BD), and one of the following: APC anti-F4/80 (BM8, 1:100; eBioscience), Alexa Fluor 647 anti-CD209b/SIGN-R1 (eBio22D1, 1:200; eBioscience), and Alexa Fluor 647 anti-CD169 (MOA-1, 1:100; AbD Serotec). Sections were washed for 10 min 3× and mounted using ProLong Gold Antifade Reagent with DAPI (Invitrogen). Images were acquired on a wide-field fluorescent microscope (Carl Zeiss) using MetaVue acquisition software (Molecular Devices) and an Orca ER B/W digital camera (Hamamatsu) at The Rockefeller University Bio-Imaging Resource Center.

Organ culture. To determine IL-12 levels in the intestines, weighed explants were cultured for 24 h in complete RPMI in the presence of penicillin, streptomycin, and gentamycin. Centrifuged supernatant was frozen and used for ELISA.

ELISA. Serum levels of MCSF, GMSCF, and Flt3L were determined by ELISA using the respective Quantikine immunoassay (R&D Systems) according to the manufacturer’s protocol. Ill2p/70 levels were determined in the supernatant of explant cultures with an IL12p70-specific ELISA (eBio22D1, 1:200; eBioscience) and used for ELISA.

Statistical Analysis. Results are given as a mean ± SE or mean ± SD. Comparisons between groups were done using two-tailed Student’s t test analysis. Survival curve comparison was performed using a log-rank Mantel-Cox test. Statistical significance was determined as p-values less than 0.05.

We are grateful to members of the Nussenzweig laboratory for helpful discussion, reagents, or critical reading of the manuscript. We would like to thank K. Velinzon and L. Shatalina for cell sorting. We express special thanks to Dr. Singing Way (University of Minnesota, MN) for his gift of the Acta L monococytes strain. This work was supported in part by National Institutes of Health (NIH) grant number AI051573. M.C. Nussenzweig is an Howard Hughes Medical Institute investigator. H.A. Schreiber was supported by a NIH Ruth L. Kirschstein Individual Postdoctoral Fellowship F32 AI096721. J. Loschko was supported by Deutsche Forschungsgemeinschaft DFG LO1864/1.

The authors report no competing financial interests.
