Linking crystal structure with temperature-sensitive vibrational modes in calcium carbonate minerals

Ben Xu and Kristin M. Poduska*

We demonstrate a correlation between how an IR-active vibrational mode responds to temperature changes and how it responds to crystallinity differences. Infrared (IR) spectroscopy was used to track changes in carbonate-related vibrational modes in three different CaCO₃ polymorphs (calcite, aragonite, and vaterite) and CaMg(CO₃)₂ (dolomite) during heating. Of the three characteristic IR-active carbonate modes, the in-plane bending mode (ν₄) shows the most pronounced changes with heating in polymorphs that have planar carbonate arrangements (calcite, aragonite, and dolomite). In contrast, this mode is virtually unchanged in vaterite, which has a canted arrangement of carbonate units. We correlate these trends with recent studies that identified the ν₄ mode as most susceptible to changes related to crystallinity differences in calcite and amorphous calcium carbonate. Thus, our results suggest that studies of packing arrangements could provide a generalizable approach to identify the most diagnostic vibrational modes for tracking either temperature-dependent or crystallinity-related effects in IR-active solids.

1 Introduction

Fourier transform infrared spectroscopy (FTIR) has been used to study the constituents of naturally occurring and laboratory synthesized samples for decades. Since sample preparation methods and measurement geometries can have dramatic effects on the widths and intensities of FTIR peaks, there has been a general disregard for quantitative comparisons of structural order from such spectra. However, recent studies have demonstrated that differences in long-range periodicity (crystallinity) can be extracted from FTIR spectra. Calcite has been an excellent test case because it has three well separated IR absorption bands, and because there are a range of different degrees of crystalline order that it can accommodate, ranging from amorphous to single crystalline. In other materials, such as apatite, the effects of crystallinity on peak widths can be more challenging to track when there are overlapping IR bands. FTIR has proven to be useful for tracking phase transitions in geological samples, developing screening techniques for archaeological materials, and for characterizing biominerals.

In this work, we investigate the temperature dependencies of peak positions and peak widths in the FTIR spectra of different carbonate minerals (geogenic sources of spar calcite, spar aragonite, and dolomite), as well as laboratory-prepared samples of calcite and vaterite. We find that there are different temperature dependencies for two prominent vibrational modes, and that these differences correlate with the packing arrangements of the carbonate units in the different crystal structures. Our analyses suggest that crystallinity differences and temperature dependency differences affect the vibrational modes of these carbonate materials in a similar manner. This offers a new way to help identify vibrational modes that could be indicators of crystallinity differences by using temperature-dependent spectral data.

2 Experimental details

Geogenic carbonate samples included calcite spar (Chihuahua, Mexico), aragonite spar (Minglanilla, Spain), and dolomite (Port au Choix, Newfoundland, Canada). Representative powder X-ray diffraction data, shown in Fig. 1, confirm the phase compositions of these geogenic samples. Calcite (space group R̅3̅C, compared with JCPDS 83-1762) has a = 4.990(1) Å and c = 17.063(3) Å; dolomite (space group R̅3̅C, compared with JCPDS 75-1655) has a = 4.816(3) Å and c = 16.02(1) Å; and aragonite (space group Pmcn, compared with JCPDS 71-2396) has a = 4.967(4) Å, b = 7.96(1) Å, and c = 5.746(5) Å. All XRD data were collected using a Rigaku Ultima IV system with Cu Kα radiation, and lattice constant refinements from Jade (Materials Data Inc.) were compared with JCPDS standards.
Spectra were baseline corrected using Bruker OPUS 7.0 software, after which the peak positions, amplitudes, and full width at half maximum (FWHM) values were extracted from Lorentzian peak fits (Wavemetrics IgorPro v6.31). Lorentzian functions are widely utilized for peak fitting in IR and Raman spectra,15,16 and recent studies have demonstrated that the IR-active $\nu_2$ and $\nu_4$ modes in calcite are well matched by this function.17 For accurate comparisons, the same wavenumber regions were fitted across all temperature ranges for each different mineral phase: calcite ($\nu_2$ at 800–960 cm$^{-1}$ and $\nu_4$ at 660–760 cm$^{-1}$), aragonite ($\nu_2$ at 780–920 cm$^{-1}$ and $\nu_4$ at 660–760 cm$^{-1}$), vaterite ($\nu_2$ at 800–960 cm$^{-1}$ and $\nu_4$ at 680–780 cm$^{-1}$), and dolomite ($\nu_2$ at 800–960 cm$^{-1}$ and $\nu_4$ at 700–760 cm$^{-1}$).

3 Results

At room temperature, different polymorphs of CaCO$_3$ (calcite, aragonite and vaterite) and the Mg–carbonate dolomite have clearly distinguishable X-ray diffraction patterns (Fig. 1) and FTIR spectra (Fig. 2). The vibrational modes associated with these FTIR peaks have been well documented in the literature,6,7 and our results are in good agreement. We find that the

![Fig. 1](image1)

![Fig. 2](image2)
out-of-plane bend $\nu_2$ (near 870 cm$^{-1}$) and the in-plane bend $\nu_4$ (near 720 cm$^{-1}$) are the only distinct peaks in the mid-IR range that can be fitted well with a single Lorentzian function across all four mineral phases. Thus, the $\nu_2$ and $\nu_4$ modes are the ones that we consider in detail here. Some of the remaining vibrational modes in these carbonates present overlapping peaks, including $\nu_3$ (near 1450 cm$^{-1}$), and combined modes $\nu_1 + \nu_4$ and $\nu_1 + \nu_3$ (near 1800 cm$^{-1}$ and 2500 cm$^{-1}$, respectively). Unlike calcite and dolomite, aragonite and vaterite have IR active $\nu_1$ modes at 1082 cm$^{-1}$ and 1090 cm$^{-1}$, respectively. Aragonite also has an additional peak in the $\nu_4$ range, as noted in Fig. 2(c).

FTIR spectra of calcite (lab-synthesized and geogenic spar), vaterite, aragonite, and dolomite were monitored while heating from 293 K to 768 K at 25 degree increments. Additional experiments at low temperatures were carried out on lab-synthesized and geogenic spar calcite. Fig. 3 illustrates representative temperature-dependent peak trends for calcite. Others have reported that calcite bonding distances expand and that carbonate ions distort at high temperatures.18,19 This is consistent with our findings, since both $\nu_3$ and $\nu_5$ peaks shift to lower wavenumbers and decrease in intensity with increasing temperature in both lab-synthesized and geogenic calcite. However, there are other temperature-dependent changes to these two spectral peaks as well. First, $\nu_4$ broadens with increasing temperature, while in contrast, the $\nu_2$ peak width is nearly constant (Fig. 4). Second, the $\nu_4$ peak intensity decreases more rapidly than the $\nu_2$ intensity as temperature increases.

A comparison of high-temperature effects to FTIR peaks among all four types of carbonate minerals is provided in Table 1. The comparison temperature (598 K) is below any possible phase transition. As a rule, peak positions show a slight shift to lower wavenumber values upon heating. The lone exception is the aragonite $\nu_4$ peak near 700 cm$^{-1}$, which moves to a higher wavenumber. The peak width trends show more pronounced differences. Dolomite, calcite, and aragonite show very little change in the $\nu_2$ FWHM, while the $\nu_4$ peak broadens with increasing temperature. Vaterite behaves differently, with its $\nu_2$ and $\nu_4$ peaks both showing constant widths during heating.

Table 1. Summary of high temperature changes (at 598 K, relative to 293 K) to the out-of-plane $\nu_2$ and in-plane $\nu_4$ bending modes. Data are compared for calcite (lab-synthesized and geogenic spar), aragonite, vaterite, and dolomite. Note that aragonite has two distinct $\nu_4$ peaks at 713 cm$^{-1}$ and 700 cm$^{-1}$.

| Mode | Sample            | $\delta$ position (cm$^{-1}$) | $\delta$ FWHM (cm$^{-1}$) | $\delta$ FWHM/FWHMRT (%) |
|------|-------------------|--------------------------------|----------------------------|---------------------------|
| $\nu_2$ | Calcite synth | $-1.7 \pm 0.1$ | $-0.3 \pm 0.3$ | $-2 \pm 2$ |
| | Calcite spar     | $-1.5 \pm 0.1$ | $-0.3 \pm 0.3$ | $-2 \pm 3$ |
| | Dolomite         | $-2.5 \pm 0.1$ | $0.5 \pm 0.2$ | $4 \pm 2$ |
| | Aragonite        | $-2.3 \pm 0.1$ | $1.5 \pm 0.5$ | $9 \pm 3$ |
| | Vaterite         | $-2.2 \pm 0.1$ | $-0.1 \pm 0.2$ | $2 \pm 2$ |
| $\nu_4$ | Calcite synth | $-0.7 \pm 0.1$ | $1.8 \pm 0.2$ | $42 \pm 5$ |
| | Calcite spar     | $-0.7 \pm 0.1$ | $1.0 \pm 0.3$ | $15 \pm 4$ |
| | Dolomite         | $-1.9 \pm 0.2$ | $3.4 \pm 0.3$ | $48 \pm 5$ |
| | Aragonite (713)  | $-0.4 \pm 0.1$ | $1.6 \pm 0.4$ | $40 \pm 10$ |
| | Aragonite (700)  | $1.0 \pm 0.3$ | $2.6 \pm 0.9$ | $90 \pm 40$ |
| | Vaterite         | $-2.2 \pm 0.3$ | $0.3 \pm 1.1$ | $2 \pm 8$ |

Fig. 3 FTIR spectra of lab-synthesized calcite (a, b) and geogenic spar calcite (c, d) at different temperatures. The arrows indicate that the $\nu_2$ and $\nu_4$ peaks shift to lower wavenumber values and have smaller amplitudes at higher temperatures.
At temperatures above 598 K, our experiments demonstrate that both aragonite and vaterite undergo phase transitions to form calcite, as reported by others. The \( \nu_4 \) peaks are most indicative of these changes, shown in Fig. 5. The aragonite peak at 700 cm\(^{-1} \) disappears above 698 K (Fig. 5(a)), and the vaterite peak near 740 cm\(^{-1} \) disappears above 748 K (Fig. 5(b)). Up to the maximum heating capacity of our high temperature stage (768 K), dolomite shows no evidence of a phase change (Fig. 5(c)). For calcite, Fig. 4 indicates that there are no statistically significant discontinuities in the \( \nu_4 \) or \( \nu_2 \) peak positions or widths. For example, the small changes that occur to the calcite peak widths near 700 K (Fig. 4(b)) are within the range of the error bars on each data-point. Therefore, calcite does not show any evidence of a phase change within the temperature range of the present study.

4 Discussion

Changes in the IR spectra of solid materials during heating can be related to changes in the crystal lattice (such as phase transitions) or to the anharmonic nature of vibrations within the material. In the present study, the maximum measurement temperatures were safely below the decomposition temperature for calcite and dolomite (~1000 K), but aragonite and vaterite each convert to calcite within this temperature range (at 748 K and 698 K, respectively) in agreement with the literature. For this reason, we choose to focus on the changes to spectral peak widths and positions that occur at temperatures below any phase transitions in these materials.

In simple terms, adding thermal energy to a solid can provide information about the degree of anharmonicity of the atomic interaction potentials. For example, larger shifts in peak positions with a given temperature change signify a softer, more anharmonic interatomic potential. Recently, these kinds of effects have been explored in the temperature-dependent IR peak positions and width trends in apatite and kaolinite. A simple model was employed to describe weakly anharmonic oscillations and their quantum saturation limit at low temperatures. In brief, these previous studies report a linear temperature dependence for peak widths and positions at higher temperatures, which they attribute to anharmonic effects. However, below some threshold temperature, the temperature dependence diminishes, and peak widths and positions are constant; this is assumed to be the result of quantum saturation. Thus, there is an effective minimum peak width that can be achieved for a given IR vibrational mode once the material is cooled below a specific temperature threshold. This threshold temperature is determined empirically rather than from calculations, due to the complex and varied factors that contribute to spectral peak shapes and positions in real systems.

In the present study, we find that four calcium carbonate minerals (calcite, dolomite, aragonite, and vaterite) do not show a particularly strong temperature dependence in their peak positions or widths when compared to apatite or other minerals. Our working temperatures (298–768 K) appear to be far above the quantum saturation limit for the \( \nu_4 \) peak, since their widths show approximately linear temperature dependencies for all four carbonates. However, the \( \nu_2 \) peak width shows little change, suggesting that the quantum saturation temperature for this mode is far above ambient temperatures.

To explore these saturation effects in more detail, Fig. 4 shows low temperature peak width and position data for calcite \( \nu_2 \) and \( \nu_4 \) from many different microscopic regions of a sample. We achieved this by collecting numerous spectra at different areas on a KBr-embedded pellet sample, knowing that the spatial arrangement of the calcite particles within the KBr matrix will be slightly different at each location, and thus the peak widths will be slightly different due to differences in scattering effects (data below 300 K in Fig. 4). However, the spatial arrangement of particles at any given spot remains fixed during the course of the temperature-dependent measurements, since the calcite is not mobile in the KBr matrix. Therefore, collecting spectra from a single spot as the temperature changes shows peak width changes that are due solely to temperature-dependent effects (data above 300 K in Fig. 4). We note that the spread in peak widths at different measurement spots (low temperature data in Fig. 4) introduces scatter into the data, which is larger than the temperature-dependent trends that we can detect while measuring at a single location (high temperature data in Fig. 4). However, even with this large scatter, it is evident that the \( \nu_2 \) peak widths at higher temperatures are not statistically different than at lower temperatures. This is not the case for the \( \nu_4 \) peak widths, since there is a clear...
As described above, carbonate moieties have four possible vibrational modes, which are \( \nu_1 \) (in-plane symmetric stretching), \( \nu_2 \) (out-of-plane bending), \( \nu_3 \) (in-plane asymmetric stretching) and \( \nu_4 \) (in-plane bending). In dolomite, calcite and aragonite, the carbonate ions are arranged in layered structures and their \( \nu_2 \) mode (out-of-plane) is less affected by temperature changes than the \( \nu_4 \) (in-plane) mode. On the other hand, vaterite has carbonate units that are canted relative to each other and not in layers, and there are also partial occupancies that lead to built-in disorder. We propose that it is this structural difference – the non-planar arrangement of carbonate units – that makes the vaterite \( \nu_4 \) mode less changed as a function of temperature.

It is noteworthy that there are other reports of \( \nu_4 \) peak width changes in calcium carbonate phases, albeit in a different context. Recent studies based on experiments and density functional theory (DFT) demonstrate that the calcite \( \nu_4 \) peak broadens significantly more than \( \nu_2 \) when going from highly crystalline structures to a truly amorphous structure. The authors conclude that peak broadening, without a shift in peak position, is consistent with poorer long-range periodicity in calcite. At first glance, it might appear that comparing crystallinity differences (mixtures of amorphous and crystalline calcite) with temperature-dependent spectral features (changes in the anharmonicity of the vibrational modes) is not straightforward. However, we suggest that it is significant that the same peak \( \nu_4 \) is most affected in both scenarios. For calcite, this in-plane bending mode appears to be the most responsive to changes in its structural environment, whether those changes are due to temperature or structural disorder. For example, we note that there is slightly larger temperature-dependent broadening in the \( \nu_4 \) peak for our rapidly formed laboratory-synthesized calcite compared with the geogenically formed spar calcite (Table 1). To extrapolate this link between temperature and structural disorder with other carbonate minerals beyond calcite is somewhat speculative, since theoretical studies are lacking. The DFT studies that work well in demonstrating the peak broadening between amorphous calcium carbonate and calcite cannot easily be extended to compare with other CaCO₃ polymorphs, since the energy minima for these different structures are quite similar.

5 Conclusions

Extending the idea of tracking crystallinity-dependent peak signatures with temperature-dependent experiments to cases beyond carbonate-containing minerals is an intriguing possibility, and it has not been explored. There are many potential materials that could be candidates for future studies. For example, there are reports of using features from vibrational spectra to track differences in crystallinity in silicon to identify the presence and proportion of amorphous components. In this case, factor analysis showed that Raman spectra have exactly two independent spectral features, one of which can be attributed to crystalline Si while the other is assigned to...
amorphous Si. Others have identified a crystallinity-sensitive IR mode in SiO₂ that corresponds to an octahedral site that is easily disrupted in the Si–O tetrahedral network,¹ and temperature-dependent studies in glassy SiO₂ have also been conducted.¹⁴ Crystallinity has also been tracked in experimental studies of apatite¹²,³⁵ and aragonite.³

One possible advantage of using temperature as a screening strategy for crystallinity dependent vibrational modes is that one sample is all that is needed. This could be a more time-effective option when detailed theoretical calculations are not feasible.
