Aim: The aim of the study was to determine how the addition of a DNA oligonucleotide cargo to 3-nm gold glyconanoparticles would affect tissue distribution. Methods: Gold glyconanoparticles with 1–6 covalently bound oligonucleotides (40 nt dsDNA) were injected into rats and allowed to circulate for 10 min. Organs were harvested and gold quantitated by inductively coupled plasma mass spectrometry. Cellular localization of the nanocarriers was determined by electron microscopy. Results & conclusion: Addition of DNA cargo to the nanocarriers prevented localization in the kidney but increased localization in liver hepatocytes and splenic macrophages. There was no significant change in heart, lung or brain. DNA increases the size and adds a strong negative charge to the nanoparticles, which radically affects tissue distribution.

Keywords: brain • DNA oligonucleotides • electron microscopy • gold nanoparticles • kidney • liver • spleen • tissue distribution

In recent years, there has been great interest in the potential for gene therapy or gene editing to treat conditions caused by single-gene defects, many of which affect the CNS [1]. One approach is the use of miRNAs, IncRNAs and siRNA to suppress production of defective proteins. Another technique is direct editing of the defective gene in tissue cells. Both methods require delivery of oligonucleotides to specific cell types in the target tissue. Although direct injection into a site in the target tissue is possible, delivery of the treatment by intravascular infusion is less invasive and may allow a better distribution in the tissue. Treating diseases of the brain is particularly difficult as the tight junctions between brain endothelial cells prevent movement of large biomolecules, including oligonucleotides, across the blood–brain barrier (BBB) [2]. The more general problem is that any treatment delivered systemically usually has to cross vascular endothelium before it can reach cells in the tissue [3]. The ability of large biomolecules to cross the endothelium either by a paracellular or transcellular route depends on the type of microvascular endothelium within each tissue.

Various studies have used nanoparticles (nanocarriers) to deliver an oligonucleotide cargo to cells. There are two basic types of such nanocarrier: nanoparticles with the oligonucleotide incorporated into the core, which are usually > 50 nm in diameter, or smaller nanocarriers with the oligonucleotides bound to the outside. Earlier studies in vitro had shown that gold nanoparticles (GNPs) with a 1.5-nm core and a coat of covalently bound sugar molecules (total diameter ~3 nm) cross human brain endothelial cells [4] and are taken up by kidney endothelial cells and lung microvascular endothelium at considerably higher levels than the brain endothelium [4,5]. Transport occurs partly by vesicular transcytosis and partly by direct movement across the apical and basal plasma membranes via the cytosol, depending on the formulation and charge of the nanoparticle [5].

These gold glyconanoparticles (sugar-coated GNPs) are particularly versatile as carriers of therapeutic biomolecules because the bound sugar lends itself to an ‘exchange reaction’ with other biomolecules (cargo) that have a free –SH group. This technique has been used to attach oligonucleotides and polypeptides to the nanoparticles. The conjugates are stable for months when stored in an oxidizing environment but progressively...
release their cargo in a reducing environment. To have a biological effect, nanocarriers with bound oligonucleotides must enter the cytoplasm of the target cell and then release their cargo. These 3-nm gold glyconanoparticles are small enough to enter the cytosol by transfer across the plasma membrane [6], and they can then release their cargo by exchange reaction with glutathione in the cytoplasm [7]. The potential for disease treatment has been demonstrated by studies showing that gold–RNA or gold–DNA conjugates can modulate gene expression [8], confirming that the transported oligonucleotides retain their biological activity after internalization by target cells. Another advantage of GPNs is their safety [9]. Gold glyconanoparticles similar to those used in this study but with different cargoes have been US FDA-approved for treatment of glioma [10] and are already used in clinical trials for treatment of diabetes.

In vivo, the bound coat of sugar molecules maintains solubility, prevents aggregation and limits removal of nanoparticles by the mononuclear phagocyte system. However, one drawback of smaller nanoparticles (<5 nm) is that they tend to become localized in the kidney and/or excreted in urine. It has been assumed that their small size allows them to pass through the fenestrated endothelium of the glomerulus [11], and there is no mechanism for reabsorption. Examination of the tissue distribution of glucose-coated GNPs by inductively coupled plasma (ICP) mass spectrometry, 10 min after intravascular infusion into rats, showed that the majority were localized in the kidney, with much smaller amounts in cerebral cortex, lung and liver [12]. To increase the half-life and availability of these very small nanocarriers, it would be necessary to reduce losses through the kidney.

Attachment of cargo molecules to the glyconanoparticles can radically alter their physicochemical characteristics and their interaction with endothelial cells. For example, coupling 40-nt double-stranded DNA oligonucleotides to the outside of the nanoparticles makes them negatively charged, increases their hydrodynamic diameter to approximately 7 nm and increases the rate of transcytosis of the carriers up to tenfold and cargo 50-fold [13].

The aim of this study was to determine whether attachment of an oligonucleotide cargo to the gold nanocarriers affects their tissue distribution and cellular localization in vivo. Two formulations of nanoparticle were used, one with 1–3 bound oligonucleotides per nanoparticle (NP-DNA-40LO) and the other with 3–6 oligonucleotides per nanoparticle (NP-DNA-40HI) [13]. They were compared with the unconjugated glyconanoparticle (NP-Gal). Double-stranded DNA of 40-nt length was chosen as the cargo molecule because it is less susceptible to degradation than RNA, and this length of oligonucleotide is of the size typically used for therapeutic purposes.

The results demonstrate that addition of the oligonucleotide cargo causes a major tissue redistribution of the nanoparticles in vivo, markedly reducing excretion by the kidney and increasing uptake by hepatocytes. It shows that changes to the size, charge and formulation of a nanocarrier of this type will have a substantial effect on its bioavailability and the potential for targeting the nanocarrier to a specific tissue. These nanocarriers would be very effective for delivering oligonucleotides to liver hepatocytes, but delivery to other tissues would require additional targeting molecules on the nanoparticles.

**Materials & methods**

**Gold glyconanoparticles, oligonucleotides & attachment to nanoparticles**

The GNPs, obtained from Midatech Pharma Plc (Cardiff, UK), were synthesized using a modified Brust-Schiffrin method [14] and characterized in water using dynamic light scattering (DLS) on a Nano ZSP Zetasizer (Malvern Instruments, Malvern, UK). They were capped during synthesis with thiol-C2-galactose. The characteristics of these glyconanoparticles (NP-Gal) are summarized in Supplementary Figure 1.

The method for production and characterization of the gold glyconanoparticles with bound oligonucleotides has been described previously [13]. It involves a chemical exchange reaction in which the ligand with a free -SH group exchanges with the C2-galactose which is bound to the gold core via a sulfur atom. In this case, a 20-nt, thiolated ssDNA oligonucleotide (5′ thiol-C6-AAT ATC GCG GAC AGA AGA CG 3′), obtained from Sigma-Aldrich (Gillingham, UK), was attached to the NP-Gal by a 48-hour exchange reaction. Before attachment to the glyconanoparticles, Tris(2-carboxyethyl)phosphine (TCEP), in 0.1 M tris/HCl, pH 7.5, was used to reduce the DNA to yield free thiol monomers. This was achieved by incubating the oligonucleotide (7.5 mM in 50 μl) at room temperature for 4 h with TCEP at a molar ratio of 1:1.25 (DNA:TCEP). After reduction, the oligonucleotide was attached to the NPs by an exchange reaction. NPs (2 mg/ml equivalent of gold) were mixed with reduced 20 nt ssDNA at a molar ratio of 1:14 in a 0.5 ml Eppendorf tube, in a sealed container flushed with nitrogen gas to exclude oxygen. The reaction was allowed to continue for 48 h at room temperature.

To synthesize nanoparticles with 40-nt double-stranded DNA, this NP-DNA-20th preparation was first hybridized with an equimolar amount of 40 nt ssDNA, with its 3′ sequence complementary to the 20-nt ssDNA bound to the NP (5′-AAAAGCTCTGCTGTTTCCCGTCTTTCTGTCGCGATATT-3′) for 30 min. Then,

Intracarotid infusion was chosen as a potential method for optimizing delivery to the CNS, and i.v. infusion requires less technical expertise and is more widely used for intravascular delivery of therapeutic agents.

On the day of the experiment, rats were anesthetized with ketamine (100 mg/kg, i.p.)/xylazine (10 mg/kg, i.p.). For intracarotid infusion, the left common internal and external carotid arteries were exposed. The latter was then retrogradely catheterized with a polyethylene tube (PE-10) after its branches were ligated. The tip of the catheter was placed and implanted in the external carotid artery approximately 1 mm distal to the carotid bifurcation to infuse nanoparticles. Each rat was injected with 200 μg/kg rat body weight of NP-Gal, NP-DNA-40<sup>LO</sup> or NP-DNA-40<sup>HI</sup> (gold concentration) over 1 min into the left internal carotid artery (for i.c. injection) and the penile vein (for i.v. injection). The nanoparticles were left to circulate for 10 min in the blood (Figure 1). This time was selected as it allows a first pass through the brain before passage through the pulmonary circulation and distribution in the systemic circulation, before any significant level of excretion can occur. After 10 min, the thoracic cavity was exposed following an additional i.p. administration of ketamine (50 mg/kg, i.p.) with xylazine (5 mg/kg). Two milliliters of blood were collected from the heart and stored in heparin, and the animals were transcardially perfused for approximately 20 min with 75 ml of 0.9% saline to remove the remaining blood. Post perfusion, brain, kidney, liver, lung, spleen and heart were collected. For paired organs, one was fixed and
the other frozen. The other organs were cut in half, and one half was fixed in 2% paraformaldehyde and 2.5% glutaraldehyde and the other half was frozen. (Brain was split coronally at bregma +1 and the anterior portion fixed and the posterior portion frozen.) Fixed samples were used for electron microscopy and frozen samples for inductively coupled plasma mass spectrometry (ICP-MS). For the ICP-MS, the tissue samples were digested with 25% tetramethyl ammonium hydroxide with 0.2% Triton ×100, and neutralized with 1% HCl. The analysis was carried out at Midatech Pharma plc, Bilbao, and results expressed as nanograms of gold per gram of tissue.

Tissue staining & transmission electron microscopy
The tissues for transmission electron microscopy (TEM) analysis were kept in fixative for 2 h at 4°C and then stored in PBS at 4°C. Tissue sections of 100-μm thickness were cut with a microtome and placed in 0.1 M Sørensen's phosphate buffer (PB) at 4°C or frozen at -20°C in PB with sucrose and ethylene glycol until use.

The sections were stained for 40 min using Aurion LM silver enhancer according to the manufacturer's instructions and then imaged using a light microscope.

An adjacent tissue section to the one stained with LM silver enhancer was selected, and highly stained regions of interest were cut from that tissue section. Selected sections for all groups for all organs were placed in glass vials and permeabilized with 0.05% Triton ×100 for 3× with 0.1 M PB. Sufficient Aurion EM silver enhancer (~150 μl) was applied to cover each tissue sample for 2 h at room temperature. Tissues were washed 3× with distilled water, and 1% osmium tetroxide in PB was applied for 45 mins at room temperature. The tissue samples were re-washed 3× with 0.1 M PB, and dehydrated in acetone (30%, 10 min: 50%, 10 min: 90%, 10 min: 100% twice, 20 min each: 100% with molecular sieve, 20 min).

After dehydration, the tissue sections were incubated in a 50:50 mixture of 100% acetone and Epon resin and placed on a rocker overnight. The next day, the tissue sections were penetrated with fresh resin twice for 2 h. After that, tissue sections were flat embedded in Aclar sheets and incubated for 48 h at 60°C. Meanwhile, capsule-shaped resin blocks were prepared using gelatin capsules as shape former and 13–15 drops of resin added and incubated for 48 h at 60°C. After 48 h, the tissue section embedded in Aclar sheets was glued onto the resin capsules and micro-sectioned for TEM analysis. Ultrathin sections of 80 nm were cut and counterstained with 3% uranyl acetate for 30 min followed by Reynolds lead citrate for 10 min. The sections were imaged on a JEOL 1010 electron microscope at 80 kV.

Statistical methods
Data were analyzed, and graphs prepared using Graphpad Prism 8.0. Tests used, replication and p-values are reported in the figure legends.

Results
Gold glyconanoparticles & DNA-conjugated glyconanoparticles
The gold glyconanoparticles used in this study have a gold core with a surface coat of covalently bound C2-galactose. The spherical gold core of the nanoparticles was 1.3 nm in diameter, as determined by transmission electron microscopy, and the size of the glyconanoparticles was 3.63 ± 1.09 nm (mean ± SD) measured by DLS with a zeta potential of −28.6 ± 7.01 mV. As determined by molecular mass of the gold core (~20,000) and physical size, these nanoparticles have approximately 100 gold atoms in the core and 40 covalently bound C2-galactose molecules on the outside. The characteristics of these nanoparticles were reported previously [13] and are summarized in Supplementary Figure 1. These glyconanoparticles are designated ‘NP-Gal’.

DNA oligonucleotides (40 nt length, Supplementary Figure 2) were attached to the gold core of the NP-Gal by an exchange reaction. The size of the gold core of the DNA-conjugated NP-Gal was determined by TEM (Supplementary Figures 3 & 4) and the hydrodynamic diameter by FPLC gel filtration. These data have been reported previously [13] and are summarized in Supplementary Figure 1.

Two formulations of DNA-conjugated gold glyconanoparticles were prepared with either low levels of covalently bound oligonucleotides (NP-DNA-40LO) or high levels of oligonucleotides (NP-DNA-40HI). The two formulations were examined by an electrophoretic mobility shift assay (Supplementary Figure 5) the NP-DNA-40HI preparation had 3–6 bound oligonucleotides per NP-Gal carrier and the NP-DNA-40LO preparation had 1–3 oligonucleotides per NP-Gal [13,15].

Tissue distribution of gold nanocarriers with bound oligonucleotides

The nanoparticles were infused into the internal carotid artery of rats over the course of 1 min and were allowed to circulate for 10 min before the animals were perfused and tissues collected. The quantity of gold in different tissues was measured by ICP-MS (Figure 2).

It was noted that the unconjugated glyconanoparticles, NP-Gal, accumulated in kidney 10 min after infusion. This finding was as expected for nanoparticles <5 nm [16] because they are cleared through the fenestrated endothelium of glomerular capillaries. The results were comparable to a previous study with glucose-coated GNPs of a similar size [12]. Compared with kidney (4329 ng/g), the concentration of NP-Gal was much smaller in the brain (91 ng/g), liver (50 ng/g), spleen (132 ng/g) and other organs, whereas some remained in the blood (657 ng/g).

For both, NP-DNA-40LO and NP-DNA-40HI, the nanoparticles accumulated at high levels in the liver and spleen, and there was almost no accumulation in kidney. The tissue distribution following intravenous infusion (Figure 3) was very similar to the results after intracarotid infusion. Addition of oligonucleotides to the nanoparticles stopped accumulation in the kidney but caused accumulation in liver and spleen, with no significant change in heart, lung or brain. Because addition of oligonucleotides to these carriers increases their rate of transcytosis across brain endothelium in vitro [13], one aim of this experiment was to determine whether addition of oligonucleotides would increase passage across brain endothelium in vivo. However, the rapid accumulation of the NP-DNA-40 nanocarriers in liver and spleen meant that relatively low levels of nanoparticles remained in the blood, and therefore the amount available in the circulation to cross the brain endothelium was also low.
Cellular distribution in the kidney
To understand the basis for the change in tissue distribution of nanocarriers caused by attachment of oligonucleotides, the tissues were examined by light and electron microscopy. We hypothesized that the lack of NP accumulation in kidney was due to their inability to cross the fenestrated glomerular endothelium. This could be explained by the increased size and/or high negative charge of the NP-DNA-40 nanocarriers.

Macroscopic examination of GNPs was performed using silver enhancement, which reacts with GNPs and increases their size by depositing silver on their surface. Where the concentration of GNPs (and therefore silver) is high in a tissue, such areas appear brown.

Silver-enhanced kidney sections of animals treated with NP-Gal demonstrated staining throughout the kidney including the renal pelvis. Staining was lower for animals treated with NP-DNA-40HI and was primarily in the Bowman capsules, appearing as dark spots on the cortex (Figure 4). For animals treated with NP-DNA-40LO staining was seen in the Bowman capsules, cortex and in the loops of Henle, with a small amount in the renal pelvis (Figure 4). There was no difference related to whether the NP-DNA-40 nanoparticles had been injected intravenously or into the carotid artery.

When observed by TEM, GNPs are intensely electron-dense and appear as black spots on the tissue, readily distinguishable from cellular structures. NP-Gal nanoparticles in the kidney were located in the Bowman capsule and in the brush borders of the proximal tubular epithelium indicating that they had already passed through the glomerular filtration barrier (Figure 5). In animals treated with NP-DNA-40LO and NP-DNA-40HI, smaller numbers of nanoparticles were observed in the proximal tubular epithelium and brush border (Supplementary Figure 6).

Cellular distribution in the liver & spleen
Although the NP-DNA-40 nanocarriers did not accumulate in the kidney, this alone does not account for the concomitant large increase in liver and spleen; if the increase was due to an increase in bioavailability, one would expect also to see an increase in lung and heart and this did not happen (Figures 2 & 3). We hypothesized that the increased size or negative charge of NP-DNA-40LO and NP-DNA-40HI may have facilitated their accumulation in mononuclear phagocytes and Kupffer cells in the liver - the capillaries in the liver and spleen are discontinuous and lined by phagocytes and are therefore directly accessible to the nanocarriers [17].

In accordance with the ICP-MS data, silver staining of the liver sections was stronger in animals treated with NP-DNA-40LO or NP-DNA-40HI compared with NP-Gal. However, this was difficult to visualize in macroscopic sections because of the intrinsic color of the organ.

TEM images showed that in all cases the nanoparticles were primarily localized in the cytoplasm of hepatocytes. Contrary to the original hypothesis, no nanoparticles were observed in Kupffer cells for any of the three groups (Figure 6).

In the spleen, it was not possible to see differences in the level of silver staining macroscopically due to the intrinsic dark color of the organ. In the TEM images, there was a small number of nanoparticles in the red pulp, for animals treated with NP-Gal, but none in the white pulp and the capsule. For animals treated with NP-DNA-40LO and NP-DNA-40HI, many nanoparticles were observed in the macrophages of the red pulp and in the capsule for both treated groups; again, none were observed in the white pulp (Supplementary Figure 7).
Gold-oligonucleotide nanocarriers in vivo

Research Article

Cellular distribution in the brain

A small proportion of the injected nanocarriers accumulated in brain in this study, but there was no significant difference between the amounts in each treatment group (Figures 2 & 3). Previous studies have shown that glucose-coated GNP s move rapidly within the brain and can be found in neurons, astrocytes and endothelium within 10 min of infusion [12]. In this study, light microscopy of coronal sections of brain with silver enhancement showed darker staining in choroid plexus and median eminence that lack a full BBB. Some staining was also observed in striatum and areas of the cortex (Supplementary Figure 8). However, there was no consistent difference in staining of the ipsilateral (injected) and contralateral side of the coronal sections or of sections from rats that had received different treatments.

TEM images of areas of the cerebral cortex of animals injected with NP-DNA-40LO showed silver-stained GNP s in endothelial cells, pericytes and astrocytes (Figure 7). A similar distribution of nanoparticles was found in animals in the other two treatment groups.

Discussion

The key finding from this study was that addition of a 40 nt dsDNA cargo to the 2 nm gold glyconanoparticles caused a major change in their tissue distribution—accumulation in the kidney was almost completely blocked, and nanoparticles became primarily localized in liver and spleen (Figures 2 & 3). Note that the comparison in this study is between nanoparticles with a DNA cargo (NP-DNA-40) and nanoparticles without a cargo (NP-Gal, control). We did not include a saline only control because the two methods used, ICP-MS and silver-enhanced electron microscopy.
microscopy, both detect gold, and we have previously noted that if no gold is injected, none can be detected in the tissues [12].

The design of this study was intended to determine the fate of the nanoparticles immediately after injection and to allow comparison with a previous study using similar nanoparticles [12]. It does not, however, provide information on the long-term persistence of the nanoparticles in different tissues. Previous work has implied that initial tissue distribution of gold NPS is strongly related to their surface coating, whereas persistence is related to size – smaller NPs are cleared relatively quickly [18]. Even within the 10-min timeframe of the experiments described here, the nanoparticles were almost completely cleared from the blood. In this respect, our findings are similar to those seen with 22-nm dextran-coated GNPs (no DNA cargo) injected into mice, where 90% of the injected dose was cleared from blood within 20 min, and nanoparticles were subsequently found (at 24 h), primarily in liver and spleen [19]. However, in contrast to that study, the smaller GNPs used here were localized in the cytosol of hepatocytes, with very few in phagocytic cells. This difference in distribution may be related to the nanoparticle size/charge, the presence of the DNA cargo or the time at which the organs were sampled. For example, at pH 7.5 the addition of
the DNA oligonucleotides (pKa 2) changes the surface charge from near-neutral to strongly negative and increased the hydrodynamic diameter of the nanoparticles from 1.8 up to 7 nm (Supplementary Figure 1).

The low levels of oligonucleotide-coated GNP s in kidney in our study may be because NP-DNA-40LO and NP-DNA-40HI are larger in size than the unconjugated NP-Gal. Within the kidney, the NP-Gal base nanoparticles were localized throughout the organ, including the renal pelvis. In contrast, the NP-DNA-40HI nanoparticles were confined to the Bowman capsule/glomerulus, whereas staining with the NP-DNA-40LO formulation was more widely distributed in the cortex (Figure 4). The simplest explanation for these findings is that the progressive increase in size of the NPs with bound DNA, limits their ability to cross the glomerular filtration barrier. The attachment of additional oligonucleotides increases the size of the nanoparticles from 3 to 7 nm, making them too large to cross the fenestrated glomerular endothelium, which has a cut-off of approximately 5 nm [11]. Hence, the smaller Gal-NP can move through the nephron and are seen in the brush border of the tubular epithelium and the renal pelvis.

Figure 7. Transmission electron microscopy images of the cerebral cortex of a rat injected with NP-DNA-40LO. Nanoparticles (arrows) were detected in brain endothelium (A), astrocytes in brain parenchyma (B) and in a pericyte and astrocytes (C).
Endothelium has a strong negative charge due the glyocalyx, which is substantially lacking in vitro \cite{20,21}. Therefore, an alternative possibility is that the negative charge of the DNA inhibits NP-DNA access to the endothelial surface in the glomerulus. However, in vivo it is not certain that these nanoparticles would be negatively charged. In the presence of serum, charged GNPs bind serum proteins of the opposite charge, which reduces or even reverses their charge \cite{22,23}. For these reasons, the most likely explanation for the failure of NP-DNA to enter the nephron is that they are larger than the basic NP-Gal carrier.

Many studies have noted that nanoparticles >10 nm accumulate in the liver \cite{22,24} due to uptake by Kupffer cells and mononuclear phagocytes. However, we observed that the NPs were only in hepatocytes. We considered the possibility that the nanoparticles were binding to a 'galactose receptor'. Rat hepatocytes and liver macrophages have two different receptors that bind glycoproteins, which are both inhibited by N-acetylgalactosamine \cite{25}. It seems unlikely that the enhanced uptake of NP-DNA by the hepatocytes can be explained by this galactose receptor; the receptor recognizes galactosyl groups on glycoproteins linked by their C1 atom, whereas the galactose attached to the GNPs is linked at C6, and therefore presented in a different orientation to that recognized by the receptor. Furthermore, the NP-Gal nanoparticles are not taken up in significant amounts in the liver (Figures 2 & 3). This implies that it is the addition of the DNA that alters the ability of hepatocytes to take up the nanoparticles. In this case the change in tissue distribution is less likely to be due to the increase in size of the nanocarriers but is instead due to the high negative charge imparted by the DNA cargo.

Although the addition of DNA reduced losses of the nanocarriers through the kidney, the level of uptake by the brain, lung or heart was not significantly increased. One aim of the research program has been to develop a nanocarrier that can cross the BBB in vivo. Intracarotid injection was originally chosen as a method of delivery, that might favor uptake of the nanocarriers by brain endothelium; previous studies had shown that gold glycophosphoparticles do enter the brain preferentially on the injected side \cite{12}. In this study, there was no significant difference in the brain uptake when intracarotid and intravenous injection was compared. This finding suggests that during the first pass through the cerebral circulation, only a small proportion of the nanocarriers pass the BBB, and hence intracarotid injection only offers a small advantage over i.v. injection. However, once in the brain, nanoparticles with bound DNA were observed in glial cells, up to several microns from the nearest blood vessel (Figure 7). They had therefore moved rapidly within the brain, at a similar speed to unmodified gold glycophosphoparticles \cite{12}.

While the addition of DNA to these nanocarriers has solved the problem of losses through kidney, it has not resolved how to increase transport across barrier-type brain endothelium. To increase passage of these NP-DNA across the BBB in vivo, it would be necessary to target them to brain endothelium \cite{26}. For this purpose, the transferrin and low-density lipoprotein (LDL) receptors are selectively expressed on brain endothelium \cite{27} and could be suitable targets for promoting vesicular transcytosis of nanoparticles up to 100 nm. For example, larger pegylated GNPs (25–32 nm) have been treated with antibodies to the transferrin receptor to increase their uptake by brain endothelium \cite{28}. This approach is less suitable for the glycan nanoparticles used here because a targeting antibody (6.4 nm) is larger than the nanocarrier and cargo DNA.

An alternative approach is the use of targeting peptides. Synthetic polypeptides that bind to the transferrin receptor or LDL receptor have been used to target therapeutic agents to the brain \cite{29,30}. These peptides can be modified by addition of a terminal cysteine residue, allowing them to be attached to the GNPs by an exchange reaction. For this reason, our current work on this project is aimed at increasing uptake of the nanocarriers by brain endothelium, using targeting peptides of 1–2 kDa, which do not add significantly to the size of the nanocarrier.

Although the unmodified NP-DNA do not enter the brain in large amounts, they do have great potential for gene therapy directed to liver hepatocytes. On the basis of the size of the animals used in the study (≈300 g), and an estimate of average liver weight of 12 g, the amount of gold in the liver of rats treated with NP-DNA was 2 μg/g (Figure 2) or 24 μg. Because these animals were injected with 200 μg/kg of gold, the amount in the liver (24 μg) represents 40% of the total injected dose (60 μg). This contrasts with the 0.4% entering the brain by similar calculation. Moreover, this high level of uptake into the liver occurred within 10 min of infusion. Oligonucleotides of 40-nt length were specifically selected in this study as a suitable size for gene therapy. Because the GNPs rapidly and efficiently enter the cytoplasm of hepatocytes, they are very well suited for delivering gene therapy for liver diseases \cite{31}.

**Conclusion**

This study has shown that it is essential to consider how the characteristics of a cargo molecule, in this case dsDNA oligonucleotides, affects the biodistribution of a nanocarrier. This is particularly true where the cargo molecule is...
attached to the outside of the carrier because it can then directly interact with tissue cells and endothelial cells, which have distinctive tissue-specific properties. Addition of cargo molecules to nanoparticles <5 nm significantly increases their size and reduces their ability to pass glomerular endothelium. The charge of the cargo also affects ability to interact with cells in tissues including hepatocytes and mononuclear phagocytes.

**Summary points**

- Gold glyconanoparticles (2 nm) with a covalently attached shell of C2 galactose were used as nanocarriers for a DNA cargo *in vivo*.
- The dsDNA oligonucleotides (40 nt) were covalently attached to the nanocarriers by an exchange reaction, producing 1–6 DNA molecules per nanocarrier.
- Formulations with low levels of bound DNA and high levels of bound DNA were compared with nanoparticles with no DNA cargo.
- The nanocarriers were infused into rats either intravenously or into the carotid artery and allowed to circulate for 10 min before organs were perfused and harvested.
- The tissue distribution of the nanocarriers was determined by inductively coupled plasma mass spectrometry (ICP-MS) and transmission electron microscopy.
- Addition of DNA to the carriers completely blocks their localization in kidney but promotes uptake by liver hepatocytes and splenic macrophages.
- The amounts localizing in the heart, lung and brain were not affected by addition of the DNA.
- The study demonstrates that cargo molecules such as DNA on small nanocarriers can substantially increase their size, alter their charge and radically affect tissue distribution.

Papers of special note have been highlighted as: ● of interest

1. Deverman BE, Ravina BM, Bankiewicz KS et al. Gene therapy for neurological disorders: progress and prospects. *Nat. Rev. Drug Discov.* 17(10), 641–659 (2018).

2. Crawford L, Rosch J, Putnam D. Concepts, technologies, and practices for drug delivery past the blood–brain barrier to the central nervous system. *J. Control. Release* 240, 251–266 (2016).

3. Juliano RL. The delivery of therapeutic oligonucleotides. *Nucleic Acids Res.* 44(14), 6518–6548 (2016).

● Discusses how to overcome tissue barriers to the delivery of oligonucleotides for siRNA and miRNA-based therapies. This is related to how oligonucleotides can be chemically modified to maintain stability in the plasma and how the carriers can evade the mononuclear phagocyte system.

4. Gromnicova R, Davies H, Sreekanthreddy P et al. Glucose-coated gold nanoparticles transfer across human brain endothelium and enter astrocytes *in vitro*. *PLoS ONE* 8(12), e81043 (2013).

5. Gromnicova R, Kaya M, Romero IA et al. Transport of gold nanoparticles by vascular endothelium from different human tissues. *PLoS ONE* 11(8), e0161610 (2016).

6. Verma A, Uzun O, Hu Y et al. Surface-structure-regulated cell-membrane penetration by monolayer-protected nanoparticles. *Nat. Mater.* 7(7), 588–595 (2008).
7. Male D, Gromnicova R, McQuaid C. Gold nanoparticles for imaging and drug transport to the CNS. *Int. Rev. Neurobiol.* 130, 155–198 (2016).

13. Fatima N, Gromnicova R, Loughlin J et al. Gold nanocarriers for transport of oligonucleotides across brain endothelial cells. *PLoS ONE* 15(9), e0236611 (2020).

- Describes the transport of gold nanocarriers across a 3D model of the human blood–brain barrier *in vitro*. Addition of DNA cargo to the nanocarriers enhances transcytosis of the DNA across the endothelium up to 50-fold.

14. Brust M, Walker M, Bethell D et al. Synthesis of thiol-derivatised gold nanoparticles in a two-phase liquid–liquid system. *Chem. Commun. (Camb)* 7, 801–802 (1994).
