Abstract

Corrections to hyperfine splitting and Lamb shift of order $\alpha^2(Z\alpha)^5$ induced by the diagrams with radiative photon insertions in the electron line are calculated in the Fried-Yennie gauge. These contributions are as large as $-7.725(3)\alpha^2(Z\alpha)^5/(\pi n^3)(m_r/m)^3 m$ and $-0.6711(7)\alpha^2(Z\alpha)/(\pi n^3)E_F$ for the Lamb shift and hyperfine splitting, respectively. Phenomenological implications of these results are discussed with special emphasis on the accuracy of the theoretical predictions for the Lamb shift and experimental determination of the Rydberg constant. New more precise value of the Rydberg constant is obtained on the basis of the improved theory and experimental data.
A steady and rapid progress in the spectroscopic measurements in recent years led to a dramatic increase of accuracy in the measurements of the Rydberg constant \[1, 2\], ground state \(1S\) Lamb shift in hydrogen and deuterium \[2, 3, 4\], classic \(2S - 2P\) Lamb shift in hydrogen \[5, 6, 8\], and of the muonium hyperfine splitting in the ground state \[9, 10\] (see Table 1).

These spectacular experimental achievements constitute a serious challenge to the theory and intensive theoretical efforts are necessary to match this experimental accuracy.

Theoretical work on the high order corrections to hyperfine splitting (HFS) and Lamb shift concentrated recently on calculation of nonrecoil contributions of order \(\alpha^2(Z\alpha)^5\). Their magnitude may run up to several kilohertz for HFS in the ground state of muonium, to several tens of kilohertz for \(n = 2\) Lamb shift in hydrogen and may be as large as hundreds of kilohertz for the ground state Lamb shift in hydrogen. Contributions of such order of magnitude are clearly crucial for comparison of the current and pending experimental results with the theory.

As was shown in \[11\] for hyperfine splitting and in \[12\] for the Lamb shift there are six gauge invariant sets of diagrams (see Fig.1), which produce corrections of order \(\alpha^2(Z\alpha)^5\). All these diagrams may be obtained from the skeleton diagram, which contains two external photons attached to the electron line, with the help of different radiative insertions. All contributions induced by the diagrams in Figs.1a – 1c, containing closed electron loops, were obtained recently in papers \[11, 13, 14, 15\] for the case of hyperfine splitting and in papers \[12, 16, 17, 18, 19\] for the case of the Lamb shift.

These theoretical results are now firmly established since all these corrections were calculated independently by two different groups and the results of these calculations are in excellent agreement.

We report below on the results of our calculation of the contributions of order \(\alpha^2(Z\alpha)^5\) to HFS and Lamb shift induced by the last gauge invariant set of diagrams in Fig.1f. This set includes nineteen topologically different diagrams \[24\] presented in Fig.2. The simplest way to describe these graphs is to realize that they were obtained from the three graphs for the two-loop electron self-energy by insertion of two external photons in all possible ways. Really, graphs 2a – 2c are obtained from the two-loop reducible electron self-energy diagram, graphs 2d – 2k are the result of all possible insertions of two external photons in the rainbow self-energy diagram, and diagrams 2l – 2s are connected with the overlapping two-loop self-energy graph. We have already
calculated contributions induced by the diagrams in Figs.2a – 2h and Fig.2l earlier [20, 21]. Results of the calculation of the contributions produced by the remaining diagrams in Fig.2 are presented below.

Let us start with a brief description of the main features of our approach to calculations. As was shown in [22] for HFS and in [12] for the Lamb shift, contributions to the energy splittings are given by the matrix elements of the diagrams in Fig.2 calculated between free electron spinors with all external electron lines on the mass shell, projected on the respective spin states and multiplied by the square at the origin of the Schrödinger-Coulomb wave function.

Actual calculation of the matrix elements is impeded by the ultraviolet and infrared divergences. Infrared problems are as usual more difficult to deal with than the ultraviolet ones. It is easy to realize that in the standard Feynman gauge all diagrams in Fig.2 are infrared divergent and one has to introduce the radiative photon mass to regularize this divergence. Sure, the final result for the sum of all contributions induced by the diagrams in Fig.2 is infrared finite and should admit a smooth limit for the vanishing photon mass. However, numerical recipes used in calculations of the contributions to the energy shifts make it impossible to check analytically independence of the results on the photon mass and one has to rely on the extrapolation in the infrared photon mass. Of course, such approach is still feasible, but we have preferred to use the gauge invariance of the sum of diagrams in Fig.2 and to perform all calculations in the Fried-Yennie (FY) gauge [23] for the radiative photons. All diagrams are infrared finite in this remarkable gauge and one may perform the on-mass-shell renormalization without introduction of the infrared photon mass (see, e.g., [22]) avoiding thus the problem of extrapolation to the vanishing photon mass. Of course, infrared finiteness in the FY gauge is not given for free, and one has to pay special attention to the infrared behavior of the integrand functions and to perform cancellation of spurious infrared divergences with the help of integration by parts over the Feynman parameters prior to momentum integration.

Calculation of the contributions to the energy splittings starts with putting down the universal infrared diverging skeleton integrals corresponding to the electron line with two external photons. Each contribution of order $\alpha^2(Z\alpha)^5$ arises from radiative insertions in the skeleton graph. Corrections to hyperfine splitting and Lamb shift, produced by the diagrams in Figs.1 and 2 are given by the expressions (see, e.g. [22, 12])
\[ \Delta E_{\text{HFS}} = 8 \frac{Z\alpha}{\pi n^3} \left( \frac{\alpha}{\pi} \right)^2 E_F \int_0^\infty \frac{dk}{k^2} L_{\text{HFS}}(k), \]  

(1)

and

\[ \Delta E_L = -16 \frac{(Z\alpha)^5}{\pi n^3} \left( \frac{\alpha}{\pi} \right)^2 \left( \frac{m_r}{m} \right)^3 m \int_0^\infty \frac{dk}{k^4} L_L(k), \]  

(2)

where \( k \) is the magnitude of the three-dimensional momentum of the external photons measured in the electron mass units, \( m_r = m/(1 + m/M) \) is the reduced mass of the electron-muon (or electron-proton) system and \( E_F \) is the Fermi energy of hyperfine splitting. The functions \( L(k) \) are connected with the numerator structure and spin projection of each particular graph and describe radiative corrections to the skeleton diagram. They are normalized on the skeleton numerator contributions.

It should be mentioned that some of the diagrams under consideration also contain contributions of the previous order in \( Z\alpha \). Physical nature of these contributions is especially transparent in the case of HFS. They correspond to anomalous magnetic moment, their true order in \( Z\alpha \) is lower than their apparent order and they should be subtracted from the electron factor prior to calculation of the contributions to HFS. Analogous situation holds also in the case of the Lamb shift. The only difference is that this time not only the Pauli formfactor but also the slope of the Dirac formfactor of the electron is capable to produce lower order contribution to the splitting of the energy levels (see, e. g. [12], [14] and [17]). Technically cases of lower order contributions both to HFS and to the Lamb shift are quite similar. Lower order terms are produced by the constant terms in the low-frequency asymptotic expansion of the electron factor in the case of the hyperfine splitting and by the terms proportional to the exchanged momentum squared in the low-frequency asymptotic expansion of the electron factor in the case of the Lamb shift.

These lower order contributions are connected with integration over external photon momenta of characteristic atomic order \( mZ\alpha \) and the approximation based on the skeleton integrals in eq. (1) and eq. (2) is inadequate for their calculation. In the skeleton integral approach these previous order contributions emerge as the infrared divergences induced by the low-frequency terms in the electron factors. We subtract leading low-frequency terms in the
low-frequency asymptotic expansions of the electron factors, when necessary, and thus get rid of the previous order contributions.

The results of our calculations of the contributions to HFS and Lamb produced by different diagrams in the FY gauge are presented in Table 2.

For the total correction of order $\alpha^2(Z\alpha)^5$ to the HFS and the Lamb shift produced by all diagrams in Fig.2 we obtain

$$\Delta E_{HFS}^{(1f)} = -0.6711 (7) \frac{\alpha^2(Z\alpha)^5}{\pi n^3} E_F, \quad (3)$$

and

$$\Delta E_L^{(1f)} = -7.725 (3) \frac{\alpha^2(Z\alpha)^5}{\pi n^3} \left(\frac{m_r}{m}\right)^3 m. \quad (4)$$

While this work was in progress two other papers were published where the contributions of the diagrams in Fig.2 to HFS [15] and the Lamb shift [24] were calculated. The authors of these works used a completely different approach to calculations, in particular, they worked in the Feynman gauge and, hence, all contributions of individual diagrams in these works are infrared divergent. The numbers cited in [15, 24] are obtained with the help of extrapolation of the presumably infrared finite sum of all contributions in Fig.2 to the vanishing infrared photon mass. Despite the great differences in the approaches used in the present work and in [15, 24] numerical factors in eq. (3) and eq. (4) are compatible with $-0.63(4)$ in [15] and with $-7.61(16)$ in [24], respectively. Our numbers are about two orders of magnitude more precise and further improvement of accuracy may be achieved. The reason for this increased accuracy is the use of the FY gauge, where one can avoid the extrapolation in the photon mass. The price we had paid for this advantage is the more tiresome analytic work needed to cancel all would be infrared divergences before integration.

Numerically the correction to muonium HFS in the ground state produced by the diagrams in Fig.2 is equal to

$$\Delta E_{HFS}^{(1f)} = -0.3701 (4) \text{ kHz.} \quad (5)$$

and the total contribution of order $\alpha^2(Z\alpha)E_F$ is given by

---

1Detailed account of our calculations will be presented in a separate publication.
\[ \Delta E_{HFS}^{(1a-1f)} = 0.4264 \text{ (4) kHz}. \] (6)

Taking into account other theoretical contributions to HFS and especially some small contributions obtained recently (see, e.g., reviews in [15, 25]) and using for calculation the value of the fine structure constant as obtained in [26] one may obtain the theoretical value for the muonium HFS in the ground state

\[ \Delta E_{HFS} = 4463.302.55 \text{ (0.18) (0.18) (1.33) kHz}, \] (7)

where the first error in parenthesis reflects the uncertainty of the fine structure constant itself and the second is induced by the uncertainty of the contribution of order \( \alpha(Z\alpha)^2E_F \). The third, and by far the largest contribution to the error in the theoretical value of HFS is defined by the experimental error in measuring electron-muon mass ratio \( m/M \).

The agreement between theory and experiment is excellent. We will not dwell on the HFS problem any more here since the phenomenological situation and the influence of the result in eq.(3) on the value of the electron-muon mass ratio and the fine structure constant was discussed in great detail recently [15, 25].

The case of Lamb shift deserves more comments. Numerically the corrections to the 1\( S \) and 2\( S \) Lamb shifts produced by the diagrams in Fig.2 are equal to

\[ \Delta E_L^{(1f)}(1S) = -334.2 \text{ (1) kHz}, \] (8)
\[ \Delta E_L^{(1f)}(2S) = -41.78 \text{ (2) kHz}, \]

while respective total contributions of order \( \alpha^2(Z\alpha)^5m \) are given by

\[ \Delta E_L^{(1a-1f)}(1S) = -296.9 \text{ (1) kHz}, \] (9)
\[ \Delta E_L^{(1a-1f)}(2S) = -37.12 \text{ (2) kHz}. \]

Let us discuss the sign and the scale of the correction in eq.(8). The sign may be determined by considering the electron factor, as defined in eq.(4). The low-frequency asymptotic behavior of the electron factor is described by the expression (see, e.g., [17])
\[ L(k) \approx (-2F'_1(0) - \frac{1}{2}F_2(0)) \ k^2 = -0.7046225 \ k^2, \]  

(10)

where \( F_1(k^2) \) and \( F_2(k^2) \) are the two-loop contributions to the ordinary Dirac and Pauli form factors of the electron (contribution of the graphs with vacuum polarization insertions in the photon line is omitted in eq.(10)), respectively. We use in eq.(10) the well-known values for the slope of the Dirac form factor and of the Pauli form factor at zero [29, 30]. As was explained above one has to subtract from the electron factor this leading low-frequency term which produces contribution to the Lamb shift of previous order in \( Z\alpha \).

It is well known from the general principles that the unsubtracted electron factor has at most logarithmic behavior at infinity. Hence, the high momentum behavior of the subtracted electron factor is completely defined by the subtraction term in eq.(10). Then it is clear from eq.(2), where the subtracted electron factor plays the role of the integrand, that the contribution to the Lamb shift induced by the graphs in Fig.2 has the negative sign. One may even make an estimate of this contribution from the known asymptotic behavior of the integrand but we choose a less technical path in discussion of the magnitude of this contribution.

It may seem at first sight that the magnitude of the corrections induced by the diagrams in Fig.1 as presented in eq.(8) are too large. We would like to emphasize that, quite opposite, this correction has exactly the scale one had to envisage before calculations. Let us discuss this point in slightly more detail. It is helpful to recollect that the main contribution to the Lamb shift is a radiative correction itself and so it is misleading to normalize all contributions to the Lamb shift with the help of this leading order contribution. In this respect the case of the Lamb shift differs drastically from the case of HFS, where the leading Fermi contribution is not the radiative correction but the classic effect of the interaction of two magnetic moments and sets the natural scale for all radiative corrections. Main contribution to the Lamb shift has the form \( 4m(Z\alpha)^4/n^3 \times \text{slope of the Dirac form factor} \), where the slope is roughly speaking \( \alpha/\pi \cdot (1/3) \cdot \ln(Z\alpha)^{-2} \). The skeleton factor which sets the scale for the different contributions to the Lamb shift is \( 4m(Z\alpha)^4/n^3 \) and to make an estimate of any correction to the Lamb shift one has to extract this skeleton factor. All other entries in the leading order contribution to the Lamb shift are produced by the radiative correction, and it is necessary to take into account that the number which should be of
order one, as predicts the common wisdom for radiative corrections, is the factor $1/3$ before the logarithm which remains after extraction of the factor $\alpha/\pi$, characteristic for the one-loop radiative corrections. The other subtlety to be taken into account in estimating the orders of magnitude of different corrections is that, unlike the case of radiative corrections to the scattering amplitudes, in the bound state problem not every factor $\alpha$ is accompanied by an extra factor $\pi$ in the denominator. This is a well known feature of the Coulomb problem.

Let us consider as an exercise in the art of making educated estimates the correction of order $\alpha(Z\alpha)^5m$ calculated analytically long time ago [27, 28]. According to the considerations above the scale of this correction should be set by the factor $4\alpha(Z\alpha)^5/n^3m$ and the only problem of the theory is to calculate the number of order one before this factor. Analytic calculation [27, 28] produces this factor in the form $1 + 11/128 - 1/2\log 2 \approx 0.739$ in excellent agreement with our qualitative considerations. Now it is easy to realize that the natural scale for the correction of order $\alpha^2(Z\alpha)^5$ is set by the factor $4\alpha^2(Z\alpha)^5/(\pi n^3)m$. The coefficient before this factor obtained above and in [24] is about $-1.9$ and there is nothing unusual in its magnitude for a numerical factor corresponding to a radiative correction.

Consider now current status of the Lamb shift theory. Theoretical predictions presented below are obtained with the help of the expressions for the Lamb shift contributions as collected in the reviews [31, 32], amended, besides corrections obtained above and in [24], with some other recent results presented in the Table 3. Note that the correction of order $\alpha^2(Z\alpha)^6$ in this Table is again of reasonable magnitude since its scale is set by the factor $4\alpha^2(Z\alpha)^6/(\pi^2 n^3)m$ as one may easily check with the help of the arguments used above in the discussion of the contribution of order $\alpha^2(Z\alpha)^5$. On the background of this factor numerical factor $2/27$ before the logarithm cube is quite moderate.

Last line in Table 3 contains a new recoil correction corresponding to the insertions in the Coulomb photon of the muon or hadron vacuum polarization operators. Respective contribution for the muon insertion contains an evident extra electron-muon mass ratio squared suppression factor relative to the leading vacuum polarization contribution. We estimated hadron con-

\footnote{K. Pachucki and S. Karshenboim are also considering these contributions (private communication from S. Karshenboim).}
tribution approximating the spectral function below 1 GeV according to the vector dominance model and above 1 GeV we simply used the asymptotic quark value for the spectral function.

We use in calculation of the theoretical values for the Lamb shift new values for the self-energy contributions to the coefficient $C_{60}$ for the $1S$- and $2S$-states [37], and to the function $G_{SE}$ for the $2P_{1/2}$-state [33] and for the $4S_{1/2}$-state [38]. We also use new values $G_{VP}(1S_{1/2}) = -0.6187$, $G_{VP}(2S_{1/2}) = -0.8089$, $G_{VP}(2P_{1/2}) = -0.0640$ and $G_{VP}(4S_{1/2}) = -0.8066$ for the Uehling part of the vacuum polarization contribution. These numbers are the sum of contributions of order $\alpha(Z\alpha)^6$ and of additional terms of higher order in $Z\alpha$.

From the theoretical point of view the accuracy of calculations is limited by the magnitude of the yet uncalculated contributions to the Lamb shift. First, there are pure recoil contributions of order $(Z\alpha)^6(m/M)m$ which may be as large as 1.3 kHz for the $1S$-state and 0.16 kHz for the $2S$-state. As far as we know, such terms were never discussed in the literature [31]. It is claimed in [39] that there are no such contributions besides recoil corrections obtained in [34], but, unfortunately, no proof of this statement was published. We will accept that such corrections are absent, especially taking into account that according to the estimates above they are in any case too small to influence really the comparison of the theory with the experimental results.

Unknown correction of order $\alpha^3(Z\alpha)^4$ is induced by the three-loop slope of the Dirac form factor of the electron and by the three-loop electron vacuum polarization. Natural scale for this correction is set by the factor $4\alpha^3(Z\alpha)^4/(\pi^3 n^3)m$ and we envisage the contributions about 17 kHz for the $1S$-state and 2 kHz for the $2S$-state.

Next come uncalculated corrections of order $\alpha^2(Z\alpha)^6$. Contribution of this order is a polynomial in $\ln(Z\alpha)^{-2}$, starting with log cube. The factor before log cube was calculated in [33] and the contribution of the log squared terms to the difference $E_L(1S) - 8E_L(2S)$ was obtained in [7]. However, the calculation of respective contributions to the separate energy levels is still missing. In this conditions it is fair to take the log squared contribution to the interval $E_L(1S) - 8E_L(2S)$ as an estimate of the scale of all yet uncalculated corrections of this order. We thus assume that uncertainties induced by the yet uncalculated contributions of order $\alpha^2(Z\alpha)^6$ constitute 15 kHz and 2 kHz.

The derivation of this result will be published elsewhere.
for the 1S- and 2S-states, respectively.

The scale of the self-energy correction of order $\alpha(Z\alpha)^7$ is set by the factor $4\alpha(Z\alpha)^7/n^3$. This contribution is a linear polynomial in $\ln(Z\alpha)^{-2}$. We are aware of two recent attempts to make an estimate of this contribution [40, 7], but, unfortunately, its final magnitude seems to be still unavailable.\footnote{P. Mohr is now working on the extraction of this correction from his respective high $Z\alpha$ results (Private communication from P. Mohr).}

Relying on the scale factor above and the estimates in [40, 7] we assume that the corrections of order $\alpha(Z\alpha)^7$ are as large as 17 kHz and 2 kHz to the 1S- and 2S-states, respectively.

All other theoretical contributions to the Lamb shift are smaller than those just discussed. Hence, we assume that the theoretical uncertainty of the expression for the Lamb shift is about 28 kHz for the 1S-state and about 4 kHz for the 2S-state.

The other limit on the accuracy of the theoretical calculation of the Lamb shift is put by the accuracy of the measurements of the proton rms charge radius. As is well known there are two contradictory experimental results for this radius [11, 12] and at least one of these experimental results should be in error. The accuracy of the proton rms charge radius claimed by the authors of [11, 12] produces uncertainty about 32 kHz for the 1S-state and about 4 kHz for the 2S-state.

Let us compare theoretical and experimental data for the classic $2S_{1/2} - 2P_{1/2}$ Lamb shift. The most precise experimental data as well as the results of our theoretical calculations are presented in Table 4. Theoretical results for the energy shifts in Table 4 contain errors in the parenthesis where the first error is determined by the yet uncalculated contributions to the Lamb shift, discussed above, and the second reflects the experimental uncertainty in the measurement of the proton rms charge radius. We have used experimental result [6] taking into account recent theoretical correction discovered in [1]. Note, however, that this correction does not effect any of our conclusions. There are two immediate conclusions of the data in Table 4. First, as already mentioned in [24], the results of the proton rms radius measurement in [11] should be in error since respective value of the proton charge radius is clearly inconsistent with all results of the Lamb shift measurements. Second, we have to reject either the result of the most precise measurement of the $2S_{1/2} - 2P_{1/2}$ splitting, or the experimental value of the proton charge radius as measured in
Since the Lamb shift value in [8] contradicts theoretical value calculated employing the rms radius in [42] by more than five standard deviations. Results of two other measurements of the classic Lamb shift are compatible with the theory, so we will below accept the value of the proton charge radius as obtained in [42]. We will return to the numbers in three last lines in Table 4 below.

We do not include theoretical predictions for the deuterium Lamb shift in Table 4, since, taking into account current discrepancies in determination of the deuteron charge radius and solid status of the Lamb shift theory, it seems preferable to use the deuteron Lamb shift data for extracting the value of this charge radius rather than for comparison of the Lamb shift theory and experiment.

Next we turn to the discussion of the $1S$ Lamb shift. Unfortunately, its extraction from the experimental data is less straightforward. The experimentalists managed to separate measurement of the $1S$ Lamb shift from the measurement of the Rydberg constant by comparing the frequencies of two transitions with different main quantum numbers and excluding the large levels separation depending on the Rydberg constant. In this manner certain combinations of $1S$, $2S$ and of higher levels Lamb shifts are experimentally obtained. It is pretty easy to compare these experimental data in [1, 2, 3, 4] with the theory above and after trivial calculations we have found an excellent agreement between the theory and experiment. We will not put down these results here.

Unbiased extraction of the $1S$ Lamb shift from the experimental data is still a problem. It is impossible to avoid using to this end the experimental value of the $2S$ Lamb shift, and the emerging value of the $1S$ Lamb shift depends thus on the experimental result for the $2S_{1/2} - 2P_{1/2}$ splitting. Higher levels Lamb shifts, which also enter the problem may be safely calculated with sufficient accuracy. The standard approach accepted by all experimental groups consists in adopting one or the other $2S_{1/2} - 2P_{1/2}$ experimental result and extracting thus the value of the $1S$ Lamb shift. All values in Table 1 for the $1S$ Lamb shift are obtained in this manner with the help of experimental values in [3] or in [8] for the classic Lamb shift. These values should be compared with our theoretical prediction

$$\Delta E_L(1S) = 8\,172\,729\, (28)\, (32)\, \text{kHz}, \quad (11)$$
where again the first error is determined by the yet uncalculated contributions to the Lamb shift and the second reflects the experimental uncertainty in the measurement of the proton rms charge radius.

The results of all experiments mentioned in Table 1 are pretty consistent and their agreement with the theoretical value in eq. (11) is satisfactory but not spectacular. It is necessary to recollect at this point that the “experimental values” in the Table depend on the experimental value of the $2S_{1/2} - 2P_{1/2}$ Lamb shift adopted in their extraction and the change of the $1S$ Lamb shift value under transition from one experimental $2S_{1/2} - 2P_{1/2}$ Lamb shift value to another may be significant.

It would be helpful to find a way to extract the value of the $1S$ Lamb shift from the experimental data unambiguously without reference to the $2S_{1/2} - 2P_{1/2}$ experimental results, which, while being compatible with the theory, seem to be somewhat larger than the theoretical prediction. A natural way to reach this goal is to use the theoretical relation between the $1S$ and $2S$ Lamb shifts. A good deal of theoretical contributions to the Lamb shift scale as $n^3$ and, hence, vanish in the difference $8E_L(2S) - E_L(1S)$. In particular, all main sources of the theoretical uncertainty, namely, proton charge radius contribution and almost all yet uncalculated corrections to the Lamb shift mentioned above vanish. Significant contribution to this difference may be produced only by the term of the form $\alpha^2(Z\alpha)^6 \ln(Z\alpha)^{-2}$, which was calculated recently [7]. This term produces correction about 14 kHz and the accuracy of the difference under consideration is determined by the yet uncalculated single log contribution of the same order. Such term would not change the log squared term by more than fifty percent and, hence, the uncertainty of the difference under consideration is about 7 kHz. Hence, we obtain the relation

$$8E_L(2S) - E_L(1S) = \Delta,$$

where $\Delta = 187234 (7)$ kHz.

Now one may obtain self-consistent values for the $1S$ Lamb shift directly from the experimental data in Refs.[3, 4, 2] with the help of the relations

$$E_L(1S) = \frac{8}{3}(F_{1S-2S} - 4F_{2S-4S_{1/2}}) - \frac{32}{3}E_L(4S_{1/2}) + \frac{5}{3}\Delta,$$  

$$E_L(1S) = \frac{8}{3}(F_{1S-2S} - 4F_{2S-4P_{1/2}}) - \frac{32}{3}E_L(4P_{1/2}) + \frac{5}{3}\Delta,$$
\[ E_L(1S) = \frac{40}{19} (F_{1S-2S} - \frac{16}{5} F_{2S-8D_{5/2}}) - \frac{128}{19} E_L(8D_{5/2}) + \frac{21}{19} \Delta. \] (15)

Numerical results are presented in Table 5. These results have somewhat larger errors than the respective results in Table 1, however, they do not depend on the experimental value of the \(2S_{1/2} - 2P_{1/2}\) Lamb shift and on the value of the proton charge radius. The accuracy of the self-consistent numbers in Table 5 is mainly determined by the accuracy of the frequency measurements in [3, 2, 4]. Factor 4-5 reduction of the experimental errors would lead to a self-consistent determination of the \(1S\) Lamb shift with the same accuracy as for the values cited in Table 1. One may even invert the usual approach to the \(2S_{1/2} - 2P_{1/2}\) and \(1S\) Lamb shift values and extract values of the \(2S-2P\) Lamb shift from the respective self-consistent \(1S\) values (see three last lines in Table 4). These values of the \(2S_{1/2} - 2P_{1/2}\) Lamb shift are consistent with the results of the direct measurements of the \(2S_{1/2} - 2P_{1/2}\) Lamb shift but have somewhat larger error bars. However, self-consistent values of the \(2S_{1/2} - 2P_{1/2}\) Lamb shift would become quite competitive with the results of the direct measurements after the 4-5 times reduction of the current experimental errors in the frequency measurements would be achieved.

Reduction of the errors of the values of the \(1S\) and \(2S_{1/2} - 2P_{1/2}\) Lamb shifts opens new ways to a more precise determination of the Rydberg constant. We would like to mention two new directions in the determination of the Rydberg constant value besides the one adopted now (see, e.g., [1, 2]). First, one can use the self-consistent value of the \(1S\) Lamb shift and respective \(2S_{1/2} - 2P_{1/2}\) Lamb shift to get the value of the Rydberg constant. Today such approach leads to a loss of accuracy in comparison with the current experimental value of the Rydberg constant (see Table 6, where the first error in the self-consistent values of the Rydberg constant is determined by the accuracy of the self-consistent Lamb shift values and the second is determined by the accuracy of the frequency measurement), but greater accuracy may be achieved in future. Important advantage of such approach is that the value obtained in this way is independent of the direct experimental results on \(2S_{1/2} - 2P_{1/2}\) Lamb shift and of the value of the proton charge radius. Second new approach is simply to reject the experimental data on the Lamb shifts and to use for the determination of the Rydberg constant directly the data on the frequencies of transitions between the levels with different main quantum numbers. Such approach becomes feasible now since the accuracy
of the theoretical expression for such transitions is defined by the theoretical error of the expression for the 1S (or 2S) Lamb shift which is about 28 kHz (and is even smaller for the 2S Lamb shift) as discussed above and is thus smaller than the experimental error of the frequency determination. Respectively, values of the Rydberg constant are again presented in Table 6, where the first error is determined by the accuracy of the theoretical expression, the second is defined by the experimental error of the frequency measurement, and the third one is determined by the experimental error in the determination of the proton charge radius. The values of the Rydberg constant in two last lines in Table 6 derived from independent experimental data [2, 1] are pretty consistent. These values are more accurate than the ones obtained by other methods and are the most precise contemporary values of this constant. Natural drawback of this approach is, of course, the dependence of the obtained value of the Rydberg constant on the proton charge radius.

In conclusion we would like to emphasize that the high accuracy of the Lamb shift theory opens new perspectives in determination of the Rydberg constant and of the Lamb shift in the 1S- and 2S-states. Four directions of experimental investigations, namely, more precise measurement of the transitions between levels with different main quantum numbers, more precise measurement of the 1S and 2S Lamb shifts, and direct measurement of the proton charge radius seem especially promising. It is very important that all these experiments are mutually complementary, since they may lead to the values of the Rydberg constant of comparable accuracy based on the different kinds of experimental data. On the theoretical side calculation of the still unknown corrections to the energy levels discussed above with the goal of reduction of the theoretical error in determination of the 1S Lamb shift to the level of 1 kHz (and, respectively, of the 2S Lamb shift to several tenth of kHz) seems to be both quite perspective and feasible.

We are deeply grateful to S. G. Karshenboim who took part at the initial stage of this project as described in [20, 21]. M. E. is deeply grateful to H. Grotch for fruitful collaboration on the other corrections of order $\alpha^2(Z\alpha)^5$ to the Lamb shift and for numerous helpful discussions. We are indebted to P. Mohr for helpful communications on the vacuum polarization contributions to the Lamb shift and for providing us his new results prior to publication. We highly appreciate useful communications with M. Boshier on the preliminary results of the new measurement of the 1S Lamb shift [4]. M. E.
acknowledges helpful discussions on the physics of hyperfine splitting and Lamb shift with T. Kinoshita, D. Owen and K. Pachucki.

The analytic calculations above were partially performed with the help of the REDUCE. Final numerical calculations with the help of the VEGAS program were conducted at the Maui High Performance Computing Center and we highly appreciate the opportunity to use these facilities. Through the use of the MHPCC, this research was sponsored in part by the Phillips Laboratory, Air Force Materiel Command, USAF, under cooperative agreement number F29601-93-2-0001. The views and conclusions contained in this document are those of the authors and should not be interpreted as necessarily representing the official policies or endorsements, either expressed or implied, of Phillips Laboratory or the U.S. Government. Part of this work was done during the visit of M.E. to the Penn State University. He is deeply grateful to the colleagues at the Physics Department of the Penn State University and especially to H. Grotch for kind hospitality. The research described in this publication was made possible in part by grant #R2E000 from the International Science Foundation and was also supported by the Russian Foundation for Fundamental Research under grant #93-02-3853. Work of M.E. was supported in part by the National Science Foundation under grant #NSF-PHY-9120102.
