Abstract
Background: Periodontitis is a chronic inflammatory disorder involving the periodontium. The precise nature of the association between periodontitis and psoriasis has not been determined. Objective: This nationwide population-based study investigated the relationship between periodontitis and the risk of psoriasis. Methods: A health screening database, which is a sub-dataset of the Korean National Health Insurance System database, was used in this study. Subjects with \( n = 1,063,004 \) and without \( n = 8,655,587 \) periodontitis who underwent health examinations from January to December 2009 were followed for 9 years. Results: In multivariable analysis, compared to the non-periodontitis group, periodontitis patients had a significantly higher risk of developing psoriasis (hazard ratio 1.116, 95% confidence interval 1.101–1.13). Non-smokers with periodontitis had an 11% increase in risk of psoriasis and smokers with periodontitis had a 26.5% increase in risk of psoriasis compared to non-smokers without periodontitis. Conclusion: Our study highlights periodontitis as a potential independent risk factor for psoriasis, increasing awareness of the synergistic role of smoking and periodontitis in the pathogenesis of psoriasis.
assessed the associations between periodontitis and immune-mediated systemic inflammatory disorders [6–8]. Bacterial colonization in the oral cavity may induce an exaggerated immune response in a susceptible host, leading to an inflammatory process associated with autoimmune disorders [6, 9, 10]. Indeed, patients with periodontitis tend to have higher incidence and prevalence rates of obesity, diabetes mellitus, CVD, and rheumatoid arthritis [9, 11–13]. Although several previous studies have suggested a link between periodontitis and psoriasis, the precise nature of the association and its underlying mechanism have not been determined [7, 14, 15]. Moreover, no large-scale, nationwide cohort studies have examined whether periodontitis increases the risk of psoriasis. Therefore, we investigated the relationship between periodontitis and risk of psoriasis using the National Health Insurance System (NHIS) claims database in Korea.

Materials and Methods

Data Source

The representative health screening database of the Korean NHIS was used in this study. The NHIS is a single, essential health insurance program that covers approximately 97% of the Korean population. The remaining 3% of the population with low income is covered by a medical aid program, and their data have been integrated into the NHIS database [16]. Therefore, since 2006, the NHIS database actually includes the whole Korean population. Health checkups are managed by the government and are implemented by almost all of the Korean population. NHIS members are encouraged to undergo a health checkup every 2 years. Patient demographic information and medical claims are included in the NHIS database. The database is based on the International Classification of Disease, Tenth Revision, Clinical Modification (ICD-10-CM) codes.

Study Population

From the NHIS database, patients aged ≥20 years who underwent health screening from January 2009 to December 2009 were included in the study. We applied a 12-month washout period to exclude patients with prediagnosed periodontitis and psoriasis. Patients were excluded if they were <20 years of age, were missing data, or were diagnosed with psoriasis prior to the health screening. Ultimately, 1,063,004 subjects with periodontitis and 8,655,587 subjects without periodontitis and a total 9,718,591 subjects were followed for 9 years from January 2009 to December 2017 (Fig. 1). We identified patients with newly diagnosed psoriasis during the follow-up period, based on the claims data. Patients with periodontitis and psoriasis were identified using the ICD-10-CM codes (chronic periodontitis [K05.3], psoriasis [L40]). Periodontitis is usually treated through scaling, subgingival curettage, or periodontal surgery based on the depth of the periodontal pocket and bone destruction, and is covered by the NHIS in Korea. Therefore, the periodontitis group was divided into three stages, according to the severity of periodontitis, based on therapeutic procedures including scaling, subgingival curettage, and periodontal surgery [17, 18].

Data and Baseline Comorbidities

Information on height, weight, waist circumference, systolic blood pressure, diastolic blood pressure, fasting plasma glucose, total cholesterol, low-density lipoprotein levels, high-density lipoprotein levels, body mass index (BMI, kg/m²), smoking status (non-smoker, ex-smoker, or current smoker), alcohol consumption (non-drinker, mild drinker [<30 g/day], or heavy drinker [≥30 g/day]), physical activity, and socioeconomic status was obtained from the health screening program. Comorbid diseases were defined according to both diagnostic codes and associated prescribed medication during the study period [16].

Fig. 1. Flowchart of included patients.
Statistical Analyses

The baseline characteristics of the study population are expressed as numbers and percentages or means ± standard deviations. Differences in clinical characteristics according to the presence of psoriasis were analyzed using Student *t* test or *χ*² test. To evaluate the risk of incident psoriasis, Cox proportional hazards regression analyses were performed to calculate the hazard ratio (HR) and 95% confidence interval (CI). After adjustment for demographic factors, the multivariable HR and 95% CI were calculated. Model 1 was adjusted for age and sex. Model 2 was adjusted for age, sex, alcohol consumption, physical activity, BMI, diabetes mellitus, hypertension, dyslipidemia, and income level. Subgroup analyses were performed according to periodontitis and smoking status. The study population was divided into the following four groups: no periodontitis with/without smoking, and periodontitis with/without smoking. Cumulative incidence curves were plotted using the Kaplan-Meier method and statistical significance was examined using the log-rank test. Statistical analyses were performed using SAS software version 9.4 (SAS Institute, Cary, NC, USA), and two-sided *p* < 0.05 was considered to indicate statistical significance.

Results

Baseline Characteristics of the Study Population

From January 2009 to December 2009, we identified 1,063,004 patients with periodontitis and 8,655,587 patients without. The baseline and clinical characteristics of the study population are summarized in Table 1.

Risk of Psoriasis in Periodontitis Patients

Table 2 shows the incidence rates of psoriasis and risk of psoriasis according to the presence of periodontitis. The incidence rates of psoriasis per 1,000 person-years were 3.477 in patients with periodontitis and 2.904 in the non-periodontitis group. In multivariable analysis, compared to the non-periodontitis group, patients with periodontitis (HR 1.116, 95% CI 1.101–1.13) had a significantly higher risk of developing psoriasis. However, subgroup analysis according to periodontitis severity showed no difference in psoriasis risk.

Table 1. Characteristics of the study population

|                        | No periodontitis | Periodontitis | *p* value |
|------------------------|------------------|---------------|-----------|
| Number                 | 8,655,587        | 1,063,004     | <0.0001   |
| Sex                    |                  |               |           |
| Male                   | 4,727,593 (54.62%) | 585,936 (55.12%) |           |

| Severe               | 34,494   | 822       | 3.31632                               | 1.076 (1.005, 1.152) |         | 1.077 (1.005, 1.153) |

Data are expressed as hazard ratios and 95% confidence intervals. <sup>a</sup> Model 1 was adjusted for age and sex. <sup>b</sup> Model 2 was adjusted for age, sex, smoking status, alcohol drinking status, exercise status, household income, BMI, and comorbidities of type 2 diabetes mellitus, hypertension, and hyperlipidemia.

**Table 3.** Risks and incidence rates of psoriasis in each subgroup, stratified according to periodontitis and smoking status

| Group                                      | n     | Psoriasis | Incidence per 1,000 person-years | Model 2<sup>a</sup> |
|--------------------------------------------|-------|-----------|-----------------------------------|---------------------|
| No periodontitis, non-smoker               | 6,368,815 | 129,480 | 2.82462                           | 1 (ref.)            |
| No periodontitis, smoker                    | 2,286,772 | 51,085   | 3.12515                           | 1.118 (1.105, 1.131)|
| Periodontitis, non-smoker                   | 811,546  | 19,621    | 3.36481                           | 1.11 (1.094, 1.127) |
| Periodontitis, smoker                       | 251,458  | 6,873     | 3.8449                            | 1.265 (1.234, 1.296)|

Data are expressed as hazard ratios and 95% confidence intervals. <sup>a</sup> Model 2 was adjusted for age, sex, smoking status, alcohol drinking status, exercise status, household income, BMI, and comorbidities of type 2 diabetes mellitus, hypertension, and hyperlipidemia.

**Risk of Psoriasis in Subgroup Depending on Periodontitis and Smoking**

Table 3 shows the results of multivariable Cox proportional hazards regression analysis for the association between each subgroup and incident psoriasis, classified into four subgroups according to presence of periodontitis and smoking status. Non-smokers with periodontitis exhibited an 11% increase in the risk of psoriasis (HR 1.11, 95% CI 1.094–1.127) compared to non-smokers without periodontitis, whereas smokers with periodontitis exhibited a 26.5% increase in the risk of psoriasis (HR 1.265, 95% CI 1.234–1.296) compared to non-smokers without periodontitis.

**Cumulative Incidence Rates of Psoriasis**

Kaplan-Meier analysis revealed that the cumulative incidence rate of psoriasis was significantly higher in patients with periodontitis than in the non-periodontitis group throughout the entire study period (log-rank test, p < 0.0001) (Fig. 2).

**Discussion**

This nationwide population-based cohort study evaluated the association between periodontitis and the risk of psoriasis. We found a significantly increased risk of incident psoriasis among patients with periodontitis compared to patients without. Moreover, the risk of psoriasis was significantly higher in the periodontitis/smoker group than in the non-periodontitis/smoker and periodontitis/non-smoker groups. The cumulative incidence rate of psoriasis was significantly higher in patients with periodontitis than in patients without periodontitis throughout the entire study period.
Consistent with our findings, two previous meta-analysis studies demonstrated that periodontitis was associated with a 1.55-fold (pooled relative risk 1.55, 95% CI 1.35–1.77) and 2.87-fold (pooled relative risk 2.87, 95% CI 1.75–4.69) increased risk of psoriasis compared to the absence of periodontitis [6, 19]. Among the studies included in previous meta-analysis studies were reports conducted in Asia (Taiwan) and Western countries (United States, Norway, Greece, and Italy), all of which support that periodontitis increases the risk of psoriasis [20–24]. Similarly, a cohort study in Taiwan found a higher risk of psoriasis in patients with periodontitis (HR 1.52, 95% CI 1.38–1.70) compared to non-periodontitis subjects [20]. In addition, there is a previous report suggesting the association between periodontal bone loss and the risk of psoriasis [21]. Epidemiological studies have recently reported a link between periodontitis and psoriasis, and several studies have reported that severe psoriasis may increase the severity and risk of periodontitis [7, 22, 25–27]. A longitudinal cohort study of the Danish population found an increased risk of periodontitis in patients with psoriasis, with the highest risk found in patients with psoriatic arthritis [7]. Moreover, the severity of periodontitis has been shown to be correlated with the severity of psoriasis [25]. However, few studies have examined the severity of psoriasis according to the severity of periodontitis. Most of these studies were conducted with small numbers of patients through meta-analyses, cohort studies, and case-control studies, and the severity was often unclassified or classified into two stages, and some were based on self-reported severity [6, 20, 21, 25]. In this study, subgroup analysis according to periodontitis severity showed no difference in psoriasis risk. This study differs from previous studies in that it is a large population-based study and classified the severity of periodontitis into three stages based on therapeutic procedures, such as scaling, subgingival curettage, and periodontal surgery. Although the classification of the severity of periodontitis according to treatment method has not yet been clearly verified, it is meaningful in that it reflects the severity in the actual treatment environment, and further validation of severity classification might be needed.

Although the exact mechanism by which periodontitis acts as a risk factor for psoriasis has not been identified, there is increasing evidence that periodontitis and psoriasis share several common immunopathogenic processes [14, 25]. First, the inflammatory environments in periodontitis and psoriasis share many similarities. Studies have suggested that Porphyromonas gingivalis is the main pathogen of periodontitis and that it activates innate and adaptive immune responses. It is also suggested that in periodontitis, immune activation by dysbiotic pathogens may trigger a systemic inflammatory reaction similar to psoriasis [7, 28]. The microenvironment in periodontitis induces proinflammatory cytokines, such as tumor necrosis factor alpha, interleukin (IL)-1β, and IL-17, and reduces IL-4 and IL-10, which is also observed in psoriasis [14, 22, 26, 29].

Second, periodontitis and psoriasis share common risk factors and comorbidities, and it is thought that this may serve as a link between the two diseases [30, 31]. Several reports suggest that patients with periodontitis exhibit an increased risks of metabolic syndrome and CVD, which is a common comorbidity in psoriasis [8, 13, 30, 32, 33]. Chronic periodontitis has been suggested to be a distant source of inflammatory byproducts associated with insulin resistance and obesity [13, 34, 35]. The association between metabolic syndrome and periodontitis consists of a constant low-grade inflammatory status, which can lead to the development of insulin resistance and imbalanced interactions between cytokines and the periodontium [34]. In addition, there is emerging evidence that bacterial infection and modulation of inflammation are key elements in the development of insulin resistance, which causes CVD [32, 33]. Antibodies against periodontal pathogens react with host antigens and cause systemic inflammation and endothelial dysfunction [33]. In patients with periodontitis mastication, tooth brushing, and
Periodontitis and the Risk of Psoriasis

Periodontitis is a potential independent risk factor for psoriasis, and periodontitis and smoking may synergistically increase the risk of psoriasis.

There are several limitations to this study. (1) The diagnoses of periodontitis and psoriasis were conducted on the basis of the NHIS claim data, without direct review of medical records. Also, NHIS database records lack detailed information regarding the severity and type of psoriasis and family history of the study population. Diagnosis in the NHIS claim database is performed by a dentist for periodontitis and a dermatologist for psoriasis, respectively. However, the possibility of misclassification bias due to the limitation of the claim database must be considered. (2) Some patients included in this study might have had psoriasis that was not previously diagnosed. In addition, since only patients who visited the hospital and were diagnosed were included in the study, patients who did not visit the hospital were not included, and there is a possibility of selection bias. Moreover, it is difficult to exclude the possibility that reverse association may have occurred due to previously undiagnosed psoriasis patients. (3) Health checkups are managed by the government and are implemented by NHIS subscribers, which is almost all of the Korean population. They are recommended to undergo health checkups every 2 years, and the data are entered into the health checkup database. Although almost all of the Korean population are included in the health checkup database, it is difficult to exclude the possibility that some healthy patients might not access the health checkup system. Therefore, a kind of semi-“healthy user bias” should be considered.

Despite these limitations, the major strengths of this study are its large sample size and nationally representative patient population. In addition, the database used is maintained by the government and public organizations that provide national health information, which makes the data stable. Finally, we controlled for confounding factors such as BMI, smoking status, alcohol consumption status, and physical activity level.

In conclusion, our study highlights periodontitis as a potential independent risk factor for psoriasis, increasing the awareness of the role of periodontitis in the pathogenesis and comorbidities of psoriasis. The results suggest that periodontitis and smoking may synergistically increase the risk of psoriasis. Patients with periodontitis should be monitored for psoriasis, and increased focus on lifestyle correction may be warranted.

Key Message

Periodontitis is a potential independent risk factor for psoriasis, and periodontitis and smoking may synergistically increase the risk of psoriasis.
