OBJECTIVE — Gestational diabetes is a risk factor for large-for-gestational-age (LGA) newborns, but many LGA babies are born to mothers with normal glucose tolerance. We aimed to clarify the association of maternal glycemia across the whole distribution with birth weight and risk of LGA births in mothers with normal glucose tolerance.

RESEARCH DESIGN AND METHODS — We undertook a population-based gestational diabetes screening in an urban area of Hungary in 2002–2005. All singleton pregnancies of mothers ≥18 years of age, without known diabetes or gestational diabetes (World Health Organization criteria) and data on a 75-g oral glucose tolerance test at 22–30 weeks of gestation, were included (n = 3,787, 78.9% of the target population). LGA was determined as birth weight greater than the 90th percentile using national sex- and gestational age–specific charts.

RESULTS — Mean ± SD maternal age was 30 ± 4 years, BMI was 22.6 ± 4.0 kg/m², fasting blood glucose was 4.5 ± 0.5 mmol/l, and postload glucose was 5.5 ± 1.0 mmol/l. The mean birth weight was 3,450 ± 476 g at 39.2 ± 1.2 weeks of gestation. There was a U-shaped association of maternal fasting glucose with birth weight (Pcurve = 0.004) and risk of having an LGA baby (lowest values between 4 and 4.5 mmol/l, Pcurve = 0.0004) with little change after adjustments for clinical characteristics. The association of postload glucose with birth weight (P = 0.03) and the risk of an LGA baby (P = 0.09) was weaker and linear.

CONCLUSIONS — Both low and high fasting glucose values at 22–30 weeks of gestation are associated with increased risk of an LGA newborn. We suggest that the excess risk related to low glucose reflects the increased use of nutrients by LGA fetuses that also affects the mothers’ fasting glucose.

the first 2 years of the screening program, the ascertainment rate was >99% of all pregnant women delivered in the hospital (17,18).

The screening database captured 5,335 pregnancies between 1 January 2002 and 30 April 2005. Our target population did not include women aged <18 years at the time of delivery (n = 8), women with twin pregnancies (n = 115), or women with known pregestational diabetes or gestational diabetes mellitus (n = 411), leaving a total of 4,801 pregnancies for further analysis. We excluded 641 women with an early or late OGTT (<22 or >30 weeks of gestation at the time of analysis), 45 women because of missing birth weight data or delivery before 24 weeks of gestation, 266 because of missing or incomplete blood glucose data, and 62 because of missing data on covariates. Thus, the final analytic sample consisted of 3,787 women (78.9% of the women in the target population).

Measurements
All 75-g OGTTs were performed in the morning hours (before 10 a.m.) between 22 and 30 weeks of gestation. Women were instructed to follow an unrestricted diet for at least 3 days before the test and to come for the investigation after at least 8 h of fasting. After the collection of fasting blood samples, women were asked to drink 75 g of anhydrous glucose in 250–300 ml of water. Blood samples, also taken 2 h after the glucose load, were collected into fluoride-containing tubes. Venous plasma glucose was measured in the central laboratory of the hospital using a glucose-oxidase–based method. Gestational diabetes mellitus was diagnosed if either the fasting venous plasma glucose was \( \geq 7.0 \text{ mmol/l} \) or the 2-h postload venous plasma glucose was \( \geq 7.8 \text{ mmol/l} \).

Data on birth weight and sex of the newborn were extracted from the discharge documentation. LGA was determined as a birth weight greater than the 90th percentile on sex- and gestational age–specific national charts (19).

Gestational age was primarily based on the date of the last menstrual period and was substituted by the result of a first-trimester ultrasound examination (\( \sim 8–12 \) weeks of gestation) if information on the last menstrual period was missing or if there was a \( >2 \)-week discrepancy between the two estimates.

At the time of the OGTT, anthropometric measurements (height and weight) were performed and BMI was calculated. Systolic and diastolic blood pressures were determined by a trained nurse using a standard mercury sphygmomanometer. The mean arterial pressure was calculated as \( (2 \times \text{diastolic blood pressure} + \text{systolic blood pressure})/3 \). After delivery a detailed questionnaire was completed during a face-to-face interview by a trained researcher (A.P.). Family history of diabetes among first-degree relatives, age of the mother, smoking status during pregnancy (yes or no), ethnicity (Caucasian or other), and parity (0, 1, or \( \geq 2 \)) were recorded.

Statistical analysis
Descriptive statistics are given as means \( \pm \text{SD} \) for continuous variables and percentages for categorical variables. After investigation of crude frequencies of LGA babies according to fasting and 2-h post-load glucose categories, we computed binary logistic regression models with LGA as the outcome and glucose categories as dummy variables (fasting glucose \( \leq 3.5, 3.51–4.0, 4.01–4.5, 4.51–5.0, 5.01–5.5, \) and \( \geq 5.51 \text{ mmol/l} \) and 2-h postload glucose \( \leq 4.0, 4.01–4.8, 4.81–5.6, 5.61–6.4, 6.41–7.2, \) and \( \geq 7.21 \text{ mmol/l} \), the third category being the reference category in both analyses. Odds ratios (ORs) and 95% CIs were adjusted for ethnicity, parity of the mother, and sex of the newborn (model 1) and then were further adjusted for maternal age, BMI, smoking, family history of diabetes, gestational age at the OGTT, mean arterial blood pressure, and height (model 2). Similar generalized linear models using logit link were computed with continuous fasting and postload blood glucose and their squared terms (to test for nonlinearity) as independent variables instead of glucose categories and to estimate probabilities and their CIs on continuous glucose scales.

Further analyses applying general linear modeling examined associations of maternal glucose with birth weight describing crude and adjusted birth weights (and SEM) in the above glucose categories. Then we applied similar models to test for linear and curvilinear trends in these associations with linear and quadratic glucose terms (as required). We estimated birth weights from these models after adjusting for covariates (model 1 and model 2) as described above. All statistical analyses were done using SPSS for Windows 16.0. Two-tailed \( P < 0.05 \) was considered statistically significant.

RESULTS—Characteristics of the mothers and newborns and pregnancy outcomes are summarized in Table 1. The mean age of the subjects was 29.7 years, and the mean fasting and 2-h postload glucose levels were 4.5 and 5.5 mmol/l, respectively. There were 12 stillbirths and no maternal deaths in the target population.

Risk of LGA newborns according to the fasting and 2-h postload glucose levels
The frequency of LGA newborns across the predefined fasting and postload glucose categories is shown in Table 2. Fasting blood glucose showed a nonlinear relationship with the risk of LGA: compared with the reference group (4.01–4.5 mmol/l) both lower and higher maternal fasting glucose levels were associated with increased risk (Table 2). The curvilinear association was statistically significant in a model simultaneously including continuous fasting glucose and its square irrespective of adjustments (\( P_{\text{curve}} = 0.044 \) for model 1 and \( P_{\text{curve}} = 0.044 \) for model 2) (Fig. 1A).

Postload glucose showed a weaker association with the risk of LGA and only the highest maternal glucose category was related to elevated risk in a model adjusted for sex, ethnicity, and parity. However, this association was attenuated and became nonsignificant after further adjustments (Table 2). In the logistic regression analysis using continuous glucose values as predictors, the squared term was nonsignificant (\( P_{\text{curve}} = 0.46 \)) and the linear association between postload glucose and the risk of LGA was weak and only borderline significant (OR 1.08 [95% CI 0.99–1.17], per 1 mmol/l increase in postload glucose, \( P = 0.08 \) for model 1; \( P = 0.07 \) [0.98–1.17], per 1 mmol/l increase in postload glucose, \( P = 0.13 \) for model 2).

Birth weight according to the fasting and 2-h postload glucose levels
The crude birth weight showed a U-shaped association with the predefined fasting glucose categories with the lowest values in the third group (4.01–5.0 mmol/l) and higher values at both ends of the glucose distribution (Table 3). The association between continuous maternal fasting glucose levels and birth weight followed a quadratic function; the lowest birth weight values were between 4 and 4.5 mmol/l (\( P_{\text{curve}} < 0.0001 \) for model 1) (Fig. 1B). This association was robust

| Caucasian (%)                                | 98.4    |
| Mean arterial pressure (mmHg)*               | 81.4 ± 9.1 (73.3–86.7) |
| Blood glucose (mmol/l)*                     |         |                |
| Fasting                                      | 4.5 ± 0.5 (4.2–4.8) |
| 2-h                                          | 5.5 ± 1.0 (4.8–6.2) |
| Length of gestation at the time of OGTT (weeks)| 25.5 ± 1.8 (24–27) |
| Any smoking during pregnancy (%)             | 4.4     |
| Diabetes among first-degree relatives (%)    | 12.8    |
| Nulliparous (%)                              | 56.9    |
| Newborn                                      |         |                |
| Gestational age at delivery (weeks)          | 39.2 ± 1.2 (39–40) |
| Birth weight (g)                             | 3,450 ± 476 (3,150–3,750) |
| Male sex (%)                                 | 51.6    |
| LGA (%)†                                     | 16.5    |

Data are % or means ± SD (interquartile range). n = 3,787. *Age, BMI, and mean arterial pressure were obtained at the OGTT (22–30 weeks of gestation). †LGA was determined as a birth weight greater than the 90th percentile on sex- and gestational age-specific national charts.

There was a linear association between 2-h postload glucose and birth weight (P = 0.03 for model 1) with no evidence of curvilinearity (Table 3, Fig. 1C). Again, further adjustment had little effect on the models (P = 0.002 for model 2, detailed data not shown).

CONCLUSIONS

Short summary

In this population-based screening program of gestational diabetes mellitus using a 75-g OGTT, the risk of LGA newborns was nonlinearly related to fasting glucose levels among predominantly Caucasian women residing in an urban area of Hungary. Increased risk was found to adjustment for covariates (P_{curve} = 0.01 for model 2; detailed data not shown).

Comparison with other studies

Although there are several population-based screening studies for gestational diabetes mellitus, only a few reported fasting glucose values at the time of the screening (5,7–11,13,14,20). This is not surprising because the widely accepted American Diabetes Association Position Statement generally recommends prescreening with a glucose challenge test that is performed irrespective of fasting status. An OGTT is recommended only in the case of an abnormal result (21).

However, at least six previous studies had data on maternal fasting glucose. Two of the medium-sized studies did not report tests for nonlinearity or risk for categorical glucose groups and thus were not informative regarding the U-shaped association between fasting glucose and the risk of LGA (9,20). Two other studies reported formal tests of nonlinearity for the fasting glucose–LGA relationship: One showed no clear inflection point for these associations but observed an elevated risk in the lowest glucose category (7). The HAPO study found no significant deviation from linearity (8). Despite its very large sample size, some circumstances should be mentioned that might have reduced sensitivity to observe elevated LGA at the low end of maternal fasting glucose. First, the HAPO study involved a multinational, multiethnic population, leading to several tests for interactions in the analysis and thus limiting the power for showing a relationship that might only hold for certain ethnicities. Second, because of the excessive number of outcomes investigated, the HAPO investigators had to correct their P values for multiple testing, which may have increased the risk of a type I error (rejecting a null hypothesis when it is true). Third, in the categorical analysis of fasting glucose, their lowest group was defined as glucose levels <4.2 mmol/l, which does not differentiate the three lowest categories used in the present analysis (8). Furthermore, when we combined the first three groups into one category in our data, the relationship...
between fasting glucose categories and LGA seemed to be linear (data available on request). There is a further study that reports on macrosomia (birth weight over a certain cutoff value) as a function of fasting glucose levels and suggests no deviation from linearity (5).

Literature data are not much more detailed regarding the relationship between fasting glucose and birth weight. At least four studies reported positive correlations with various strengths between birth weight and fasting glucose without testing for nonlinearity (11,13,14,20). One of these investigated the shape of the fasting glucose–birth weight relationship and found that the linear association between fasting glucose and birth weight holds only for the middle ranges of the glucose distribution (7).

We did not observe a U-shaped association between postload glucose and size of newborn, and the linear trend found was only suggestive. In previous studies, a linear relationship between 2-h postload glucose and the risk of LGA or macrosomia was a frequent observation before adjustment for covariates (5,7–10,12,15). Whereas some studies reported a strong linear relationship after several adjustments (8,9), others, similarly to us, found weak or nonsignificant relationships between postload glucose and the risk of LGA or macrosomia (5,10). In our study, this observation was related to mothers with normal glucose tolerance; that is, those at the low and moderate but not at the

| ≥5.51 mmol/l              | 3,537 (3,437–3,637)    | 3,559 (3,461–3,657) | 3,549 (3,452–3,646) |

| 2-h postload glucose categories | Crude birth weight (g) | Model 1* | Model 2† |
|-------------------------------|------------------------|----------|----------|
| ≤4.0 mmol/l                  | 3,440 (3,383,3,496)    | 3,459 (3,403–3,515) | 3,453 (3,398–3,508) |
| 4.01–4.8 mmol/l              | 3,427 (3,392–3,462)    | 3,451 (3,416–3,487) | 3,443 (3,409–3,478) |
| 4.81–5.6 mmol/l              | 3,450 (3,422–3,478)    | 3,479 (3,449–3,508) | 3,486 (3,458–3,515) |
| 5.61–6.4 mmol/l              | 3,454 (3,424–3,485)    | 3,479 (3,448–3,511) | 3,488 (3,458–3,519) |
| 6.41–7.2 mmol/l              | 3,466 (3,426–3,506)    | 3,498 (3,457–3,538) | 3,511 (3,471–3,550) |
| ≥7.21 mmol/l                 | 3,484 (3,416–3,552)    | 3,521 (3,453–3,588) | 3,530 (3,465–3,595) |

Data are means (95% CI). *Model 1 is adjusted for ethnicity, parity of the mother, and sex of the newborn. †Model 2 is adjusted for ethnicity, parity of the mother, sex of the newborn, maternal age, BMI, smoking, family history of diabetes, gestational age at the OGTT, mean arterial blood pressure, and height.
Maternal glycemia and macrosomia

high end of the 2-h postload glucose distribution (glucose levels >7.8 mmol/l). In general, 2-h postload glucose seems to be a weaker predictor of birth weight than fasting glucose, similarly to our findings with or without further adjustments (7,14,15).

Possible mechanisms

Elevated risk of an LGA newborn and an increased birth weight at the high end of the maternal glucose distribution supports the Pedersen (22) hypothesis, which suggesting that maternal hyperglycemia (even within the normal range) increases the levels of fetal insulin, leading to accelerated growth and macrosomia in the fetus. We propose fetal hyperinsulinemia as a plausible mechanism underlying the association between low fasting glucose and risk of LGA newborns. Fetal insulin is probably the most important growth hormone during intrauterine development, and increases in fetal insulin levels are related to accelerated growth (1,2). Fetal hyperinsulinemia may lead to lower maternal glucose levels by increasing fetoplacental siphoning of maternal glucose in normoglycemic mothers (2,23). In line with this reasoning, there is some evidence to show a decrease in glucose levels as gestation progresses in women with hyperinsulinemic newborns, whereas glucose levels are increasing in mothers with normoinsulinemic newborns (24). All the above together suggest a common mechanism (fetal hyperinsulinemia) linking lower fasting glucose levels and the risk of LGA or increased birth weight. Further studies are warranted to test this hypothesis.

Study strengths and limitations

Our study benefits from the universal use of the 75-g OGTT in an ethnically homogeneous population as this allowed us to reliably explore the low end of the glucose distribution. A similar shape of the association was confirmed for both categorical and continuous glucose levels as predictors, and we were able to adjust for a wide range of known confounders of macrosomia in our analysis. The women who were excluded based on missing data were more likely to be from ethnic minorities and to be smokers, but their general characteristics were very similar to those of the population investigated; thus, it is unlikely that this exclusion had a large effect on our findings (supplemental data, available at http://care.diabetesjournals.org/cgi/content/full/dc09-1088/DC1). Although the exclusion of women meeting the World Health Organization criteria for gestational diabetes mellitus reduced the high end of the glucose distribution, this is unlikely to have selectively removed the smaller babies from the lowest categories or the larger babies from the middle ranges, so we think that our findings of a nonlinear association of fasting glucose with birth weight and macrosomia are valid. We used the latest published percentile charts for the definition of LGA newborns; however, it obviously does not correspond to our target population, given the 16.5% rate of LGA in this study (19). This result is in agreement with an overall increase in the prevalence of large babies worldwide (1). We believe that a general increase in birth weight would not invalidate our findings on the risk of LGA and definitely would not affect the associations found for birth weight. However, we investigated a surrogate pregnancy outcome, and thus it remains unclear whether the LGA babies of mothers with decreased fasting glucose have an otherwise poor obstetric outcome compared with normal-weight babies.

Implications

In a large-scale study we found that the prediction of a LGA newborn and birth weight may be improved by adding the square of fasting glucose value to the known predictors. Further research is needed to determine whether our findings are generalizable to other populations and to examine fetal hyperinsulinemia and other potential underlying mechanisms for the excess risk of LGA babies among mothers with low fasting glucose.
