Running title: High-content screen for EpCAM regulators

Keywords: epithelial cell adhesion molecule (EpCAM), signal transduction, high-throughput screening (HTS), anticancer drug, intramembrane proteolysis.

Abstract

Epithelial cell-adhesion molecule (EpCAM) is a transmembrane protein that regulates cell cycle progression and differentiation and is overexpressed in many carcinomas. The EpCAM-induced mitogenic cascade is activated via regulated intramembrane proteolysis (RIP) of EpCAM by ADAM and gamma secretases, generating the signaling-active intracellular domain EpICD. Because of its expression pattern and molecular function, EpCAM is a valuable target in prognostic and therapeutic approaches for various carcinomas. So far, several immunotherapeutic strategies have targeted the extracellular domain of EpCAM. However, targeting the intracellular signaling cascade of EpCAM holds promise for specifically interfering with EpCAM’s proliferation-stimulating signaling cascade. Here, using a yellow fluorescence protein-tagged version of the C-terminal fragment of EpCAM, we established a high-content screen (HCS) of a small-molecule compound library (n = 27,280) and characterized validated hits that target EpCAM signaling. In total, 128 potential inhibitors were initially identified, of which one compound with robust inhibitory effects on RIP of EpCAM was analyzed in greater detail. In summary, our study demonstrates that the development of an HCS for small-molecule inhibitors of the EpCAM signaling pathway is feasible. We propose that this approach may also be useful for identifying chemical compounds targeting other disorders involving membrane cleavage–dependent signaling pathways.

The epithelial cell adhesion molecule (EpCAM) is a calcium-independent homophilic cell adhesion molecule that belongs to the family of cellular adhesion molecules (CAM) (1). The EPCAM gene belongs to the tumor-associated antigen gene family GA-733 (2-4). Since EpCAM is overexpressed on a variety of carcinomas, it has been discovered numerous times by different groups and has been given various names. These names are based on the antibody
or cDNA that were used for the identification of this antigen (5,6). However, EpCAM is used as its primary name since 2007 (7). Up to now, a variety of functions of this protein have been described, ranging from cell adhesion (1,8) to cell signaling that is involved in regulation of cell cycle and differentiation (9-16). Additionally, EpCAM is used as prognostic marker and therapeutic target in carcinomas (17-19).

In normal tissue, EpCAM displays a highly selective expression pattern in pluripotent embryonic stem cells (ESCs) (20,21), hepatocytic progenitors (5,22,23), and epithelia (24). This expression is re-activated or enforced in the vast majority of carcinoma (25) and in cancer stem cells (26). The maintenance of the undifferentiated state of ESCs is strongly connected with EpCAM expression levels (6,16,20,27). In carcinomas, EpCAM is highly overexpressed and (re-)distributed over the whole cell surface, which is frequently associated with cytoplasmic and nuclear staining (6,28-31). In many cancer types, EpCAM overexpression is associated with a poor prognosis for the patient, e.g. lung, ovarian and breast cancer as well as pancreatic, gallbladder and prostate carcinoma (18,32-38). Exceptions to this are renal and thyroid carcinomas, in which high EpCAM expression is associated with an increased survival (39,40). However, there are also cancer types such as gastric cancer in which the association of EpCAM expression with the outcome for patients was inconclusive (37). Recently, EpCAM was found to also be expressed on tumor cells of acute myeloid leukemia (AML), with EpCAM-positive leukemic cells showing a greater resistance to chemotherapy (41).

EpCAM has a promoting role in cell proliferation. Several in vitro and in vivo studies demonstrated an induction of cell proliferation due to EpCAM overexpression and a decreased cell proliferation after EpCAM down-regulation (9,10,14,42). Induction of EpCAM expression leads to an upregulation of the oncogenic transcription factor c-Myc, which eventually results in upregulation of Cyclin A, D and E (9,14). Regulation of Cyclin D1 expression was additionally demonstrated to occur through binding of the intracellular domain EpICD to consensus sequences of the CCND1 promoter (14).

EpCAM is a 34 to 42 kDa type I membrane protein consisting of 314 aa, and can be divided in three domains: a large extracellular domain (EpEX) of 242 aa, a transmembrane domain (TMD) of 23 aa and a short intracellular domain (ICD) of 26 aa (43-45). The matured extracellular domain consists of an epidermal growth factor (EGF)-like domain (aa 27-59), a thyroglobulin (TY) type 1A domain (aa 66-135) and a third cysteine-free motif that appears to be unrelated to any other known molecule (6,46,47). EpCAM is processed by regulated intramembrane proteolysis (RIP) (10), which is induced by juxtacrine signaling (48). Thereby, EpCAM molecules on two different cells interact with each other or with an yet unknown ligand, which leads to the activation of RIP. The first step is a cleavage by ADAM proteases, in which EpEX is shed from the remaining C-terminal fragment (CTF = TMD + EpICD) of EpCAM (10,49). Soluble EpEX can act as ligand for EpCAM, thereby enhancing the EpCAM signaling cascade in a paracrine way. Cleavage by membrane-associated α-secretases of the ADAM family is the prerequisite for the second step of RIP, which is conducted by γ-secretase (10). This subsequent step leads to the release of small, soluble extracellular fragments (EpCAM-αβ-like) and the cytoplasmatic EpICD, which can vary in length owing to differential cleavage (50). hEpICD is part of a large protein complex together with FHL2, β-catenin and the transcription factor Lef-1 (10). This complex translocates into the nucleus and activates the transcription of EpCAM-target genes, which are genes involved in cell proliferation and growth, cell death and reprogramming (9,10,14,51-53). Via the interaction with FHL2 and its binding to β-catenin and Lef-1, EpCAM is linked to the Wnt pathway (52). Additionally, EpEX shedding can be conducted by the β-secretase BACE1 under acidic conditions, probably following endocytosis of EpCAM in acidified intracellular vesicles (50).
Due to its preferential strong expression in carcinomas, EpCAM is a suitable target for cancer therapy (6, 54). Therefore, EpCAM has been the target of different immunotherapeutic approaches, e.g. monoclonal antibodies, vaccination and toxin- or tumor necrosis factor-related apoptosis-inducing ligand (TRAIL)-conjugated antibodies (55-60). The first immunotherapeutic anti-EpCAM antibody was Edrecolomab, which was produced in ascites of mice (61, 62). However, a clinical activity in adjuvant setting could not be confirmed (63, 64). In April 2009, the rat-mouse hybrid monoclonal antibody Catumaxomab (Removab®) was approved in the European Union for treatment of malignant ascites (65). Other EpCAM-directed antibodies are currently under development (6, 66). Though, targeting of the intracellular EpCAM signaling cascade is an alternative and promising approach (67).

In the present study, we have addressed the development of inhibitors of EpCAM signaling through a High-Content Screening (HCS) approach. We established an automated, fluorescence-based imaging approach to investigate living cells with respect to alterations of cellular pathways upon administration of small inhibitory molecules. We subsequently performed an HCS with 28,000 compounds for the identification of hits that specifically inhibit the intracellular EpCAM signaling cascade. For the observed hits, verification procedures and assessment of their toxicity and specificity towards EpCAM were established. One compound is described that shows significant effects on the intramembrane cleavage and thus signaling cascade of EpCAM. Hence, identification of small molecule inhibitors of EpCAM in the newly established HCS bears potential for the future development of inhibitory substances.

Results

Establishment of a High-Content Screen (HCS)
In order to establish a HCS for modulators of the EpCAM cleavage and signaling pathway, hEpCAM-negative human embryonic kidney HEK293 cells (9, 10) (Figure S1A) were stably transfected with a plasmid expressing a fusion of the pre-activated C-terminal fragment of EpCAM with yellow fluorescent protein (hEpCAM-CTF-YFP). This fusion protein allows for the spatial detection of EpCAM–cleavage products in different compartments of the cell (Figure 1A, B). Treatment of cells with a compound that affects the intramembrane cleavage and/or signaling of EpCAM should result in an accumulation of YFP fluorescence in specific cellular compartments such as the membrane, the cytoplasm or the nucleus (Figure 1B). As control, fluorescence intensities in subcellular compartments of compound-treated cells were referred to intensities in DMSO-treated cells. If the compounds gave about 50 % more YFP signal intensity in one of the four cell regions (nucleus, ring (i.e. cytoplasm), membrane and/or cell) as obtained in the DMSO solvent control and if the number of selected cells per well exceeded a pre-defined threshold (> 20 nuclei selected per well), this compound was regarded as a hit.

Fluorescence intensities in each subcellular compartment were calculated using the Columbus High-Content Imaging and Analysis Software, and included several sequential steps (Figure 1C). In order to allow the automated software to distinguish between different compartments, the nucleus was stained with Hoechst3342 and the cell membranes with the Cell Mask dye. In the first step, all cells were identified by their nuclear Hoechst3342 staining. Subsequently, all cells that did not meet certain imaging criteria, regarding roundness and area (for details see Experimental Procedures), were excluded from further analysis (selection of population; Figure 1C). During subsequent steps, the cytoplasm of each cell was selected and thereafter the nucleus, cytoplasm and membrane regions were defined, and YFP-intensities assessed. The value of the calculated YFP intensity in each region was normalized to the size of the region and to the number of the analyzed cells (Figure 1C). For the identification of small molecule inhibitors targeting the intracellular EpCAM signaling cascade, a suitable HCS setting had to be established. Hence, optimal conditions for imaging (magnification and imaging method), staining of the cells and optimal cell number...
per well had to be determined. Therefore, HEK293 hEpCAM-CTF-YFP cells were treated with the \(\gamma\)-secretase inhibitor DAPT, which inhibits cleavage of hEpCAM-CTF-YFP (10) and thereby leads to stabilization and accumulation of this fragment at the cell membrane, resulting in a significant increase of YFP fluorescence at the cell membrane. After this treatment, cells were stained and imaged under different conditions regarding imaging methods (confocal versus non-confocal), magnification (40x versus 60x), cell density (3,000 versus 5,000 cells/well) and staining (DRAQ5 versus CellMask), evaluated, compared and the optimum conditions were chosen for performing the HCS (Figure S1B). To streamline the screening procedure, three areas of each well were imaged instead of entire wells. Analysis revealed 40x magnification with 3,000 cells per well and CellMask staining to be optimal for the HCS (Figure S1B). When comparing results of confocal imaging and non-confocal imaging, it could be shown that confocal imaging facilitates significant differentiation between the cell regions regarding YFP-intensities (Figure S1B).

**Performance of HCS and first validation of hits**

The initial screen was performed with 28,000 small molecules at a final concentration of 8 \(\mu\)M. DMSO and DAPT (10 \(\mu\)M) were used as negative and positive control, respectively. HEK293-hEpCAM-CTF-YFP cells (Figure 1A,C) were automatically seeded onto 384-well plates, treated with the compounds, stained, fixed and the effects of the compound-treatment on the cells were analyzed (Figure 2A). For every initial screening plate, the Z’-score (71) was calculated for every subcellular compartment (membrane region, cytoplasm, nucleus and YFP total). If at least the Z’-score for one region was between 0.3 and 1.0, the respective screening plate was included in further analysis (Figure S2). After initial screening and analysis, 128 compounds were identified as primary hits (hit rate: 0.45 %). These hits were re-analyzed in a five-point titration (80 – 0.15 \(\mu\)M), by which 59 compounds could be confirmed. Since the read-out of the screen was fluorescence, it was important to exclude false-positive results arising from auto-fluorescence of compounds. Therefore, YFP-lacking HEK293-hEpCAM-CTF cells were treated with the respective compounds and their fluorescence signal was analyzed. As a result, 51 additional compounds were excluded due to autofluorescence (data not shown) (Figure 2B). Of the remaining eight compounds, seven showed accumulation of CTF-YFP at the membrane and compound #66 showed accumulation of EpICD-YFP in the cytoplasm (Figure 2C). These compounds were considered as high-confidence hits and studied further with regards to toxicity, effects on intramembrane cleavage of hEpCAM, effects on the transcriptional level of EpCAM target genes and effects on cell proliferation.

**Cytotoxicity of compounds**

Since general cytotoxicity of a compound is detrimental to its use as potential drug, we assessed the effects of the eight compounds on viability, cytotoxicity and apoptosis. In order to find a potential EpCAM-specific effect, four different EpCAM-positive and –negative cell lines were used. These are EpCAM-negative HEK293 wild-type cells, HEK293-hEpCAM cells, and two endogenously EpCAM-expressing cell lines, HCT-8 cells and FaDu hypopharynx cells. These cell lines were automatically seeded onto 384-well plates, treated with the verified hits from our screen, the drug staurosporine as positive control (80 – 0.15 \(\mu\)M) or DMSO (negative control), and analyzed after 16 h incubation. Results were related to DMSO as a control (Figure 3A). In none of the cases did we observe cell-type specific differences in viability, cytotoxicity or apoptosis. Staurosporine expectedly led to a strongly decreased viability (--) and strongly increased cytotoxicity and apoptosis (++). Compound #7 did not show any effects on the cells, whereas compounds #13 and #66 strongly impaired cell viability. Compounds #4, #6, #9, #10 and #51 had only minor effects on the cells (for a detailed presentation of the results, see Supplementary figures S3-S7).
Effects of compounds on regulated intramembrane cleavage

The effect of high-confidence hits on regulated intramembrane proteolysis of full-length hEpCAM (Figure 1A) was analyzed in membranes isolated from HEK293-hEpCAM-YFP cells. Following preincubation of cells with the indicated compounds/inhibitors, membrane fractions were isolated. To assess substrate cleavage, membrane fractions were incubated at 37 °C for 22 h in the presence of newly added compounds/inhibitors. DMSO was used as vehicle control. Cleavage products were analyzed in immunoblot experiments using anti-GFP antibodies (which recognizes YFP). After 22 h incubation without inhibitor or with DMSO, hEpCAM-YFP (66 kDa) was cleaved into the membrane-associated CTF-YFP (35 kDa) and the soluble intracellular domain (ICD) of EpCAM (hEpICD-YFP; 31 kDa) (Figure 3B, left panel). Incubation with the ADAM protease inhibitor GI254023X (GI) and β-secretase inhibitor (C3) led to inhibition of cleavage of hEpCAM-YFP. This inhibits the formation of hEpCAM-CTF-YFP, but still allows for the cleavage of already formed fractions of this fragment into hEpICD-YFP (Figure 1A). ADAM/BACE inhibition in conjunction with the γ-secretase-inhibitor DAPT abrogated hEpICD-YFP formation (Figure 3B, left panel). The effects of compounds on EpCAM cleavage were quantified from Western blots (n=3 independent experiments) by calculating the ratios of the intensities of hEpICD-YFP/CTF-YFP bands relative to EpICD/CTF DMSO 22 h control. Compounds #4, #6, #9, #10 and #13 show a reduced signal. However only compound #13 significantly decreased hEpICD-YFP intensity (0.11 ± 0.04) when using the strict one-way ANOVA analysis with Bonferroni correction. Compound #13 did not significantly impede CTF formation, which indicates that this compound has an influence on γ-secretase-mediated cleavage of the CTF fragment of full-length EpCAM (Figure 3B, right panel). For details of one-way ANOVA see Table S1.

Effects on EpCAM target gene transcription

For the investigation of a possible effect of compound-treatment on EpCAM target gene transcription, the expression level of CCND1 (cyclin D1) was assessed. In order to define an EpCAM-specific effect on proliferation, HCT-8 colorectal adenocarcinoma wild-type and a CRISPR-Cas9-mediated EPCAM KO clone of HCT-8 cells (50) were tested and results compared. Inhibition of EpICD formation through treatment with DAPT resulted in an average of 13 % reduction of CCND1 transcript levels in EpCAM+ HCT-8 cells, but not in EpCAM-KO HCT-8 cells (Figure 4A). Further analysis of relative expression levels revealed a significant decrease after treatment with compound #4, #6, #9, #10, #13, #51 and #66 in HCT-8 wild-type cells (Figure 4A, left panel, p<0.05). In HCT-8 KO cells, compound #4 and #6 led to a significant decrease of CCND1 expression level (Figure 4A, right panel, p<0.05), suggesting an EpCAM-independent effect. Comparison of expression levels in wild-type cells and in KO cells showed that compound #10 led to statistically significant reduction of CCND1 exclusively in HCT-8 wild-type cells, which indicates an EpCAM-specific effect.

Effect on proliferation of cells

In order to address a potential EpCAM-specific effect of the compounds on cell proliferation, HCT-8 wild-type and EpCAM-KO cells were treated with compounds, DAPT or DMSO. Over a period of seven days, cell numbers were determined on a daily basis, using the automated Operetta Imaging System. None of the compounds showed a significant difference between EpCAM-positive and – negative cells. Compound #66 did not show an effect on cell proliferation. Compounds #9, #10 and #7 had minor effects on the proliferation of HCT-8 wild-type and KO cells. Compounds #4, #6, #13 and #51 almost completely inhibited cell proliferation of both cell lines at the given concentration (Figure 4B,C).

Screening of analogs

Based on the results of the membrane-cleavage assays and similarities in chemical scaffolds, analogs of compounds #4, #9, #10 and #13 were selected. In total, 39 new compounds were assessed: 13 analogs of compound #4, four analogs of compound #9, 13 analogs of
compound #10 and nine analogs of compound #13 were chosen. These compounds were compared with the original compounds in a 10-point titration (80 – 0.15 µM) with the primary screening assay in HEK293-hEpCAM-CTF-YFP cells (data not shown). The effects of all compounds were visually assessed regarding their efficiency and toxicity. If an analog showed comparable or a better effect with simultaneously less toxicity, this compound was used for further studies. Furthermore, an assessment of the analogs using HEK293-hEpCAM cells showed no autofluorescence for any of them (data not shown). In summary, nine out of 39 analogs were chosen for further studies (Figure 5).

Cytotoxicity of analogs
In order to test the toxicity characteristics of the original compounds and the nine analogs, their effects on the viability of cells were tested. Therefore, different EpCAM-positive and –negative cell lines were treated with DMSO, staurosporine (positive control) or compounds and analyzed after 16 h incubation. There were no observable differences in viability, cytotoxicity and apoptosis between EpCAM-positive and –negative cell lines. Remarkably, none of the analogs of compound #13 showed any toxic effect on the cells, whereas the original compound #13 showed a strong reduction in viability (two independent experiments with three replicates each; compare Figure 6A with Figure 3A; Supplementary Figures S8-S12). Thus, analogs of #13 have an improved toxicity profile.

Effects of analogs on intramembrane cleavage of hEpCAM
The effect of the selected nine analogs on hEpCAM-cleavage was analyzed on isolated membranes of HEK293-hEpCAM-YFP cells. As before, the ratio of the intensities of the HEpCAM-CTF-YFP/hEpICD-YFP bands was calculated relative to the CTF/EpICD DMSO 22 h control (Figure 6B). Compound #13_1 (0.33 ± 0.07), #13_7 (0.36 ± 0.14) showed a significant decrease of CTF/EpICD-YFP intensity but these effects were no improvement when compared to the original compound #13 (0.11 ± 0.04) (Figure 3B). In contrast to the primary hits #9 and #10, the analogs #9_0 (0.29 ± 0.12), #10_4 (0.57 ± 0.08), #10_6 (0.26 ± 0.07), #10_9 (0.38 ± 0.16), #10_10 (0.3 ± 0.09) and #10_12 (0.29 ± 0.01) reduced significantly the CTF/EpICD-YFP intensity, which also indicates an influence on γ-secretase cleavage for these compound series. For the remaining analog #4_7 no significant, reproducible effects were observed. For details of one-way ANOVA see Table S2.

Effects of analogs on EpCAM target-gene transcription
For the investigation of a possible effect of the analogs on EpCAM-dependent CCND1 expression, HCT-8 wild-type and -KO cells were treated with DMSO (control) or analogs of compound #10. Our analysis was restricted to analogs of compound #10 because this compound was the only one that showed an EpCAM-specific effect (see Figure 4A). In wild-type cells, compounds #10_4 and #10_12 showed a significant decrease of CCND1 expression (Figure 7A, left panel, p<0.05). In KO cells, only compound #10_12 showed a significant effect (Figure 7A, right panel, p<0.01). Comparison of expression levels in wild-type and KO cells showed that compound #10_12 led to significant reduction of CCND1 in HCT-8 wild-type cells (Figure 7A). In summary, these findings indicate that only compound #10_4 has a modest but EpCAM-specific effect.

Effects of compound #10 and analogs on cell proliferation
In order to confirm potential EpCAM-specific effects of compound #10 analogs on cell proliferation, HCT-8 wild-type and -KO cells were treated with analogs, DAPT, or DMSO as control. Cell numbers were automatically counted every 24 hours for a total duration of seven days. No difference could be seen between HCT-8 wild-type and HCT-8 EpCAM KO cells for any compound. Additionally, none of the analogs of compound #10 showed significant effects on cell proliferation (Figure 7B).
Discussion
EpCAM signaling based on RIP is an attractive target for potential small molecule inhibitors, which might be effective in carcinoma cells. The rationale for this approach relies on the strong overexpression of EpCAM primarily in cancer cells and an apparently preferential RIP-dependent cleavage in tumor cells (10). In fact, most recent data suggest that signaling through EpICD does not impact proliferation of normal liver cells (22), whereas EpICD regulates gene expression and tumor progression in hepatocellular carcinomas (72). In order to identify potential inhibitors of EpCAM cleavage, we have successfully established a HCS using the pre-cleaved and highly reactive C-terminal fragment of EpCAM in a YFP-fused version.

This HCS yielded robust (Z-scores between 0.5 and 0.9; Figure S2) and reproducible results. Effects seen in the initial screen could be reconfirmed in hit picking campaigns with the same compounds as well as with newly ordered compounds. An advantage of the here-performed HCS is that by measuring an increase in YFP-fluorescence in a specific subcellular compartment, possible modes of actions of the hits can already be anticipated. Therefore, further characterization of a given hit compound and its effect can be done in a more targeted way. In the here-performed screen seven compounds showed accumulation of YFP at the membrane. Based on this information, we performed membrane assays that confirmed that these compounds indeed affect γ-secretase cleavage of EpCAM.

After investigating the effects of the eight high-confidence hits on cell viability, proliferation, target gene expression, and regulated intramembrane proteolysis, four compounds showed promising results: Compounds #4, #9, #10 and #13. Therefore, analogs of these compounds were chosen and investigated under the same conditions as before, which allowed us to analyze the structure-activity relationship (SAR). For the efficacy of compound #4, a 2-methoxysubstitution on the right-hand aromatic ring seemed to be crucial. If this substitution is in any other position, the compound lost its efficacy (e.g. compounds #4_2 and #4_5). The fluorine-derivatized compounds showed a very weak effect (#4_3 and #4_4). The only alternative is a chloride instead of a methoxy substitution; however, this compound #4_6 was more toxic than #4 and less effective. Compounds #4_7 and #4_9 have a Cl and F substitution at the left aromatic ring, respectively. Additionally, they show a benzyl-cycloalkylamin at the right aromatic ring. The cycloalkyl seemed to be important, since derivatives without this residue do not have any effect (e.g. #4_10 and #4_13). The structures of compound #9 and #10 have a very similar scaffold. The basic backbone consisting of a 2+1 ring system is consistent and only altered by differential substituents. It seems that a secondary amine (R1-NH-R2) has a somewhat better efficacy than N-substitution. For analogs of #13_0, it was shown that a benzyl group drastically reduces cytotoxicity but shows comparable effectiveness (#13_1). Moreover, compounds substituted at the exo-N (#13_5-#13_9) also show similar effects and toxicity as the analogs, which are substituted at the N within the aromatic ring. The benzyl group reduces the cytotoxicity of these compounds as well. In general, compound #4 and #13 are structurally similar in that they show the same basic backbone except for compound #13 having an oxygen atom instead of sulfur atom in the five-membered ring. All benzyl-substituted derivatives show the best effects and additionally decrease cellular toxicity for analogs of compound #13.

The five-point and ten-point serial dilutions were performed with compounds from stock aliquots and newly provided by the supplier, respectively. In some cases, the effect shown in the initial HCS campaign was not reproducible. Several reasons might account for this. Since the compounds for HCS were stored in multiwell plates in DMSO at -20 °C, freeze-thaw cycles might have led to degradation of the compounds and thus changing efficiency. Thus, in some cases a degradation product might have been the cause of inhibitory effects observed in the initial screen. Moreover, newly provided compound samples might differ in their purity and identity of possible contaminants.
In summary, in this study we have established a robust and reliable HCS for inhibitors and identified compounds that affected the membrane-cleavage of EpCAM. Our work demonstrates the feasibility of a HCS against EpCAM signaling pathway that is potentially also applicable for other disorders involving membrane-cleavage dependent signaling pathways.

**Experimental procedures**

**Cell lines**

Human embryonic kidney cells (HEK293), human colon carcinoma cell line HCT-8, and human hypopharyngeal carcinoma cell line FaDu were cultivated in Dulbecco’s Modified Eagle Medium (DMEM) with 10 % FCS, 1 % Fungizone and 1 % penicillin/streptomycin. All cell lines were grown in a 5 % CO$_2$ atmosphere at 37 °C. HCT-8 CRISPR-Cas9-mediated EpCAM KO clones were prepared by T. Tsaktanis as previously described (50). All cell lines have been confirmed by STR-typing at the Helmholtz Zentrum München.

**Transfections and expression vectors**

Transfections were performed using the MATra reagent (Iba, Goettingen, Germany) according to manufacturer’s instructions. Stable selection of transfectants was done by using puromycin (1 µg/mL) in the culture medium starting at day one after transfection. Human EpCAM (hEpCAM) full length (314 aa) was cloned without YFP. The CTF mimic of hEpCAM termed hEpCAM-CTF-YFP consists of a signal peptide sequence MPRLLTPLCLLLLLPALAARGLR, a Myc-tag (EQKLISEEDL), CTF sequence of hEpCAM (251-315), Flag-tag (DYKDDDDK), the TEV recognition site (ENLYFQG) and YFP. The constructs were cloned into the 141 pCAG-3SIP expression vector using Nhel and EcoRI restriction sites.

**Coating of screening plates**

Prior to seeding, 384-well plates (Perkin Elmer) were coated with 10 % (w/v) poly-D-lysine (PDL; Sigma-Aldrich). PDL was solubilized in ddH$_2$O. 20 µL PDL were incubated for 1 h at RT and washed twice with 20 µL PBS per well and air dried. Coated plates were stored at 4 °C until further use.

**Staining and fixation of cells**

For staining of cells, Hoechst33342 (1:1000; Life Technologies) and 3.5 µg/mL CellMask™ Deep Red Plasma membrane Stain (Invitrogen) were added to pre-warmed DMEM medium. 25 µL medium per well was added to the cells and incubated for 10 min at 37 °C. Afterwards, the medium was removed and 20 µL 2 % (w/v) paraformaldehyde (PFA)
per well were added and incubated for 20 min at RT. Finally, plates were washed twice with PBS and immediately used for screening.

**Performance of High-Content Screen**

HEK293 cells stably expressing EpCAM-CTF-YFP were automatically seeded (ELX406 plate washer and dispenser, BioTek, Winooski, USA; 3,000 cells in 50 µL/well) on PDL-coated 384-well plates. In the initial HCS, compounds were tested at a concentration of 8 µM (0.8 % DMSO). Compound-treated cells were incubated o/n at 37 °C. Afterwards, cells were stained and fixed. Cells were imaged with the Operetta High-Content-Imaging System (PerkinElmer) at 40x magnification and confocal imaging method, and results were evaluated with the Columbus High Content Imaging and Analysis Software version 2.8.0 (PerkinElmer).

**Automated image analysis**

Multiparametric image analysis was performed using Columbus High Content Imaging and Analysis Software version 2.8.0 (PerkinElmer). Nuclei were detected via the Hoechst signal using Method C of Columbus software with the following parameters: common threshold (parameter determining the lower level of pixel intensity for the whole image that may belong to nuclei), 0.30; area (to tune the merging and splitting of nuclei during nuclei detection), >30 µm²; split factor (parameter influencing the decision of the computer whether a large object is split into two or more smaller objects or not), 7.0; individual threshold (parameter determining the intensity threshold for each object individually), 0.4; and contrast (parameter setting a lower threshold to the contrast of detected nuclei), 0.05. Method C to find nuclei provides good results for images with low background or with size variations of nuclei and supports images with large variations in intensity or contrast of nuclei.

In a next step, the area of nuclei was determined and filtered by nucleus area [µm²] > 100. For this subpopulation called “Nuclei selected,” the cell mask fluorescence intensity was used to define the cytoplasm by using the building block “Find Cytoplasm”. The building block “Select Cell Region” was then used to distinguish membrane, nucleus and ring (cytoplasm) region. The building block “Calculate Intensity Properties” was used to calculate the YFP intensity in the different cell compartments. In the last step, we defined five output parameters:

- Nuclei Selected - Number of Objects
- Nuclei Selected - Intensity Nucleus Region YFP Mean - Median per Well
- Nuclei Selected - Intensity Membrane Region YFP Mean - Median per Well
- Nuclei Selected - Intensity Ring Region YFP Mean - Median per Well
- Nuclei Selected - Intensity Cell YFP Mean - Median per Well

**Inhibitors**

Inhibition of α- and β-secretase was performed by using 3 µM GI and 3 µM C3, respectively. γ-secretase was inhibited by using 10 µM DAPT in HCS and 3 µM in membrane-based EpCAM cleavage assays.

**Membrane-based EpCAM cleavage assay**

These assays were performed as previously described (50,68,69). Briefly, cells were treated with 20 µM compound or inhibitor o/n in assay buffer (150 mM sodium citrate pH 6.4, 10 µM ZnCl₂, protease inhibitor). Cells were lysed and membrane fractions were generated by centrifugation steps (1,000 x g for 15 min and 16,000 x g for 20 min) and subsequently treated with 20 µM compounds or inhibitor as stated above for 22 h. Cleavage products were analyzed by SDS-PAGE and immunoblots.

**Immunoblot experiments**

Cells were lysed in PBS containing 1 % triton X-100 and protease inhibitors (Roche complete, Roche, Germany). The protein concentration was determined by BCA-assay (Thermo Scientific, Waltham, USA) according to manufacturer’s instructions. 20 µg of proteins were loaded onto a 12 % SDS-PAGE and separated for 15 min at 15 mA and 2 h at 30 mA. Afterwards, proteins were transferred onto a methanol-equilibrated PVDF blotting membrane. Visualization was done by anti-GFP antibody, in combination with a horseradish-peroxidase (HRP)-conjugated...
secondary antibody, HRP substrate and the ImageLab software version 5.2.1 (Biorad).

RNA isolation, cDNA synthesis and quantitative real-time polymerase chain reaction
RNA isolation was performed with the High Pure RNA Isolation Kit (Roche, Mannheim, Germany) according to manufacturer’s protocol. For removal of contaminating DNA, isolated RNA was treated twice with Turbo DNAfree kit (Ambion, Austin, USA). Reverse transcription (RT) was done with PrimeScript™ RT Master Mix (Takara, Paris, France) according to manufacturer’s instructions. qPCR experiments were performed in a LightCycler® 480 instrument (Roche) using the KAPA SYBR Fast Universal kit according to the manufacturer’s protocol. Evaluation was done by using the ΔΔct method (70).

Fluorescence-activated cell sorting (FACS) experiments
YFP- and EpCAM-expression of cell lines were assessed with a BD LSR II Flow Cytometer (BD Biosciences). Cells were incubated with a monoclonal FITC-conjugated anti EpCAM antibody (Life Technologies) diluted in 1x PBS (1:200) for 30 min at RT in the dark. Afterwards, cell were washed, resuspended in 1x PBS and transferred to FACS measurement. The results were evaluated with the FlowJo program version 10.0.8.

Viability/cytotoxicity assay
Viability, cytotoxicity and apoptosis of different cell lines were assessed in 384-well plates using the ApoTox Glo Assay according to manufacturer’s instructions (Promega) and 5.000 cells in 50 µl cell medium.

Proliferation assay
Cells were automatically seeded onto 96-well plates. After 6 h, one row was stained with 0.25 µL Hoechst 33342 and imaged with Operetta High-Content-Imaging System (Perkin Elmer). Afterwards, medium was removed and new medium containing the compounds or DMSO or DAPT as control was added. Every 24 h, one row was stained with Hoechst 33342 and imaged (D0-D7). Results were evaluated with the program Microsoft Excel.

Figure 1 Principle of High-Content Screen (HCS) and image analysis. A, Different C-terminally YFP-fused hEpCAM fragments are depicted. hEpCAM-CTF-YFP is generated by α-/β-secretase cleavage of hEpCAM-FL-YFP. Subsequent cleavage of hEpCAM-CTF-YFP leads to formation of EpICD-YFP. hEpCAM-FL-YFP is the construct used for intramembrane cleavage assays. hEpCAM-CTF-YFP and EpICD-YFP are the fragments relevant for HCS. B, Possible effects of compound treatment. Small molecules could either have no effect (left), lead to accumulation of hEpCAM-CTF-YFP at the membrane (middle), or to accumulation of hEpCAM-ICD in the cytoplasm or nucleus (right). C, Image analysis. After selection of the cells that are included in the downstream analysis, the different cell regions are defined and YFP-intensities for each region are calculated.

Figure 2 Performance and results of HCS. A, Overview of HCS process. Cells were cultivated and automatically seeded onto 384-well plates. Compound were transferred and incubated o/n before cells were stained, fixed, and finally imaged. B, Summary of hit validation. Shown are the number of remaining compounds as well as the reason for exclusion of others. C, Images of the effects of the remaining eight compounds on the cells. Treatment with DMSO shows no effect, whereas DAPT led to accumulation of hEpCAM-CTF-YFP (green) at the membrane. Seven compounds also led to accumulation of hEpCAM-CTF-YFP at the membrane. Compound #66 showed no effect at the membrane. Compound number is given above the respective image. Nuclei are stained with Hoechst33342 (blue). For a better visualization of the corresponding effects, CellMask staining is not shown in these images. Scale bar represents 50 µm. Pictures of compounds were taken with autocontrast function.

Figure 3 Effects on viability and intramembrane cleavage. A, HEK293 wild-type cells, HEK293 hEpCAM-FL cells, HCT-8 and FaDu cells were treated with compounds, DMSO or the drug staurosporine as control. Effects on cell viability, toxicity and apoptosis were summarized in the table. Data for each cell line are summarized in Supplementary Figures S3-S7. B, HEK293 hEpCAM-CTF-YFP cells were treated as indicated. Isolated membrane fractions were separated in SDS-PAGE and cleavage products were detected by a GFP-specific antibody (recognizes YFP equally well). Shown is one representative blot out of three experiments (left panel). On the right panel, the ratio of the intensities of EpICD-YFP/EpCAM-CTF-YFP bands were compared to EpICD/CTF ratio of DMSO 22h control. Shown are mean values and standard deviations of three independent experiments. Compound #13 led to a highly significant decrease of EpICD/CTF. Statistical significance was verified using one way ANOVA. P-values are given above brackets (right panel; *:p<0.0004).

Figure 4 Effects on target gene expression and cell proliferation. A, Effects on CCND1 expression was assessed with EpCAM-positive HCT-8 wild-type cells (left panel) and EpCAM-negative HCT-8 KO cells (right panel). Compounds #4, #6, #9, #10, #13, #51 and #66 showed an effect in wild-type cells, compounds #4 and #6 in KO cells. #10 yielded a significant, EpCAM-specific downregulation of CCND1 expression. Shown is the evaluation of five independent experiments. Whiskers span the 10-90 percentiles. Statistical analysis was performed using paired-sample t-test. P-values of t-tests between the cell lines are depicted by an asterisk (*:p<0.01) The red dashed line shows DMSO as reference. B, C, HCT-8 wild-type and EpCAM-KO cells were plated, treated with compounds and cell numbers were determined on a daily basis. No difference could be detected between the two cell lines. Compounds #4, #6, #13, and #51 strongly impaired cell proliferation, #7, #9 and #10 had...
minor effects, whereas #66 did not show any effect.

**Figure 5** Effects of nine selected analogs on HEK 293 hEpCAM-CTF-YFP cells. Treatment with DMSO shows no effect, whereas DAPT led to accumulation of hEpCAM-CTF-YFP (green) at the membrane. All shown analogs led to accumulation of hEpCAM-CTF-YFP at the membrane and improved efficiency or lower toxicity. Compound number is given above the respective image. Nuclei are stained with Hoechst33342 (blue). CellMask staining is not shown in order to allow for a better recognition of effects. Scale bar represents 50 µm. Pictures of compounds were taken with autocontrast.

**Figure 6** Effects on viability and intramembrane cleavage. A. HEK293 wild-type cells, HEK293 hEpCAM-FL cells, HCT-8 and FaDu cells were treated with compounds, DMSO or the drug staurosporine as control. Effects on cell viability, toxicity and apoptosis are summarized in the table. No compound showed an effect on cell viability. B. HEK293 hEpCAM-CTF-YFP cells were treated as indicated. Isolated membrane fractions were separated by SDS-PAGE and cleavage products were detected using an YFP-specific antibody. Shown is one representative blot out of three (left panel). Evaluation was done as described above. Shown are mean values and standard deviations of three independent experiments. Compound #13_1, #13_7, #10_4, #10_6, #10_9, #10_10 and #10_12 led to significant decrease of EpICD/CTF signal. Statistical significance was verified using one-way ANOVA. P-values are given above brackets (right panel; *:p<0.0004).

**Figure 7** Effects on target gene expression and cell proliferation. A. Effects on *CCND1* expression was assessed by quantitative RT-PCR with EpCAM-positive HCT-8 wild-type cells (left panel) and EpCAM-negative HCT-8 KO cells (right panel). Compounds #10_4 and #10_12 showed an effect in wild-type cells, only compound #10_12 in KO cells. Shown is the evaluation of five independent experiments. Whiskers span the 10-90 percentiles. Statistical analysis was performed using paired-sample t-test. B, C. HCT-8 wild-type and KO cells were plated, treated with compounds and cell number was determined daily. Compound #13_1 strongly impaired cell proliferation, compounds #4_7 and #13_7 only had minor effects on the proliferation of wild-type cells. All other compounds did not have an effect on cell proliferation and none of the analogs of compound #10 showed an EpCAM-specific effect. The red dashed line shows DMSO as reference.
A expected effects:
untreated cell:
no effect accumulation
of CTF-YFP
accumulation of ICD-YFP

B
untreated cell:
expected effects:
no effect accumulation of CTF-YFP accumulation of ICD-YFP

C
