Abstract

Adaptive gradient methods such as AdaGrad and its variants update the stepsize in stochastic gradient descent on the fly according to the gradients received along the way; such methods have gained widespread use in large-scale optimization for their ability to converge robustly, without the need to fine-tune the stepsize schedule. Yet, the theoretical guarantees to date for AdaGrad are for online and convex optimization. We bridge this gap by providing theoretical guarantees for the convergence of AdaGrad for smooth, non-convex functions. We show that the norm version of AdaGrad (AdaGrad-Norm) converges to a stationary point at the $O(\log(N)/\sqrt{N})$ rate in the stochastic setting, and at the optimal $O(1/N)$ rate in the batch (non-stochastic) setting—in this sense, our convergence guarantees are “sharp”. In particular, the convergence of AdaGrad-Norm is robust to the choice of all hyper-parameters of the algorithm, in contrast to stochastic gradient descent whose convergence depends crucially on tuning the step-size to the (generally unknown) Lipschitz smoothness constant and level of stochastic noise on the gradient. Extensive numerical experiments are provided to corroborate our theory; moreover, the experiments suggest that the robustness of AdaGrad-Norm extends to state-of-the-art models in deep learning, without sacrificing generalization.

Keywords: nonconvex optimization, stochastic offline learning, large-scale optimization, adaptive gradient descent, convergence

1. Introduction

Consider the problem of minimizing a differentiable non-convex function $F : \mathbb{R}^d \to \mathbb{R}$ via stochastic gradient descent (SGD); starting from $x_0 \in \mathbb{R}^d$ and stepsize $\eta_0 > 0$, SGD iterates until convergence

$$x_{j+1} \leftarrow x_j - \eta_j G(x_j), \quad (1)$$
where \( \eta_j > 0 \) is the stepsize at the \( j \)th iteration and \( G(x_j) \) is the stochastic gradient in the form of a random vector satisfying \( \mathbb{E}[G(x_j)] = \nabla F(x_j) \) and having bounded variance. SGD is the de facto standard for deep learning optimization problems, or more generally, for the large-scale optimization problems where the loss function \( F(x) \) can be approximated by the average of a large number \( m \) of component functions, \( F(x) = \frac{1}{m} \sum_{i=1}^{m} f_i(x) \). It is more efficient to measure a single component gradient \( \nabla f_i(x_j), i_j \sim \text{Uniform}\{1, 2, \ldots, m\} \) (or subset of component gradients), and move in the noisy direction \( G_j(x) = \nabla f_i_j(x) \), than to compute a full gradient \( \frac{1}{m} \sum_{i=1}^{m} \nabla f_i(x) \).

For non-convex but smooth loss functions \( F \), (noiseless) gradient descent (GD) with constant stepsize converges to a stationary point of \( F \) at rate \( O\left(\frac{1}{N}\right) \) with the number of iterations \( N \) (Nesterov, 1998). In the same setting, and under the general assumption of bounded gradient noise variance, SGD with constant or decreasing stepsize \( \eta_j = O\left(\frac{1}{\sqrt{j}}\right) \) has been proven to converge to a stationary point of \( F \) at rate \( O\left(\frac{1}{\sqrt{N}}\right) \) (Ghadimi and Lan, 2013; Bottou et al., 2018). The \( O\left(1/N\right) \) rate for GD is the best possible worst-case dimension-free rate of convergence for any algorithm (Carmon et al., 2017a); faster convergence rates in the noiseless setting are available under the mild assumption of additional smoothness (Agarwal et al., 2017; Carmon et al., 2017b). In the noisy setting, faster rates than \( O\left(\frac{1}{\sqrt{N}}\right) \) are also possible using accelerated SGD methods (Ghadimi and Lan, 2016; Allen-Zhu and Yang, 2016; Reddi et al., 2016; Allen-Zhu, 2017; Xu et al., 2017; Carmon et al., 2018).

Instead of focusing on faster convergence rates for SGD, this paper focuses on adaptive stepsizes (Cutkosky and Boahen, 2017; Levy, 2017) that make the optimization algorithm more robust to (generally unknown) parameters of the optimization problem, such as the noise level of the stochastic gradient and the Lipschitz smoothness constant \( L \) of the loss function defined as the smallest number \( L > 0 \) such that \( \|\nabla F(x) - \nabla F(y)\| \leq L \|x - y\| \) for all \( x, y \). In particular, the \( O\left(1/\sqrt{N}\right) \) convergence of GD with fixed stepsize is guaranteed only if the fixed stepsize \( \eta > 0 \) is carefully chosen such that \( \eta \leq 1/L \) – choosing a larger stepsize \( \eta \), even just by a factor of 2, can result in oscillation or divergence of the algorithm (Nesterov, 1998). Because of this sensitivity, GD with fixed stepsize is rarely used in practice; instead, one adaptively chooses the stepsize \( \eta_j > 0 \) at each iteration to approximately maximize decrease of the loss function in the current direction of \( -\nabla F(x_j) \) via either approximate line search (Wright and Nocedal, 2006), or according to the Barzilai-Borwein rule (Barzilai and Borwein, 1988) combined with line search.

Unfortunately, in the noisy setting where one uses SGD for optimization, line search methods are not useful, as in this setting the stepsize should not be overfit to the noisy stochastic gradient direction at each iteration. The classical Robbins/Monro theory (Robbins and Monro, 1951) says that in order for \( \lim_{k \to \infty} \mathbb{E}[\|\nabla F(x_k)\|^2] = 0 \), the stepsize schedule should satisfy

\[
\sum_{k=1}^{\infty} \eta_k = \infty \quad \text{and} \quad \sum_{k=1}^{\infty} \eta_k^2 < \infty. \tag{2}
\]

However, these bounds do not tell us much about how to select a good stepsize schedule in practice, where algorithms are run for finite iterations and the constants in the rate of convergence matter.
The question of how to choose the stepsize $\eta > 0$ or stepsize or learning rate schedule $\{\eta_j\}$ for SGD is by no means resolved; in practice, a preferred schedule is chosen manually by testing many different schedules in advance and choosing the one leading to smallest training or generalization error. This process can take days or weeks, and can become prohibitively expensive in terms of time and computational resources incurred.

1.1 Stepsize Adaptation with AdaGrad-Norm

Adaptive stochastic gradient methods such as AdaGrad (introduced independently by Duchi et al. (2011) and McMahan and Streeter (2010)) have been widely used in the past few years.

AdaGrad updates the stepsize $\eta_j$ on the fly given information of all previous (noisy) gradients observed along the way. The most common variant of AdaGrad updates an entire vector of per-coefficient stepsizes (Lafond et al., 2017). To be concrete, for optimizing a function $F : \mathbb{R}^d \rightarrow \mathbb{R}$, the “coordinate” version of AdaGrad updates the $d$ scalar parameters $b_j(k), k = 1, 2, \ldots, d$ at the $j$ iteration – one for each $x_j(k)$ coordinate of $x_j \in \mathbb{R}^d$ – according to $b_{j+1}(k)^2 = b_j(k)^2 + \|\nabla F(x_j)\|^2_k$ in the noiseless setting, and $b_{j+1}(k)^2 = b_j(k)^2 + |G_j(k)|^2$ in the noisy gradient setting. This common use makes AdaGrad a variable metric method and has been the object of recent criticism for machine learning applications (Wilson et al., 2017).

One can also consider a variant of AdaGrad which updates only a single (scalar) stepsize according to the sum of squared gradient norms observed so far. In this work, we focus instead on the “norm” version of AdaGrad as a single stepsize adaptation method using the gradient norm information, which we call AdaGrad-Norm. The update in the stochastic setting is as follows: initialize a single scalar $b_0 > 0$; at the $j$th iteration, observe the random variable $G_j$ such that $E[G_j] = \nabla F(x_j)$ and iterate

$$x_{j+1} \leftarrow x_j - \eta \frac{G(x_j)}{b_{j+1}} \quad \text{with} \quad b_{j+1}^2 = b_j^2 + \|G(x_j)\|^2$$

where $\eta > 0$ is to ensure homogeneity and that the units match. It is straightforward that in expectation, $E[b_k^2] = b_0^2 + \sum_{j=0}^{k-1} E[\|G(x_j)\|^2]$; thus, under the assumption of uniformly bounded gradient $\|\nabla F(x)\|^2 \leq \gamma^2$ and uniformly bounded variance $E[\xi] [\|G(x; \xi) - \nabla F(x)\|^2] \leq \sigma^2$, the stepsize will decay eventually according to $b_j \geq \frac{1}{\sqrt{2(\gamma^2 + \sigma^2)j}}$. This stepsize schedule matches the schedule which leads to optimal rates of convergence for SGD in the case of convex but not necessarily smooth functions, as well as smooth but not necessarily convex functions (see, for instance, Agarwal et al. (2009) and Bubeck et al. (2015)). This observation suggests that AdaGrad-Norm should be able to achieve convergence rates for SGD, but without having to know Lipschitz smoothness parameter of $F$ and the parameter $\sigma$ a priori to set the stepsize schedule.

Theoretically rigorous convergence results for AdaGrad-Norm were provided in the convex setting recently (Levy, 2017). Moreover, it is possible to obtain convergence rates in the offline setting by online-batch conversion. However, making such observations rigorous for nonconvex functions is difficult because $b_j$ is itself a random variable which is correlated with the current and all previous noisy gradients; thus, the standard proofs in SGD do not straightforwardly extend to the proofs of AdaGrad-Norm. This paper provides such a proof for AdaGrad-Norm.
1.2 Main contributions

Our results make rigorous and precise the observed phenomenon that the convergence behavior of AdaGrad-Norm is highly adaptable to the unknown Lipschitz smoothness constant and level of stochastic noise on the gradient: when there is noise, AdaGrad-Norm converges at the rate of $O(\log(N)/\sqrt{N})$, and when there is no noise, the same algorithm converges at the optimal $O(1/N)$ rate like well-tuned batch gradient descent. Moreover, our analysis shows that AdaGrad-Norm converges at these rates for any choices of the algorithm hyperparameters $b_0 > 0$ and $\eta > 0$, in contrast to GD or SGD with fixed stepsize where if the stepsize is set above a hard upper threshold governed by the (generally unknown) smoothness constant $L$, the algorithm might not converge at all. Finally, we note that the constants in the rates of convergence we provide are explicit in terms of their dependence on the hyperparameters.

Practically, our results imply a good strategy for setting the hyperparameters when implementing AdaGrad-Norm: given knowledge of $F^*$, set $\eta = F(x_0) - F^*$ and simply initialize $b_0 > 0$ to be very small.

- When there is no noise $\sigma = 0$, we can improve this rate to an $O(1/N)$ rate of convergence. In Theorem 2.2, we show that $\min_{j \in [N]} \|\nabla F(x_j)\|^2 \leq \varepsilon$ after
  \begin{enumerate}
  \item $N = O\left( \frac{1}{\varepsilon} \left( \left( \frac{(F(x_0) - F^*)}{\eta} \right)^2 + b_0 \left( F(x_0) - F^* \right)/\eta \right) \right)$ if $b_0 \geq \eta L$,
  \item $N = O\left( \frac{1}{\varepsilon} \left( L \left( F(x_0) - F^* \right) + \left( F(x_0) - F^* \right)/\eta \right)^2 + \frac{(\eta L)^2}{\varepsilon} \log \left( \frac{2L}{L_0} \right) \right)$ if $b_0 < \eta L$.
  \end{enumerate}
Note that the constant $(\eta L)^2$ in the second case when $b_0 < \eta L$ is not optimal compared to the known best rate constant $\eta L$ obtainable by gradient descent with fixed stepsize $\eta = 1/L$ (Carmon et al., 2017a); on the other hand, given knowledge of $L$ and $F(x_0) - F^*$, the rate constant of AdaGrad-norm reproduces the optimal constant $\eta L$ by setting $\eta = F(x_0) - F^*$ and $b_0 = \eta L$.

Practically, our results imply a good strategy for setting the hyperparameters when implementing AdaGrad-norm in practice: set $\eta = (F(x_0) - F^*)$ (assuming $F^*$ is known) and set $b_0 > 0$ to be a very small value. If $F^*$ is unknown, then setting $\eta = 1$ should work well for a wide range of values of $L$, and in the noisy case with $\sigma^2$ strictly greater than zero.

1. It is becoming common to define an $\varepsilon$-approximate stationary point as $\|\nabla F(x)\| \leq \varepsilon$ (Agarwal et al., 2017; Carmon et al., 2018, 2017a; Fang et al., 2018; Zhou et al., 2018; Allen-Zhu, 2018), but we use the convention $\|F(x)\|^2 \leq \varepsilon$ (Lei et al., 2017; Bottou et al., 2018) to most easily compare our results to those from Ghadimi and Lan (2013); Li and Orabona (2019).
1.3 Previous work

Theoretical guarantees of convergence for AdaGrad were provided in Duchi et al. (2011) in the setting of online convex optimization, where the loss function may change from iteration to iteration and be chosen adversarially. AdaGrad was subsequently observed to be effective for accelerating convergence in the nonconvex setting, and has become a popular algorithm for optimization in deep learning problems. Many modifications of AdaGrad with or without momentum have been proposed, namely, RMSprop (Srivastava and Swersky, 2012), AdaDelta (Zeiler, 2012), Adam (Kingma and Ba, 2015), AdaFTRL (Orabona and Pal, 2015), SGD-BB (Tan et al., 2016), AdaBatch (Defossez and Bach, 2017), SC-Adagrad (Mukkamala and Hein, 2017), AMSGRAD (Reddi et al., 2018), Padam (Chen and Gu, 2018), etc. Extending our convergence analysis to these popular alternative adaptive gradient methods remains an interesting problem for future research.

Regarding the convergence guarantees for the norm version of adaptive gradient methods in the offline setting, the recent work by Levy (2017) introduces a family of adaptive gradient methods inspired by AdaGrad, and proves convergence rates in the setting of (strongly) convex loss functions without knowing the smoothness parameter $L$ in advance. Yet, that analysis still requires the a priori knowledge of a convex set $K$ with known diameter $D$ in which the global minimizer resides. More recently, Wu et al. (2018) provides convergence guarantees in the non-convex setting for a different adaptive gradient algorithm, WNGrad, which is closely related to AdaGrad-Norm and inspired by weight normalization (Salimans and Kingma, 2016). In fact, the WNGrad stepsize update is similar to AdaGrad-Norm’s:

$$b_{j+1} = b_j + \frac{\|\nabla F(x_j)\|}{b_j};$$

$$b_{j+1} = b_j + \frac{\|\nabla F(x_j)\|}{(b_j + b_{j+1})}.$$  

However, the guaranteed convergence in Wu et al. (2018) is only for the batch setting and the constant in the convergence rate is worse than the one provided here for AdaGrad-Norm. Independently, Li and Orabona (2019) also proves the $O(1/\sqrt{N})$ convergence rate for a variant of AdaGrad-Norm in the non-convex stochastic setting, but their analysis requires knowledge of smoothness constant $L$ and a hard threshold of $b_0 > \eta L$ for their convergence. In contrast to Li and Orabona (2019), we do not require knowledge of the Lipschitz smoothness constant $L$, but we do assume that the gradient $\nabla F$ is uniformly bounded by some (unknown) finite value, while Li and Orabona (2019) only assumes bounded variance $\mathbb{E}_{\xi} [\|G(x; \xi) - \nabla F(x)\|^2] \leq \sigma^2$.

1.4 Future work

This paper provides convergence guarantees for AdaGrad-Norm over smooth, nonconvex functions, in both the stochastic and deterministic settings. Our theorems should shed light on the popularity of AdaGrad as a method for more robust convergence of SGD in nonconvex optimization in that the convergence guarantees we provide are robust to the initial stepsize $\eta/b_0$, and adjust automatically to the level of stochastic noise. Moreover, our results suggest a good strategy for setting hyperparameters in AdaGrad-Norm implementation: set $\eta = (F(x_0) - F^*)$ (if $F^*$ is known) and set $b_0 > 0$ to be a very small value. However, several improvements and extensions should be possible. First, the constant in the convergence rate
we present can likely be improved and it remains open whether we can remove the assumption of the uniformly bounded gradient in the stochastic setting. It would be interesting to analyze AdaGrad in its coordinate form, where each coordinate \(x^k\) of \(x \in \mathbb{R}^d\) has its own stepsize \(1/b^j(k)\) which is updated according to \(b^{j+1}(k) = b^j(k)^2 + (\nabla F(x^j))^2_k\). AdaGrad is just one particular adaptive stepsize method and other updates such as Adam (Kingma and Ba, 2015) are often preferable in practice; it would be nice to have similar theorems for other adaptive gradient methods, and to even use the theory as a guide for determining the “best” method for adapting the stepsize for given problem classes.

1.5 Notation
Throughout, \(\| \cdot \|\) denotes the \(\ell_2\) norm. We use the notation \([N] := \{0, 1, 2, \ldots, N\}\). A function \(F : \mathbb{R}^d \to \mathbb{R}\) has \(L\)-Lipschitz smooth gradient if
\[
\|\nabla F(x) - \nabla F(y)\| \leq L\|x - y\|, \quad \forall x, y \in \mathbb{R}^d
\] (3)
We write \(F \in \mathbb{C}_L^1\) and refer to \(L\) as the smoothness constant for \(F\) if \(L > 0\) is the smallest number such that the above is satisfied.

2. AdaGrad-Norm Convergence
To be clear about the adaptive algorithm, we first state in Algorithm 1 the norm version of AdaGrad we consider throughout in the analysis.

\begin{algorithm}
\begin{enumerate}
\item \textbf{Input:} Initialize \(x_0 \in \mathbb{R}^d, b_j > 0, \eta > 0\) and the total iterations \(N\)
\item for \(j = 1, 2, \ldots, N\) do
\item Generate \(\xi_{j-1}\) and \(G_{j-1} = G(x_{j-1}, \xi_{j-1})\)
\item \(b^2_j \leftarrow b^2_{j-1} + \|G_{j-1}\|^2\)
\item \(x_j \leftarrow x_{j-1} - \frac{\eta}{b^j_j} G_{j-1}\)
\end{enumerate}
\end{algorithm}

At the \(k\)th iteration, we observe a stochastic gradient \(G(x_k, \xi_k)\), where \(\xi_k, k = 0, 1, 2\ldots\) are random variables, and such that \(\mathbb{E}_{\xi_k} [G(x_k, \xi_k)] = \nabla F(x_k)\) is an unbiased estimator of \(\nabla F(x_j)\).\(^2\) We require the following additional assumptions: for each \(k \geq 0\),
\begin{enumerate}
\item The random vectors \(\xi_k, k = 0, 1, 2\ldots,\) are independent of each other and also of \(x_k\);
\item \(\mathbb{E}_{\xi_k} [\|G(x_k, \xi_k) - \nabla F(x_k)\|^2] \leq \sigma^2\);
\item \(\|\nabla F(x)\|^2 \leq \gamma^2\) uniformly.
\end{enumerate}
The first two assumptions are standard (see e.g. Nemirovski and Yudin (1983); Nemirovski et al. (2009); Bottou et al. (2018)). The third assumption is somewhat restrictive as it rules out strongly convex objectives, but is not an unreasonable assumption for AdaGrad-Norm, where the adaptive learning rate is a cumulative sum of all previous observed gradient norms.

\(^2\) \(\mathbb{E}_{\xi_k} [\cdot]\) is the expectation with respect \(\xi_k\) conditional on previous \(\xi_0, \xi_1, \ldots, \xi_{k-1}\)
Because of the variance in gradient, the AdaGrad-Norm stepsize \( \eta_k \) decreases to zero roughly at a rate between \( \frac{1}{\sqrt{2(\gamma^2 + \sigma^2)k}} \) and \( \frac{1}{\sigma \sqrt{k}} \). It is known that AdaGrad-Norm stepsize decreases at this rate (Levy, 2017), and that this rate is optimal in \( k \) in terms of the resulting convergence theorems in the setting of smooth but not necessarily convex \( F \), or convex but not necessarily strongly convex or smooth \( F \). Still, standard convergence theorems for SGD do not extend straightforwardly to AdaGrad-Norm because the stepsize \( \frac{1}{b_k} \) is a random variable and dependent on all previous points visited along the way, i.e., \( \{\|\nabla F(x_j)\|\}_{j=0}^k \) and \( \{\|\nabla G(x_j, \xi_j)\|\}_{j=0}^k \). From this point on, we use the shorthand \( G_k = G(x_k, \xi_k) \) and \( F_k = \nabla F(x_k) \) for simplicity of notation. The following theorem gives the convergence guarantee to Algorithm 1. We give detailed proof in Section 3.

**Theorem 2.1 (AdaGrad-Norm: convergence in stochastic setting)** Suppose \( F \in \mathbb{C}^1_L \) and \( F^* = \inf_x F(x) > -\infty \). Suppose that the random variables \( G_\ell, \ell \geq 0 \), satisfy the above assumptions. Then with probability \( 1 - \delta \),

\[
\min_{\ell \in \{N-1\}} \|\nabla F(x_\ell)\|^2 \leq \min \left\{ \left( \frac{2b_0}{N} + \frac{2\sqrt{2(\gamma + \sigma)}}{\sqrt{N}} \right) \frac{Q}{\delta^{3/2}}, \left( \frac{8Q}{\delta} + 2b_0 \right) \frac{4Q}{N\delta} + \frac{8Q\sigma}{\delta^{3/2}\sqrt{N}} \right\}
\]

where

\[
Q = \frac{F(x_0) - F^*}{\eta} + \frac{4\sigma + \eta L}{2} \log \left( \frac{20N(\gamma^2 + \sigma^2)}{b_0^2} + 10 \right).
\]

This result implies that AdaGrad-Norm converges for any \( \eta > 0 \) and starting from any value of \( b_0 > 0 \). To put this result in context, we can compare to Corollary 2.2 of Ghadimi and Lan (2013) giving the best-known convergence rate for SGD with fixed step-size in the same setting (albeit not requiring Assumption (3) of uniformly bounded gradient): if the Lipschitz smoothness constant \( L \) and the variance \( \sigma^2 \) are known a priori, and the fixed stepsize in SGD is set to

\[
\eta = \min \left\{ \frac{1}{L}, \frac{1}{\sigma \sqrt{N}} \right\}, \quad j = 0, 1, \ldots, N - 1,
\]

then with probability \( 1 - \delta \)

\[
\min_{\ell \in \{N-1\}} \|\nabla F(x_\ell)\|^2 \leq \frac{2L(F(x_0) - F^*)}{N\delta} + \frac{(L + 2(F(x_0) - F^*))\sigma}{\delta \sqrt{N}}.
\]

We match the \( O(1/\sqrt{N}) \) rate of Ghadimi and Lan (2013), but without a priori knowledge of \( L \) and \( \sigma \), and with a worse constant in the rate of convergence. In particular, our rate constant scales according to \( \sigma^2 \) (up to logarithmic factors in \( \sigma \)) while the result for SGD with well-tuned fixed step-size scales linearly with \( \sigma \). The additional logarithmic factor (by Lemma 3.2) results from the AdaGrad-Norm update using the square norm of the gradient (see inequality (11) for details). The extra constant \( \frac{1}{\sqrt{\delta}} \) results from the correlation between the stepsize \( b_j \) and the gradient \( \|\nabla F(x_j)\| \). We note that the recent work Li and Orabona (2019) derives an \( O(1/\sqrt{N}) \) rate for a variation of Adagrad-Norm without the assumption of uniformly bounded gradient, but at the same time requires a priori knowledge of the
smoothness constant \( L > 0 \) in setting the step-size in order to establish convergence, similar to SGD with fixed stepsize. Finally, we note that recent works (Allen-Zhu, 2017; Lei et al., 2017; Fang et al., 2018; Zhou et al., 2018) provide modified SGD algorithms with convergence rates faster than \( O(1/\sqrt{N}) \), albeit again requiring priori knowledge of both \( L \) and \( \sigma \) to establish convergence.

We reiterate however that the main emphasis in Theorem 2.1 is on the robustness of the AdaGrad-Norm convergence to its hyperparameters \( \eta \) and \( b_0 \), compared to plain SGD’s dependence on its parameters \( \eta \) and \( \sigma \). Although the constant in the rate of our theorem is not as good as the best-known constant for stochastic gradient descent with well-tuned fixed stepsize, our result suggests that implementing AdaGrad-Norm allows one to vastly reduce the need to perform laborious experiments to find a stepsize schedule with reasonable convergence when implementing SGD in practice.

We note that for the second bound in 2.1, in the limit as \( \sigma \to 0 \) we recover an \( O(\log(N)/N) \) rate of convergence for noiseless gradient descent. We can establish a stronger result in the noiseless setting using a different method of proof, removing the additional log factor and Assumption 3 of uniformly bounded gradient. We state the theorem below and defer our proof to Section 4.

**Theorem 2.2 (AdaGrad-Norm: convergence in deterministic setting)** Suppose that \( F \in C^1_L \) and that \( F^* = \inf_x F(x) > -\infty \). Consider AdaGrad-Norm in deterministic setting with following update,

\[
x_j = x_{j-1} - \frac{\eta}{b_j} \nabla F(x_{j-1}) \quad \text{with} \quad b_j^2 = b_{j-1}^2 + \|\nabla F(x_{j-1})\|^2
\]

Then \( \min_{j \in [N]} \|\nabla F(x_j)\|^2 \leq \varepsilon \) after

(1) \( N = 1 + \left\lfloor \frac{1}{\varepsilon} \left( \frac{4(F(x_0) - F^*)^2}{\eta^2} + \frac{2b_0(F(x_0) - F^*)}{\eta} \right) \right\rfloor \) if \( b_0 \geq \eta L \),

(2) \( N = 1 + \left\lfloor \frac{1}{\varepsilon} \left( 2L(F(x_0) - F^*) + \left( \frac{2(F(x_0) - F^*)}{\eta} + \eta L C_{b_0} \right)^2 + (\eta L)^2 (1 + C_{b_0} - b_0^2) \right) \right\rfloor \)

if \( b_0 < \eta L \). Here \( C_{b_0} = 1 + 2 \log \left( \frac{\eta L}{b_0} \right) \).

The convergence bound shows that, unlike gradient descent with constant stepsize \( \eta \) which can diverge if the stepsize \( \eta \geq 2/L \), AdaGrad-Norm convergence holds for any choice of parameters \( b_0 \) and \( \eta \). The critical observation is that if the initial stepsize \( \frac{b_0}{\eta} > \frac{L}{2} \) is too large, the algorithm has the freedom to diverge initially, until \( b_j \) grows to a critical point (not too much larger than \( L\eta \)) at which point \( \frac{b_j}{\eta} \) is sufficiently small that the smoothness of \( F \) forces \( b_j \) to converge to a finite number on the order of \( L \), so that the algorithm converges at an \( O(1/N) \) rate. To describe the result in Theorem 2.2, let us first review a classical result (see, for example Nesterov (1998), (1.2.13)) on the convergence rate for gradient descent with fixed stepsize.

**Lemma 2.1** Suppose that \( F \in C^1_L \) and that \( F^* = \inf_x F(x) > -\infty \). Consider gradient descent with constant stepsize, \( x_{j+1} = x_j - \frac{\nabla F(x_j)}{b} \). If \( b \geq L \), then \( \min_{j \in [N-1]} \|\nabla F(x_j)\|^2 \leq \varepsilon \) after at most a number of steps

\[
N = \frac{2b(F(x_0) - F^*)}{\varepsilon}.
\]
Alternatively, if \( b \leq \frac{L}{2} \), then convergence is not guaranteed at all—gradient descent can oscillate or diverge.

Compared to the convergence rate of gradient descent with fixed stepsize, AdaGrad-Norm in the case \( b = b_0 \geq \eta L \) gives a larger constant in the rate. But in case \( b = b_0 < \eta L \), gradient descent can fail to converge as soon as \( b \leq \eta L/2 \), while AdaGrad-Norm converges for any \( b_0 > 0 \), and is extremely robust to the choice of \( b_0 < \eta L \) in the sense that the resulting convergence rate remains close to the optimal rate of gradient descent with fixed stepsize \( 1/b = 1/L \), paying a factor of \( \log(9L^2/b_0) \) and \((\eta L)^2\) in the constant. Here, the constant \((\eta L)^2\) results from the worst-case analysis using Lemma 4.1, which assumes that the gradient \( \|\nabla F(x_j)\|^2 \approx \epsilon \) for all \( j = 0, 1, \ldots \), when in reality the gradient should be much larger at first. We believe the number of iterations can be improved by a refined analysis, or by considering the setting where \( x_0 \) is drawn from an appropriate random distribution.

3. Proof of Theorem 2.1

We first introduce some important lemmas in subsection 3.1 and give the proof of the first bound in Theorem 2.1 in Subsection 3.2.

3.1 Ingredients of the Proof

We first introduce several lemmas that are used in the proof for Theorem 2.1. We repeatedly appeal to the following classical Descent Lemma, which is also the main ingredient in Ghadimi and Lan (2013), and can be proved by considering the Taylor expansion of \( F \) around \( y \).

**Lemma 3.1 (Descent Lemma)** Let \( F \in C^1_L \). Then,

\[
F(x) \leq F(y) + \langle \nabla F(y), x - y \rangle + \frac{L}{2} \| x - y \|^2.
\]

We will also use the following lemmas concerning sums of non-negative sequences.

**Lemma 3.2** For any non-negative \( a_1, \ldots, a_T \), and \( a_1 \geq 1 \), we have

\[
\sum_{t=1}^{T} \frac{a_t}{\sum_{i=1}^{T} a_i} \leq \log \left( \sum_{i=1}^{T} a_i \right) + 1.
\]

**Proof** The lemma can be proved by induction. That the sum should be proportional to \( \log \left( \sum_{i=1}^{T} a_i \right) \) can be seen by associating to the sequence a continuous function \( g : \mathbb{R}^+ \to \mathbb{R} \) satisfying \( g(\ell) = a_\ell, 1 \leq \ell \leq T \), and \( g(t) = 0 \) for \( t \geq T \), and replacing sums with integrals. 

\[\blacksquare\]
3.2 Proof of 2.1

**Proof** For simplicity, we write $F_j = F(x_j)$ and $\nabla F_j = \nabla F(x_j)$. By Lemma 3.1, for $j \geq 0$, 
\[
\frac{F_{j+1} - F_j}{\eta} \leq -\langle \nabla F_j, \frac{G_j}{b_{j+1}} \rangle + \frac{\eta L}{2b_{j+1}^2} \|G_j\|^2 \\
= -\frac{\|\nabla F_j\|^2}{b_{j+1}} + \frac{\langle \nabla F_j, \nabla F_j - G_j \rangle}{b_{j+1}} + \frac{\eta L}{2b_{j+1}^2} \|G_j\|^2 .
\]
At this point, we cannot apply the standard method of proof for SGD, since $b_{j+1}$ and $G_j$ are correlated random variables and thus, in particular, for the conditional expectation 
\[
\mathbb{E}_{\xi_j} \left[ \frac{\langle \nabla F_j, \nabla F_j - G_j \rangle}{b_{j+1}} \right] \neq \frac{\mathbb{E}_{\xi_j} [\langle \nabla F_j, \nabla F_j - G_j \rangle]}{b_{j+1}} = \frac{1}{b_{j+1}} \cdot 0;
\]
If we had a closed form expression for $\mathbb{E}_{\xi_j} [\frac{1}{b_{j+1}}]$, we would proceed by bounding this term as 
\[
\left| \mathbb{E}_{\xi_j} \left[ \frac{1}{b_{j+1}} \langle \nabla F_j, \nabla F_j - G_j \rangle \right] \right| = \left| \mathbb{E}_{\xi_j} \left[ \left( \frac{1}{b_{j+1}} - \mathbb{E}_{\xi_j} \left[ \frac{1}{b_{j+1}} \right] \right) \langle \nabla F_j, \nabla F_j - G_j \rangle \right] \right| \\
\leq \mathbb{E}_{\xi_j} \left[ \left( \frac{1}{b_{j+1}} - \mathbb{E}_{\xi_j} \left[ \frac{1}{b_{j+1}} \right] \right) \|\langle \nabla F_j, \nabla F_j - G_j \rangle\| \right]. \tag{5}
\]
Since we do not have a closed form expression for $\mathbb{E}_{\xi_j} [\frac{1}{b_{j+1}}]$ though, we use the estimate 
\[
\frac{1}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}}
\]
as a surrogate for $\mathbb{E}_{\xi_j} [\frac{1}{b_{j+1}}]$ to proceed. Condition on $\xi_1, \ldots, \xi_{j-1}$ and take expectation with respect to $\xi_j$, 
\[
0 = \mathbb{E}_{\xi_1} [\langle \nabla F_j, \nabla F_j - G_j \rangle] = \mathbb{E}_{\xi_j} \left[ \frac{\langle \nabla F_j, \nabla F_j - G_j \rangle}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}} \right]
\]
thus, 
\[
\mathbb{E}_{\xi_j} [F_{j+1} - F_j] \\
\leq \mathbb{E}_{\xi_j} \left[ \frac{\langle \nabla F_j, \nabla F_j - G_j \rangle}{b_{j+1}} - \frac{\langle \nabla F_j, \nabla F_j - G_j \rangle}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}} \right] - \mathbb{E}_{\xi_j} \left[ \frac{\|\nabla F_j\|^2}{b_{j+1}} \right] + \mathbb{E}_{\xi_j} \left[ \frac{L\eta \|G_j\|^2}{2b_{j+1}^2} \right] \\
= \mathbb{E}_{\xi_j} \left[ \left( \frac{1}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}} - \frac{1}{b_{j+1}} \right) \langle \nabla F_j, G_j \rangle \right] - \frac{\|\nabla F_j\|^2}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}} + \frac{\eta L}{2} \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}^2} \right] \tag{6}
\]
Now, observe the term 
\[
\frac{1}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}} - \frac{1}{b_{j+1}} \\
= \frac{\|G_j\| - \|\nabla F_j\|}{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2} \left[ \frac{\|G_j\| + \|\nabla F_j\|}{\sqrt{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}} \right] - \frac{\sigma^2}{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2} \\
\leq \frac{\|G_j\| - \|\nabla F_j\|}{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2} + \frac{\sigma}{b_{j+1}^2 + \|\nabla F_j\|^2 + \sigma^2}
\]
thus, applying Cauchy-Schwarz,

\[ \mathbb{E}_{\xi_j} \left[ \frac{1}{b_j^2 + \|\nabla F_j\|^2 + \sigma^2} - \frac{1}{b_{j+1}} \right] \langle \nabla F_j, G_j \rangle \]

\[ \leq \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\| - \|\nabla F_j\| \|G_j\| \|\nabla F_j\|}{b_{j+1} \sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \right] + \mathbb{E}_{\xi_j} \left[ \frac{\sigma \|G_j\| \|\nabla F_j\|}{b_{j+1} \sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \right] \tag{7} \]

By applying the inequality \(ab \leq \frac{1}{2}a^2 + \frac{1}{2b^2}b^2\) with \(\lambda = \frac{2\sigma^2}{\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}}\), \(a = \frac{\|G_j\|}{b_{j+1}}\), and \(b = \frac{\|G_j\| - \|\nabla F_j\|}{\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}}\), the first term in (7) can be bounded as

\[ \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\| - \|\nabla F_j\| \|G_j\| \|\nabla F_j\|}{b_{j+1} \sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \right] \leq \frac{\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}}{4\sigma^2} \mathbb{E}_{\xi_j} \left[ \left( \|G_j\| - \|\nabla F_j\| \right)^2 \right] + \frac{\sigma^2}{4\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right] \]

\[ \leq \frac{\|\nabla F_j\|^2}{4\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} + \sigma \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right]. \tag{8} \]

where the last inequality due to the fact that

\[ \|G_j\| - \|\nabla F_j\| \leq \|G_j - \nabla F_j\|. \]

Similarly, applying the inequality \(ab \leq \frac{1}{2}a^2 + \frac{1}{2b^2}b^2\) with \(\lambda = \frac{2\sigma^2}{\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}}\), \(a = \frac{\sigma \|G_j\|}{b_{j+1}}\), and \(b = \frac{\|\nabla F_j\|}{\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}}\), the second term of the right hand side in equation (7) is bounded by

\[ \mathbb{E}_{\xi_j} \left[ \frac{\sigma \|\nabla F_j\| \|G_j\|}{b_{j+1} \sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \right] \leq \sigma \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right] + \frac{\|\nabla F_j\|^2}{4\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \]

\[ \tag{9} \]

Thus, putting inequalities (8) and (9) back into (7) gives

\[ \mathbb{E}_{\xi_j} \left[ \left( \frac{1}{\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} - \frac{1}{b_{j+1}} \right) \langle \nabla F_j, G_j \rangle \right] \leq \frac{\eta L}{2} \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right] + 2\sigma \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right] - \frac{\|\nabla F_j\|^2}{2\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \]

and, therefore, back to (6),

\[ \frac{\mathbb{E}_{\xi_j}[F_{j+1}] - F_j}{\eta} \leq \frac{\eta L}{2} \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right] + 2\sigma \mathbb{E}_{\xi_j} \left[ \frac{\|G_j\|^2}{b_{j+1}} \right] - \frac{\|\nabla F_j\|^2}{2\sqrt{b_j^2 + \|\nabla F_j\|^2 + \sigma^2}} \]

\[ \]
Rearranging,
\[
\frac{\| \nabla F_j \|^2}{2 \sqrt{b_j^2 + \| \nabla F_j \|^2 + \sigma^2}} \leq \frac{F_j - \mathbb{E}_{\xi_j}[F_{j+1}]}{\eta} + \frac{4\sigma + \eta L}{2} \mathbb{E}_{\xi_j} \left[ \frac{\| G_j \|^2}{b_{j+1}^2} \right]
\]
Applying the law of total expectation, we take the expectation of each side with respect to \( \xi_{j-1}, \xi_{j-2}, \ldots, \xi_1 \), and arrive at the recursion
\[
\mathbb{E} \left[ \frac{\| \nabla F_j \|^2}{2 \sqrt{b_j^2 + \| \nabla F_j \|^2 + \sigma^2}} \right] \leq \frac{\mathbb{E}[F_j] - \mathbb{E}[F_{j+1}]}{\eta} + \frac{4\sigma + \eta L}{2} \mathbb{E} \left[ \frac{\| G_j \|^2}{b_{j+1}^2} \right].
\]
Taking \( j = N \) and summing up from \( k = 0 \) to \( k = N - 1 \),
\[
\sum_{k=0}^{N-1} \mathbb{E} \left[ \frac{\| \nabla F_k \|^2}{2 \sqrt{b_k^2 + \| \nabla F_k \|^2 + \sigma^2}} \right] \leq \frac{F_0 - F^*}{\eta} + \frac{4\sigma + \eta L}{2} \mathbb{E} \left[ \frac{\sum_{k=0}^{N-1} \| G_k \|^2}{b_{k+1}^2} \right]
\]
\[
\leq \frac{F_0 - F^*}{\eta} + \frac{4\sigma + \eta L}{2} \log \left( 10 + \frac{20N (\sigma^2 + \gamma^2)}{b_0^2} \right)
\]
(10)
where the second inequality we apply Lemma (3.2) and then Jensen’s inequality to bound the summation:
\[
\mathbb{E} \sum_{k=0}^{N-1} \left[ \frac{\| G_k \|^2}{b_{k+1}^2} \right] \leq \mathbb{E} \left[ 1 + \log \left( 1 + \sum_{k=0}^{N-1} \frac{\| G_k \|^2}{b_0^2} \right) \right]
\]
\[
\leq \log \left( 10 + \frac{20N (\sigma^2 + \gamma^2)}{b_0^2} \right).
\]
(11)
since
\[
\mathbb{E} \left[ b_k^2 - b_{k-1}^2 \right] \leq \mathbb{E} \left[ \| G_k \|^2 \right]
\leq 2\mathbb{E} \left[ \| G_k - \nabla F_k \|^2 \right] + 2\mathbb{E} \left[ \| \nabla F_k \|^2 \right]
\leq 2\sigma^2 + 2\gamma^2.
\]
(12)

### 3.2.1 Finishing the proof of the first bound in Theorem 2.1

For the term on left hand side in equation (10), we apply Hölder’s inequality,
\[
\frac{\mathbb{E}|XY|}{(\mathbb{E}|Y|^3)^{\frac{1}{3}}} \leq \left( \mathbb{E}|X|^{\frac{3}{2}} \right)^{\frac{2}{3}}
\]
with \( X = \left( \frac{\| \nabla F_k \|^2}{\sqrt{b_k^2 + \| \nabla F_k \|^2 + \sigma^2}} \right)^{\frac{2}{3}} \) and \( Y = \left( \sqrt{b_k^2 + \| \nabla F_k \|^2 + \sigma^2} \right)^{\frac{2}{3}} \) to obtain
\[
\mathbb{E} \left[ \frac{\| \nabla F_k \|^2}{2 \sqrt{b_k^2 + \| \nabla F_k \|^2 + \sigma^2}} \right] \geq \frac{\left( \mathbb{E} \| \nabla F_k \|^{4/3} \right)^2}{2 \sqrt{\mathbb{E} [b_k^2 + \| \nabla F_k \|^2 + \sigma^2]}} \geq \frac{\left( \mathbb{E} \| \nabla F_k \|^{4/3} \right)^2}{2 \sqrt{b_0^2 + 2(k + 1)(\gamma^2 + \sigma^2)}}
\]

where the last inequality is due to inequality (12). Thus (10) arrives at the inequality

\[
N \min_{k \in [N-1]} \left( \frac{\mathbb{E} \left[ \| \nabla F_k \|^{4/3} \right]}{2 \sqrt{b_0^2 + 2N(\gamma^2 + \sigma^2)}} \right)^3 \leq \frac{F_0 - F^*}{\eta} + \frac{4\sigma + \eta L}{2} \left( \log \left( \frac{1 + 2N (\sigma^2 + \gamma^2)}{b_0^2} \right) + 1 \right).
\]

Multiplying by \( \frac{2 \sigma + 2\sqrt{2N(\gamma + \sigma)}}{N} \), the above inequality gives

\[
\min_{k \in [N-1]} \left( \mathbb{E} \left[ \| \nabla F_k \|^{4/3} \right] \right)^3 \leq \left( \frac{2b_0 \sqrt{N}}{N} + \frac{2 \sqrt{2(\gamma + \sigma)}}{\sqrt{N}} \right) C_F
\]

where

\[
C_F = \frac{F_0 - F^*}{\eta} + \frac{4\sigma + \eta L}{2} \log \left( \frac{20N (\sigma^2 + \gamma^2)}{b_0^2} + 10 \right).
\]

Finally, the bound is obtained by Markov’s Inequality:

\[
P \left( \min_{k \in [N-1]} \| \nabla F_k \|^2 \geq \frac{C_N}{\delta^{3/2}} \right) = P \left( \min_{k \in [N-1]} \left( \| \nabla F_k \|^2 \right)^{2/3} \geq \left( \frac{C_N}{\delta^{3/2}} \right)^{2/3} \right) \\
\leq \mathbb{E} \left[ \min_{k \in [N-1]} \| \nabla F_k \|^{4/3} \right] C_N^{2/3} \\
\leq \delta
\]

where in the second step Jensen’s inequality is applied to the concave function \( \phi(x) = \min_k h_k(x) \).

### 3.2.2 Finishing the proof of the first bound in Theorem 2.1

First, observe with probability \( 1 - \delta' \) that

\[
\sum_{i=0}^{N-1} \| \nabla F_i - G_i \|^2 \leq \frac{N\sigma^2}{\delta'}.
\]

Let \( Z = \sum_{k=0}^{N-1} \| \nabla F_k \|^2 \), then

\[
b_{N-1}^2 + \| \nabla F_{N-1} \|^2 + \sigma^2 = b_0^2 + \sum_{i=0}^{N-2} \| G_i \|^2 + \| \nabla F_{N-1} \|^2 + \sigma^2 \\
\leq b_0^2 + 2 \sum_{i=0}^{N-1} \| \nabla F_i \|^2 + 2 \sum_{i=0}^{N-2} \| \nabla F_i - G_i \|^2 + \sigma^2 \\
\leq b_0^2 + 2Z + 2N\sigma^2 \delta'
\]
In addition, from inequality (10), i.e.,
\[
\mathbb{E} \left[ \frac{\sum_{k=0}^{N-1} \|\nabla F_k\|^2}{2\sqrt{b_{N-1}^2 + \|\nabla F_{N-1}\|^2 + \sigma^2}} \right] \leq \frac{F_0 - F^*}{\eta} + \frac{4\sigma + \eta L}{2} \log \left( 10 + \frac{20N(\sigma^2 + \gamma^2)}{b_0^2} \right) \triangleq C_F
\]
we have with probability \(1 - \hat{\delta} - \delta'\) that
\[
C_F \geq \frac{\sum_{k=0}^{N-1} \|\nabla F_k\|^2}{2\sqrt{b_{N-1}^2 + \|\nabla F_{N-1}\|^2 + \sigma^2}} \geq \frac{Z}{2\sqrt{b_0^2 + 2Z + 2N\sigma^2/\delta'}}
\]
That is equivalent to solve the following quadratic equation
\[
Z^2 - \frac{8C_F^2}{\delta} Z - \frac{4C_F^2}{\delta^2} \left( b_0^2 + \frac{2N\sigma^2}{\delta'} \right) \leq 0
\]
which gives
\[
Z \leq \frac{4C_F^2}{\delta^2} + \sqrt{\frac{16C_F^4}{\delta^4} + \frac{4C_F^2}{\delta^2} \left( b_0^2 + \frac{2N\sigma^2}{\delta'} \right)} \leq \frac{8C_F^2}{\delta^2} + \frac{2C_F}{\delta} \left( b_0 + \frac{\sqrt{2N}\sigma}{\sqrt{\delta'}} \right)
\]
Let \(\hat{\delta} = \delta' = \frac{\delta}{2}\). Replacing \(Z\) with \(\sum_{k=0}^{N-1} \|\nabla F_k\|^2\) and dividing both side with \(N\) we have with probability \(1 - \hat{\delta}\)
\[
\min_{k \in [N-1]} \|\nabla F_k\|^2 \leq \frac{4C_F}{N\delta} \left( \frac{8C_F}{\delta} + 2b_0 \right) + \frac{8\sigma C_F}{\delta^{3/2}\sqrt{N}}
\]

4. Proof of Theorem 2.2

4.1 The Lemmas

We will use the following lemma to argue that after an initial number of steps \(N = \left\lceil \frac{(\eta L)^2 - b_0^2}{\tau} \right\rceil + 1\), either we have already reached a point \(x_k\) such that \(\|\nabla F(x_k)\|^2 \leq \varepsilon\), or else \(b_N \geq \eta L\).

**Lemma 4.1** Fix \(\varepsilon \in (0,1]\) and \(C > 0\). For any non-negative \(a_0, a_1, \ldots\), the dynamical system
\[
\begin{align*}
b_0 &> 0; \\
b_j^2 + 1 &= b_j^2 + a_j
\end{align*}
\]
has the property that after \(N = \left\lceil \frac{C^2 - b_0^2}{\tau} \right\rceil + 1\) iterations, either \(\min_{k=0;N-1} a_k \leq \varepsilon\), or \(b_N \geq \eta L\).
Proof If \( b_0 \geq \eta C \), we are done. Else \( b_0 < C \). Let \( N \) be the smallest integer such that \( N \geq \frac{C^2 - b_0^2}{\varepsilon} \). Suppose \( b_N < C \). Let \( N \) be the smallest integer such that

\[
N \geq C^2 - b_0^2 \varepsilon.
\]

Suppose \( b_N < C \). Then

\[
C^2 > b_N^2 = b_0^2 + \sum_{k=0}^{N-1} a_k > b_0^2 + N \min_{k \in [N-1]} a_k \Rightarrow \min_{k \in [N-1]} a_k \leq \frac{C^2 - b_0^2}{N}
\]

Hence, for \( N \geq \frac{C^2 - b_0^2}{\varepsilon} \), \( \min_{k \in [N-1]} a_k \leq \varepsilon \). Suppose \( \min_{k \in [N-1]} a_k > \varepsilon \), then from above inequalities we have \( b_N > C \).

The following Lemma shows that \( \{ F(x_k) \}_{k=0}^\infty \) is a bounded sequence for any value of \( b_0 > 0 \).

**Lemma 4.2** Suppose \( F \in C_1^L \) and \( F^* = \inf_x F(x) > -\infty \). Denote by \( k_0 \geq 1 \) the first index such that \( b_{k_0} \geq \eta L \). Then for all \( b_k < \eta L, k = 0, 1, \ldots, k_0 - 1 \),

\[
F_{k_0-1} - F^* \leq F_0 - F^* + \frac{\eta^2 L}{2} \left( 1 + 2 \log \left( \frac{b_{k_0-1}}{b_0} \right) \right)
\]  
(13)

**Proof** Suppose \( k_0 \geq 1 \) is the first index such that \( b_{k_0} \geq \eta L \). By Lemma 3.1, for \( j \leq k_0 - 1 \),

\[
F_{j+1} \leq F_j - \frac{\eta}{b_{j+1}} \left( 1 - \frac{\eta L}{2b_{j+1}} \right) \| \nabla F_j \|^2 \leq F_j + \frac{\eta^2 L}{2b_{j+1}} \| \nabla F_j \|^2 \leq F_0 + \sum_{\ell=0}^{j} \frac{\eta^2 L}{2b_{\ell+1}} \| \nabla F_{\ell} \|^2
\]

\[
\Rightarrow \quad F_{k_0-1} - F_0 \leq \frac{\eta^2 L}{2} \sum_{i=0}^{k_0-2} \frac{\| \nabla F_i \|^2}{b_i^2}
\]

\[
\leq \frac{\eta^2 L}{2} \sum_{i=0}^{k_0-2} \frac{\left( \| \nabla F_i \| / b_0 \right)^2}{\left( \| \nabla F_i \| / b_0 \right)^2 + 1}
\]

\[
\leq \frac{\eta^2 L}{2} \left( 1 + \log \left( 1 + \sum_{\ell=0}^{k_0-2} \frac{\| \nabla F_{\ell} \|^2}{b_0^2} \right) \right) \quad \text{by Lemma 3.2}
\]

\[
\leq \frac{\eta^2 L}{2} \left( 1 + \log \left( \frac{b_{k_0-1}^2}{b_0^2} \right) \right).
\]

4.2 The Proof

**Proof** By Lemma 4.1, if \( \min_{k \in [N-1]} \| \nabla F(x_k) \|^2 \leq \varepsilon \) is not satisfied after \( N = \left\lceil \left( \frac{(\eta L)^2 - b_0^2}{\varepsilon} \right) \right\rceil + 1 \) steps, then there exits a first index \( 1 \leq k_0 \leq N \) such that \( \frac{b_{k_0}}{\eta} > L \). By Lemma 3.1, for \( j \geq 0 \),
\[
F_{k_0+j} \leq F_{k_0+j-1} - \frac{\eta}{b_{k_0+j}} (1 - \frac{\eta L}{2b_{k_0+j}}) \| \nabla F_{k_0+j-1} \|^2 \\
\leq F_{k_0-1} - \sum_{\ell=0}^{j} \frac{\eta}{2b_{k_0+\ell}} \| \nabla F_{k_0+\ell-1} \|^2 \\
\leq F_{k_0-1} - \frac{\eta}{2b_j} \sum_{\ell=0}^{j} \| \nabla F_{k_0+\ell-1} \|^2. 
\] (14)

Let \( Z = \sum_{k=k_0-1}^{M-1} \| \nabla F_k \|^2 \), it follows that

\[
\frac{2 (F_{k_0-1} - F^*)}{\eta} \geq \frac{2 (F_0 - F_M)}{\eta} \geq \sum_{k=k_0-1}^{M-1} \| \nabla F_k \|^2 \geq \frac{Z}{\sqrt{Z + b_{k_0-1}^2}}. 
\]

Solving the quadratic inequality for \( Z \),

\[ \sum_{k=k_0-1}^{M-1} \| \nabla F_k \|^2 \leq \frac{4 (F_{k_0-1} - F^*)^2}{\eta^2} + \frac{2 (F_{k_0-1} - F^*) b_{k_0-1}}{\eta}. \] (15)

If \( k_0 = 1 \), the stated result holds by multiplying both side by \( \frac{1}{M} \). Otherwise, \( k_0 > 1 \). From Lemma 4.2, we have

\[ F_{k_0-1} - F^* \leq F_0 - F^* + \frac{\eta^2 L}{2} \left( 1 + 2 \log \left( \frac{\eta L}{b_0} \right) \right). \]

Replacing \( F_{k_0-1} - F^* \) in (15) by above bound, we have

\[ \sum_{k=k_0-1}^{M-1} \| \nabla F_k \|^2 \leq \frac{4 (F_0 - F^*)^2}{\eta^2} + \frac{2 (F_0 - F^*) b_{k_0-1}}{\eta} + 2L (F_0 - F^*) + (\eta L)^2 \left( 1 + 2 \log \left( \frac{\eta L}{b_0} \right) \right) \]

Thus, we are assured that

\[ \min_{k=0:N+M-1} \| \nabla F_k \|^2 \leq \varepsilon \]

where \( N \leq \frac{L^2 - b_0^2}{\varepsilon} \) and \( M = \frac{C_M}{\varepsilon} \).

\textbf{5. Numerical Experiments}

With guaranteed convergence of AdaGrad-Norm and its strong robustness to the parameters \( \eta \) and \( b_0 \), we perform experiments on several data sets ranging from simple linear regression over Gaussian data to neural network architectures on state-of-the-art (SOTA) image data sets including ImageNet.
5.1 Synthetic Data

In this section, we consider linear regression to corroborate our analysis, i.e.,

\[ F(x) = \frac{1}{2m} \|Ax - y\|^2 = \frac{1}{(m/n)} \sum_{k=1}^{m/n} \frac{1}{2n} \|A_{\xi_k}x - y_{\xi_k}\|^2 \]

where \( A \in \mathbb{R}^{m \times d} \), \( m \) is the total number of samples, \( n \) is the mini-batch (small sample) size for each iteration, and \( A_{\xi_k} \in \mathbb{R}^{n \times d} \). Then AdaGrad-Norm update is

\[ x_{j+1} = x_j - \frac{\eta A^T_{\xi_j} (A_{\xi_j}x_j - y_{\xi_j}) / n}{\sqrt{b_0^2 + \sum_{\ell=0}^j \left( \|A^T_{\xi_\ell} (A_{\xi_\ell}x_\ell - y_{\xi_\ell}) \| / n \|^2}}. \]

We simulate \( A \in \mathbb{R}^{1000 \times 2000} \) and \( x^* \in \mathbb{R}^{1000} \) such that each entry of \( A \) and \( x^* \) is an i.i.d. standard Gaussian. Let \( y = Ax^* \). For each iteration, we independently draw a small sample of size \( n = 20 \) and \( x_0 \) whose entries follow i.i.d. uniform in \([0, 1]\). The vector \( x_0 \) is same for all the methods so as to eliminate the effect of random initialization in weight vector.

![Figure 1: Gaussian Data – Stochastic Setting. The top 3 figures plot the square of the gradient norm for linear regression, \( \|A^T (Ax_j - y)\| / N \), w.r.t. \( b_0 \), at iterations 10, 2000 and 5000 (see title) respectively. The bottom 3 figures plot the corresponding effective learning rates (median of \( \{b_j(\ell)\}_{\ell=1}^d \) for AdaGrad-Coordinate), w.r.t. \( b_0 \), at iteration 10, 2000 and 5000 respectively (see title).](image-url)
Since $F^* = 0$, we set $\eta = F(x_0) - F^* = \frac{1}{2m} \| Ax_0 - b \|^2 = 650$. We vary the initialization $b_0 > 0$ as to compare with plain SGD using (a) SGD-Constant: fixed stepsize $\frac{650}{b_0}$, (b) SGD-DecaySqrt: decaying stepsize $\eta_j = \frac{650}{b_0 \sqrt{j}}$, and (c) AdaGrad-Coordinate: update the $d$ parameters $b_j(k), k = 1, 2, \ldots, d$ at each iteration $j$, one for each coordinate of $x_j \in \mathbb{R}^d$.

Figure 1 plots $\| A^T (Ax_j - y) \| / m$ (GradNorm) and the effective learning rates at iterations 10, 2000, and 5000, and as a function of $b_0$, for each of the four methods. The effective learning rates are $\frac{650}{b_0}$ (AdaGrad-Norm), $\frac{650}{b_0}$ (SGD-Constant), $\frac{650}{b_0 \sqrt{j}}$ (SGD-DecaySqrt), and the median of $\{ b_j(\ell) \}^d_{\ell=1}$ (AdaGrad-Coordinate).

![Figure 2: Gaussian Data - Batch Setting. The y-axis and x-axis in the top and middle 3 figures are the same as in Figure 1. The bottom 3 figures plot the accumulated computational time up to iteration 50, 100 and 200 (see title), as a function of $b_0$.](image)

We can see in Figure 1 how AdaGrad-Norm and AdaGrad-Coordinate auto-tune the learning rate adaptively to a certain level to match the unknown Lipschitz smoothness constant and the stochastic noise so that the gradient norm converges for a significantly wider range of $b_0$ than for either SGD method. In particular, when $b_0$ is initialized too small, AdaGrad-Norm and AdaGrad-Coordinate still converge with good speed while SGD-Constant and SGD-DecaySqrt diverge. When $b_0$ is initialized too large (stepsize too small),
AdaGrad-Norm convergence over nonconvex landscapes

surprisingly AdaGrad-Norm and AdaGrad-Coordinate converge at the same speed as SGD-
Constant. This possibly can be explained by Theorem 2.2 because this is somewhat like the
deterministic setting (the stepsize controls the variance $\sigma$ and a smaller learning rate implies
smaller variance). Comparing AdaGrad-Coordinate and AdaGrad-Norm, AdaGrad-Norm is
more robust to the initialization $b_0$ but is not better than AdaGrad-Coordinate when the
initialization $b_0$ is close to the optimal value of $L$.

Figure 2 explores the batch gradient descent setting, when there is no variance $\sigma = 0$ (i.e.,
using the whole data sample for one iteration). The experimental setup in Figure 2 is the
same as Figure 1 except for the sample size $m$ of each iteration. Since the line-search method
(GD-LineSearch) is one of the most important algorithms in deterministic gradient descent
for adaptively choosing the step-size at each iteration, we also compare to this method – see
Algorithm 2 in the appendix for our particular implementation of Line-Search. We see that
the behavior of the four methods, AdaGrad-Norm, AdaGrad-Coordinate, GD-Constant, and
GD-DecaySqrt, are very similar to the stochastic setting, albeit AdaGrad-Coordinate here
is worse than in the stochastic setting. Among the five methods in the plot, GD-LineSearch
performs the best but with significantly longer computational time, which is not practical
in large-scale machine learning problems.

5.2 Image Data

In this section, we extend our numerical analysis to the setting of deep learning and show
that the robustness of AdaGrad-Norm does not come at the price of worse generalization –
an important observation that is not explained by our current theory. The experiments are
done in PyTorch (Paszke et al., 2017) and parameters are by default if no specification is
provided.\(^3\) We did not find it practical to compute the norm of the gradient for the entire
neural network during back-propagation. Instead, we adapt a stepsize for each neuron or
each convolutional channel by updating $b_j$ with the gradient of the neuron or channel. Hence,
our experiments depart slightly from a strict AdaGrad-Norm method and include a limited
adaptive metric component. Details in implementing AdaGrad-Norm in a neural network
are explained in the appendix and the code is also provided.\(^4\)

Datasets and Models  We test on three data sets: MNIST (LeCun et al., 1998), CIFAR-
10 (Krizhevsky, 2009) and ImageNet (Deng et al., 2009), see Table 1 in the appendix for
detailed descriptions. For MNIST, our models are a logistic regression (LogReg), a multi-
layer network with two fully connected layers (FulConn2) with 100 hidden units and ReLU
activations, and a convolutional neural network (see Table 2 in the appendix for details). For
CIFAR10, our model is ResNet-18 (He et al., 2016). For both data sets, we use 256 images
per iteration (2 GPUs with 128 images/GPU, 234 iterations per epoch for MNIST and 196
iterations per epoch for CIFAR10). For ImageNet, we use ResNet-50 and 256 images for
one iteration (8 GPUs with 32 images/GPU, 5004 iterations per epoch). Note that we do
not use accelerated methods such as adding momentum in the training.

We pick these models for the following reasons: (1) LR with MNIST represents the
smooth loss function; (2) FC with MNIST represents the non-smooth loss function; (3)
CNN with MNIST belongs to a class of simple shallow network architectures; (4) ResNet-

\(^3\) The code we used is originally from https://github.com/pytorch/examples/tree/master/imagenet
\(^4\) https://github.com/xwuShirley/pytorch/blob/master/torch/optim/adagradnorm.py
Figure 3: MNIST. In each plot, the y-axis is the train or test accuracy and the x-axis is $b_0$. The 6 plots are for logistic regression (LogReg) with average at epoch 1-5, 11-15 and 26-30. The title is the last epoch of the average. Note green and red curves overlap when $b_0$ belongs to $[10, \infty)$.

Experimental Details For the experiment in MNIST, in order to make the setting match our assumptions and theorem, we do not use bias, regularization (zero weight decay), dropout, momentum, batch normalization (Ioffe and Szegedy, 2015), or any other added features that help with SOTA (see Figure 3 and Figure 4). However, the architecture of ResNet by default is built with the celebrated batch normalization (Batch-Norm) method as important layers. Batch-Norm accomplishes the auto-tuning property by normalizing the means and variances of mini-batches in a particular way during the forward-propagation, and in return is back-propagated with projection steps. This projection phenomenon is highlighted in weight normalization (Salimans and Kingma, 2016; Wu et al., 2018). Thus, in the ResNet-18 experiment on CIFAR10, we are particularly interested in how Batch-Norm
interacts with the auto-tuning property of AdaGrad-Norm. We disable the learnable scale and shift parameters in the Batch-Norm layers \(^5\) and compare the default setup in ResNet \(\text{(Goyal et al., 2017)}\). The resulted plots are located in Figure 4 (bottom left and bottom right). In the ResNet-50 experiment on ImageNet, we also depart from the standard set-up by disabling the learnable parameters in the Batch-Norm layers and initializing the weights of the last fully connected layer with i.i.d. Gaussian samples with mean zero and variance \(1/1024\), so as to see the full potential of the auto-tuning property in AdaGrad-Norm (see Figure 5).

For all experiments, same initialized vector \(x_0\) is used for the same model so as to eliminate the effect of random initialization in weight vectors. We set \(\eta = 1\) in all AdaGrad implementations, noting that in all these problems we know that \(F^* = 0\) and we measure that \(F(x_0)\) is between 1 and 10. Indeed, we approximate the loss using a sample of 256 images to be \(\frac{1}{256} \sum_{i=1}^{256} f_i(x_0)\): 2.4129 for logistic regression, 2.305 for two-layer fully connected model, 2.301 for convolution neural network, 2.3848 for ResNet-18 with disable learnable parameter in Batch-Norm, 2.3459 for ResNet-18 with default Batch-Norm, and 7.704 for ResNet-50. We vary the initialization \(b_0\) while fixing all other parameters and plot the training accuracy and testing accuracy after different numbers of epochs. We compare AdaGrad-Norm with initial parameter \(b_0\) to (a) SGD-Constant: fixed stepsize \(\frac{1}{b_0}\), (b) SGD-DecaySqrt: decaying stepsize \(\eta_j = \frac{1}{b_0 \sqrt{j}}\) (c) AdaGrad-Coordinate: a vector of per-coefficient step sizes. \(^6\)

**Observations and Discussion** The experiments shown in Figures 3, 4 and 5 clearly verify that the AdaGrad-Norm convergence is extremely robust to the choice of \(b_0\), while the SGD methods and AdaGrad-Coordinate are much more sensitive. In all experiments, the convergence of AdaGrad-Norm degrades even for very small initial values \(b_0\), and shows much stronger robustness than AdaGrad-Coordinate, in particular for ResNet-50 architecture training on ImageNet data (Figure 5). Similar to the Synthetic Data, when \(b_0\) is initialized in the range of well-tuned step sizes, AdaGrad-Norm gives almost the same accuracy as SGD with constant step size; when \(b_0\) is initialized too small, AdaGrad-Norm still converges with good speed (except for CNN in MNIST), while SGDs do not. The divergence of AdaGrad-Norm with small \(b_0\) for CNN in MNIST (Figure 4, top right) can be possibly explained by the unboundedness of gradient norm in the four-layer CNN model. In contrast, the 18-layer or 50-layer ResNet model is very robust to all range of \(b_0\) in experiments (Figure 4, bottom), which is due to Batch-Norm that we further discuss in the next paragraph.

We are interested in the experiments of Batch-Norm by default and Batch-Norm without learnable parameters because we want to understand how AdaGrad-Norm interacts with models that already have the built-in feature of auto-tuning step size such as Batch-Norm. First, comparing the outcomes of Batch-Norm with the default setting (Figure 4, bottom right) and without learnable parameters (Figure 4, bottom left), we see the learnable parameters (scales and shifts) in Batch-Norm can be very helpful in accelerating the training. Surprisingly, the best step size in Batch-Norm with default for SGD-Constant is at \(b_0 = 0.1\) (i.e., \(\eta = 10\)). While the learnable parameters are more beneficial to AdaGrad-Coordinate, AdaGrad-Norm seems to be affected less. Overall, combining the two auto-tuning methods (AdaGrad-Norm and Batch-Norm) works well.

---

\(^5\) Set `nn.BatchNorm2d(planes,affine=False)`

\(^6\) We use `torch.optim.adagrad`
Figure 4: In each plot, the y-axis is the train or test accuracy and the x-axis is $b_0$. Top left 6 plots are for MNIST using the two-layer fully connected network (ReLU activation). Top right 6 plots are for MNIST using convolution neural network (CNN). Bottom left 6 plots are for CIFAR10 using ResNet-18 with disabling learnable parameter in Batch-Norm. Bottom right 6 plots are for CIFAR10 using ResNet-18 with default Batch-Norm. The points in the (top) bottom plot are the average of epoch (1-5) 6-10, epoch (11-15) 41-45 or epoch (26-30) 86-90. The title is the last epoch of the average. Note green, red and black curves overlap when $b_0$ belongs to $[10, \infty)$. Better read on screen.

At last, we add momentum to the stochastic gradient descent methods as empirical evidence to showcase the robustness of adaptive methods with momentum. Since SGD with 0.9 momentum is commonly used, we also set 0.9 momentum for our implementation of AdaGrad-Norm. See Algorithm 3 in the appendix for details. The results (Figure 6) show that AdaGrad-Norm with momentum is highly robust to initialization while SGD
Figure 5: ImageNet trained with model ResNet-50. The y-axis is the average train or test accuracy at epoch 26-30, 46-50, 86-90 w.r.t. $b_0^2$. Note no momentum is used in the training. See Experimental Details. Note green, red and black curves overlap when $b_0$ belongs to $[10, \infty)$.

with momentum is not. SGD with momentum does better than AdaGrad-Norm when the initialization $b_0$ is greater than the Lipschitz smoothness constant. When $b_0$ is smaller than the Lipschitz smoothness constant, AdaGrad-Norm performs as well as SGD with the best stepsize (0.1).

Acknowledgments

Special thanks to Kfir Levy for pointing us to his work, to Francesco Orabona for reading a previous version and pointing out a mistake, and to Krishna Pillutla for discussion on the unit mismatch in AdaGrad. We thank Arthur Szlam and Mark Tygert for constructive suggestions. We also thank Francis Bach, Alexandre Defossez, Ben Recht, Stephen Wright, and Adam Oberman. We appreciate the help with the experiments from Priya Goyal, Soumith Chintala, Sam Gross, Shubho Sengupta, Teng Li, Ailing Zhang, Zeming Lin, and Timothee Lacroix.

Appendix B. Implementing Algorithm 1 in a Neural Network

In this section, we give the details for implementing our algorithm in a neural network. In the standard neural network architecture, the computation of each neuron consists of an elementwise nonlinearity of a linear transform of input features or output of previous layer:

\[
y = \phi(\langle w, x \rangle + b),
\]

(16)

where \( w \) is the \( d \)-dimensional weight vector, \( b \) is a scalar bias term, \( x, y \) are respectively a \( d \)-dimensional vector of input features (or output of previous layer) and the output of current neuron, \( \phi(\cdot) \) denotes an element-wise nonlinearity.

For fully connected layer, the stochastic gradient \( G \) in Algorithm 1 represents the gradient of the current neuron (see the green curve, Figure 7). Thus, when implementing our algorithm in PyTorch, AdaGrad Norm is one learning rate associated to one neuron for fully connected layer, while SGD has one learning rate for all neurons.

For convolution layer, the stochastic gradient \( G \) in Algorithms 1 represents the gradient of each channel in the neuron. For instance, there are 6 learning rates for the first layer in the LeNet architecture (Table 1). Thus, AdaGrad-Norm is one learning rate associated to one channel for convolution layer.

Figure 7: An example of backpropogation of two hidden layers. Green edges represent the stochastic gradient \( G \) in Algorithm 1.
Algorithm 2 Gradient Descent with Line Search Method

8: end function

Algorithm 3 AdaGrad-Norm with momentum in PyTorch
1: Input: Initialize $x_0 \in \mathbb{R}^d$, $b_0 > 0$, $v_0 \leftarrow 0$, $j \leftarrow 0$, $\beta \leftarrow 0.9$, and the total iterations $N$.
2: for $j = 0, 1, \ldots, N$ do
3: \[ \text{Generate } \xi_j \text{ and } G_j = G(x_j, \xi_j) \]
4: \[ v_{j+1} \leftarrow \beta v_j + (1 - \beta) G_j \]
5: \[ x_{j+1} \leftarrow x_j - \frac{v_{j+1}}{b_{j+1}} \text{ with } b_{j+1}^2 \leftarrow b_j^2 + \| G_j \|^2 \]
6: end for
