Abstract

We consider the localization problem of multiple wideband sources in a multi-path environment by coherently taking into account the attenuation characteristics and the time delays in the reception of the signal. Our proposed method leaves the space for unavailability of an accurate signal attenuation model in the environment by considering the model as an unknown function with reasonable prior assumptions about its functional space. Such approach is capable of enhancing the localization performance compared to only utilizing the signal attenuation information or the time delays. In this paper, the localization problem is modeled as a cost function in terms of the source locations, attenuation model parameters and the multi-path parameters. To globally perform the minimization, we propose a hybrid algorithm combining the differential evolution algorithm with the Levenberg-Marquardt algorithm. Besides the proposed combination of optimization schemes, supporting the technical details such as closed forms of cost function sensitivity matrices are provided. Finally, the validity of the proposed method is examined in several localization scenarios, taking into account the noise in the environment, the multi-path phenomenon and considering the sensors not being synchronized.

1 Introduction

A challenging and highly demanding signal processing application is the localization of signal sources using the physical measurements at some sensors in the environment. Source localization has become an important task in various applications such as mobile communications, global positioning system (GPS), radar, sonar, navigation, seismology and geophysics\(^1\)\(^\#\).

During the recent decades various algorithms have been proposed to estimate the location of the signal sources. These methods utilize different signal characteristics at different sensors and generally can be classified in three main categories: using the time difference of arrival (TDOA); analyzing the signal direction of arrival (DOA) at distinct arrays; and using the differences in the signal amplitude or received energy level. For a constant propagation speed, the TDOA among different sensors is proportional to the source-sensor range differences and may be estimated through methods such as cross correlation (CC)\(^3\) or its generalized version (GCC)\(^3\). The source locations can then be estimated using geometric methods such as linear, spherical or hyperbolic intersections\(^3\)\(^\#\). To estimate the DOA, for narrowband signals, high resolution algorithms such as multiple signal classification (MUSIC)\(^1\)\(^\#\) and maximum likelihood (ML)\(^1\)\(^\#\) are proposed.
In [13], the authors propose an approximate maximum likelihood method (AML) for wideband signals using spectral properties of the signal when rather long sample streams are available. In this method, the corresponding cost function can be directly expressed in terms of the source locations or in a far field case may be expressed in terms of the relative time delays followed by a post processing step to find the source locations from the corresponding DOAs. The post processing step may be carried out through geometric methods such as cross bearing or a machine learning approach such as the support vector machine (SVM) method [14]. Using the differences in the signal intensity or energy level for the purpose of localization is a more recent technique [15,16]. Theoretically, this class of localization can be considered for both narrowband and wideband signals by only taking into account the attenuation information and usually neglecting the time delay information. For these methods, a precise attenuation model in the environment is inevitable for an accurate localization. Moreover, from an optimization perspective the resulting cost functions in these kind of approaches usually undergo many local optima and saddle points which require considering specific optimization schemes [17].

In this paper, we tackle the problem of localization of multiple wideband sources by coherently taking into account the TDOA and the amplitude attenuation pattern. Our method generalizes the AML approach to utilize the signal attenuation characteristics. We provide a more robust algorithm in which the targets should simultaneously satisfy the correct time delays among the sensors and provide sensible level of attenuation at each sensor. Unlike the aforementioned energy and intensity based methods which not only ignore the time delay stamps but also require knowing the signal attenuation model, we benefit using the delay information and as a generalization to our recent work in [18], leave the space for not knowing an exact signal attenuation model in the environment by suggesting an appropriate functional space for it. We minimize a cost function which is obtained through maximum likelihood approach from which the locations, attenuation model parameters and the multi-path parameters are obtained. To apply the minimization we propose a hybrid approach combining the differential evolution algorithm [19] with the Levenberg-Marquardt algorithm [20]. This combination provides a minimization scheme which is likely to globally search for the optima and rather quickly converges to the accurate results. Through simulations and Cramér-Rao bound we verify the effectiveness of the novel method introduced in this paper.

This paper is organized as follows. In section 2 we propose a general form for the received signal at every sensor and later provide an adaptive model for the signal attenuation based on Laurent polynomials. In section 3 a maximum likelihood estimation of the source location and attenuation parameters is proposed. We also provide the Cramér-Rao bound for this estimation problem. For the purpose of minimization in section 4 a hybrid approach combining the differential evolution algorithm with the Levenberg-Marquardt is proposed for which the combination algorithm and closed form equations for calculation of the Jacobian are provided. In section 5 we examine the efficiency of proposed method through some examples and finally there are some concluding remarks in section 6.

2 Problem Definition

2.1 Signal Model

Although the general approach proposed in this paper is in theory independent of signal nature and the type of sensors used, in order to make reasonable simulations we consider acoustic source localization. Consider $N$ acoustic sources having unknown locations $r_{S_n}$. Each source is omni-directionally emitting a signal $s_n(t), n = 1, \cdots, N$ at the time frame $t$. We also consider $M$ acoustic microphones that are placed in known positions $r_{M_m}, m = 1, \cdots, M$, in the same environment. For every source in the environment, the function that describes the signal attenuation at a specific point is $\alpha(\rho)$, where $\rho$ is the distance from the point to the source. In general, the signal attenuation function may be a function of various parameters such as signal frequency, medium inhomogeneity, etc. To simplify the problem, in this paper we consider this function to be an identical form for all sources and solely function of the distance to the source. However, unlike some previous energy based localizations (e.g., see [16,17]) in which the attenuation is known to be proportional to $\rho^{-1}$, the actual form of $\alpha(\cdot)$ is considered unknown function here. This type of modeling provides an additional flexibility to the problem for more realistic scenarios where the inverse proportionality of $\alpha(\cdot)$ to $\rho$ is violated due to other parameters, such as signal
bandwidth and medium inhomogeneity. Considering \( s_n(t - 1 \times N_s/v) \) to be the signal measured 1 length unit away from every source with \( N_s \) being the samples per second and \( v \) being the propagation speed, ideally the overall received signal samples from the acoustic sources at every microphone is modeled as

\[
x_m(t) = \sum_{n=1}^{N} \alpha(\rho_{m,n}) s_n(t - \tau_{m,n}),
\]

for
\[
t = 0, 1, \ldots, n_t - 1, \quad m = 1, 2, \ldots, M.
\]

Here \( \rho_{m,n} = \| r_{m} - r_{S_n} \| \) is the distance from \( n \)th source to \( m \)th microphone and \( \tau_{m,n} = \rho_{m,n} N_s/v \) is the corresponding time samples delay in receiving the signal. The received signal in (1) is normalized to each microphone gain level in order to decrease the number of notations. A more realistic model takes into account the noise in the environment and also the signals going through a multi-path channel before arriving at every sensor, hence we rewrite the received signal as

\[
x_m(t) = \sum_{n=1}^{N} \alpha(\rho_{m,n}) s_n(t - \tau_{m,n})
\]

\[
+ \sum_{n=1}^{N} \sum_{p=1}^{P} \gamma_{m,n,p} s_n(t - \hat{\tau}_{m,n,p})
\]

\[
+ w_m(t).
\]

The term \( w_m(t) \) represents the background noise which is considered to be a zero-mean white Gaussian with variance \( \sigma^2 \) for the sake of this paper; i.e., Gaussianity is not a limiting assumption in this paper. Between the \( n \)th source and \( m \)th microphone we consider \( P_{m,n} \) indirect paths each causing \( \gamma_{m,n,p} \) loss in the signal amplitude and \( \hat{\tau}_{m,n,p} \) delay in the signal reception, modeling the multi-path phenomenon. Beside the positions \( r_{S_n} \), which are the main unknowns of the localization problem, the signals \( s_n(t) \), the multi-path parameters \( \gamma_{m,n,p} \) and \( \hat{\tau}_{m,n,p} \), and the propagation loss function \( \alpha(\cdot) \) are also unknown and should be determined based on the received signals at the sensors. The appearance of \( \tau_{m,n} \) (which is related to the unknown quantities \( r_{S_n} \)) and \( \hat{\tau}_{m,n,p} \) as the argument of an unknown signal \( s_n(t) \) causes an extra complexity for any optimization scheme performed to solve the localization problem. However this problem may be remedied by applying the discrete Fourier transform to \( 2 \) to extract the delays and form an equivalent equation in which the unknown parameters are separated in individual terms, i.e.,

\[
X_m(f) = \sum_{n=1}^{N} \alpha(\rho_{m,n}) \exp\left(-\frac{j2\pi}{n_f} f\tau_{m,n}\right) S_n(f)
\]

\[
+ \sum_{n=1}^{N} \sum_{p=1}^{P} \gamma_{m,n,p} \exp\left(-\frac{j2\pi}{n_f} f\hat{\tau}_{m,n,p}\right) S_n(f)
\]

\[
+ \xi_m(f)
\]

for
\[
f = 0, 1, \ldots, n_f - 1, \quad m = 1, 2, \ldots, M.
\]

Here, \( X_m(f) \), \( S_n(f) \) and \( \xi_m(f) \) are the data, signal and noise spectrums respectively. As stated in [13], we emphasize on the fact that for (3) to be a valid equivalent form of (2), we need \( n_t \) to be large enough to avoid edge effects and accordingly \( n_f > n_t \). In general having more samples from the signal better poses the problem.

### 2.2 A Low Order Representation of Signal Attenuation Model

As discussed earlier, our assumption about the attenuation model in the environment in this paper is an identical model for all sources, which is only dependent on the distance of the point to the acoustic source. In an ideal environment, \( \alpha(\cdot) \) can be well modeled as a multiple of \( \rho^{-1} \). Since there are different parameters involved in the attenuation modeling, \( \alpha(\cdot) \) is being considered as an unknown here. However, in order to keep the well-posedness of the problem, we choose it to be an element of a low dimensional function space. For this sake, we consider \( \alpha(\cdot) \) to be a Laurent polynomial of limited order as

\[
\alpha(\rho) = \sum_{\ell=1}^{L} \beta_\ell \rho^{-\ell}, \quad L > 0.
\]

In this model, only negative powers of \( \rho \) are considered, which is due to the fact that for an attenuation model we are physically required to have

\[
\lim_{\rho \to \infty} \alpha(\rho) = 0.
\]

In many applications the low order representation of \( \alpha(\rho) \) in [4] is acceptable enough to model the attenuation and usually considering only few terms in the series (i.e., \( L \) rather small), would suffice for the localization problem.
3 A Maximum Likelihood Estimation of the Unknowns

3.1 Derivation

Based on the general attenuation model proposed, matching the data spectrum with the model can be expressed by using (4) in (3) as

\[ X_n(f) = \sum_{n=1}^{N} \sum_{\ell=1}^{L} \beta_{\ell} p_{m,n} \exp\left(\frac{j2\pi}{n_f \gamma_m n} f_{m,n}\right) S_n(f) \]

\[ + \sum_{n=1}^{P} \sum_{\mu=1}^{L} \gamma_{m,n,\mu} \exp\left(-\frac{j2\pi}{n_f \gamma_m n} f_{m,n}\right) S_n(f) \]

\[ + \xi_n(f). \]

(6)

\[ \text{where} \]

\[ Q = \begin{bmatrix} Q(0) \\ \vdots \\ Q(n_f/2) \end{bmatrix} \]

and \( Q(f) = X(f) - \hat{K}(f) S(f) \) using the notation

\[ \hat{K}(f) = K(f) + H(f). \]

(13)

Similar to the idea in [13], for a real valued signal, we can only consider up to \( n_f/2 \) frequency bins and form \( Q \) with blocks of \( Q(f) \) for \( f = 0, 1, \ldots, n_f/2 \). We would like to highlight the fact that in [13], the zero frequency bin is ignored due to producing a constant term in the likelihood function, however in our approach the matrices \( K(f) \) and \( H(f) \) are still dependent on \( \rho_{m,n} \) and the multi-path parameters \( \gamma_{m,n,\mu} \)

The central limit theorem states that \( \xi_m(f) \), which is a transformed zero mean Gaussian random variable to the frequency domain, should be a complex zero mean Gaussian with variance \( n_1 \sigma^2 \). For every frequency bin \( f \) having \( X(f) = [X_1(f), \ldots, X_M(f)]^T \), \( S(f) = [S_1(f), \ldots, S_N(f)]^T \) and \( \xi(f) = [\xi_1(f), \ldots, \xi_M(f)]^T \), (6) can be written in a matrix form as

\[ X(f) = (K(f) + H(f)) S(f) + \xi(f) \]

(7)

where \( K(f) = R(f) \beta \) with

\[ \beta = [\beta_1, \ldots, \beta_L]^T \otimes I_{N \times N}, \]

(8)

for which \( \otimes \) represents the Kronecker product and \( I_{N \times N} \) the identity matrix of size \( N \times N \), and

\[ R(f) = [R_1(f), \ldots, R_L(f)], \]

(9)

where

\[ R_{\ell}(f) = \begin{bmatrix} \rho_{\ell,1}^e e^{-\frac{j2\pi N \gamma_m n}{n_f} f_{p_{\ell,1}}} & \cdots & \rho_{\ell,1}^r e^{-\frac{j2\pi N \gamma_m n}{n_f} f_{p_{\ell,1}}} \\ \vdots & \ddots & \vdots \\ \rho_{\ell,M}^e e^{-\frac{j2\pi N \gamma_m n}{n_f} f_{p_{\ell,M}}} & \cdots & \rho_{\ell,M}^r e^{-\frac{j2\pi N \gamma_m n}{n_f} f_{p_{\ell,M}}}. \end{bmatrix} \]

(10)

for \( \ell = 1, \ldots, L \). The matrix \( H(f) \) is related to the multi-path parameters and its elements are

\[ \left[ H(f) \right]_{(m,n)} = \sum_{p=1}^{P_{m,n}} \gamma_{m,n,\mu} \exp\left(-\frac{j2\pi}{n_f \gamma_m n} f_{m,n,\mu}\right). \]

Rewriting the negative log-likelihood function to estimate the unknown parameters \( \theta \) including the source positions, source signal spectrums, multi-path parameters and quantities \( \beta_{\ell} \), we have

\[ \theta^* = \arg\min_{\theta} Q^H Q \]

(11)

\[ \text{where} \]

\[ Q = \begin{bmatrix} Q(0) \\ \vdots \\ Q(n_f/2) \end{bmatrix} \]

for \( f = 0, 1, \ldots, n_f/2 \), and therefore the unknowns of the minimization reduce to the source positions, multi-path parameters and the attenuation coefficients.

Considering a 2D localization problem, as the case in the example section, neglecting the multi-path the vector of unknowns would be

\[ \theta = [x_{S_1}, \ldots, x_{S_N}, y_{S_1}, \ldots, y_{S_N}, \beta_1, \ldots, \beta_L]^T. \]

(16)

where \( x_{S_n} \) and \( y_{S_n} \) are the \( x \) and \( y \) components of the position vector \( r_{S_n} \). In case of multi-path, the parameters \( \gamma_{m,n,\mu} \) and \( \tau_{m,n,\mu} \) are also included in \( \theta \). The approach is clearly not only limited to 2D Cartesian systems and 3D Scenarios and other coordinate systems may be considered.
3.2 Cramér-Rao Lower Bounds for the Estimated Parameters

For an unbiased parameter estimation problem, the Cramér-Rao Lower Bound (CLRB) is a theoretical lower bound on the variance of the problem estimates. Based on [7], the total model relating the parameters of interest to the complete data set is

\[ X = G(\theta; S) + \xi. \]  

(17)

Here \( X = [X(0)^T, \ldots, X(n_f/2)^T]^T \) is the full data set, \( S = [S(0)^T, \ldots, S(n_f/2)^T]^T \) contains the signal spectrum of all the sources and \( \xi = [\xi(0)^T, \ldots, \xi(n_f/2)^T]^T \) is the corresponding noise vector. Moreover, \( G(\theta; S) = \tilde{K}S \) for which the matrix \( \tilde{K} \) explicitly dependent on \( \theta \) is

\[ \tilde{K} = \begin{bmatrix} \tilde{K}(0) & 0 & \cdots & 0 \\ 0 & \tilde{K}(1) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \tilde{K}(n_f/2) \end{bmatrix}. \]  

(18)

The CRLB is defined as the diagonal elements of the inverse Fisher matrix \( F \), which for the model in (17) is representable as [21]

\[ F = \left[ \frac{\partial G}{\partial \theta} \right]^H \mathcal{R}_\xi^{-1} \left[ \frac{\partial G}{\partial \theta} \right]. \]  

(19)

Here

\[ \theta = \begin{bmatrix} S \\ \theta \end{bmatrix}, \]  

(20)

and \( \mathcal{R}_\xi \) is the noise covariance matrix which for our problem is simply \( n_s\sigma^2 I \). The matrix \( \left[ \frac{\partial G}{\partial \theta} \right] \) is composed of the sub-blocks \( \left[ \frac{\partial G}{\partial S} \right], \left[ \frac{\partial G}{\partial \tau_{\gamma,m,n,p}} \right], \left[ \frac{\partial G}{\partial \gamma_{\gamma,m,n,p}} \right] \) and \( \left[ \frac{\partial G}{\partial \tau_{\gamma,m,n,p}} \right] \). Clearly

\[ \frac{\partial G}{\partial S} = \tilde{K}. \]  

(21)

For the \( \theta \) parameters, since \( \tilde{K} \) is composed of \( \tilde{K}(f) \), we only discuss the sensitivity of \( \tilde{K}(f) \) to every class of parameters. Based on the fact that \( K(f) = R(f)\beta \) we can write

\[ \frac{\partial \tilde{K}(f)}{\partial \beta_\ell} = \frac{\partial K(f)}{\partial \beta_\ell} = R(f)\frac{\partial \beta_\ell}{\partial \beta_\ell}, \ell = 1, 2, \ldots, L \]  

(22)

where

\[ \frac{\partial \beta_\ell}{\partial \beta_\ell} = [0, \ldots, 0, 1, \ldots, 0]^T \otimes I_{N \times N}. \]  

(23)

To calculate \( \partial \tilde{K}(f)/\partial x_{f,a}, \) we have

\[ \frac{\partial \tilde{K}(f)}{\partial x_{f,a}} = \frac{\partial R(f)}{\partial x_{f,a}} \beta, \quad n = 1, 2, \ldots, N \]  

(24)

where

\[ \frac{\partial R(f)}{\partial x_{f,a}} = \begin{bmatrix} \frac{\partial R_1(f)}{\partial x_{f,a}} & \cdots & \frac{\partial R_L(f)}{\partial x_{f,a}} \end{bmatrix}. \]  

(25)

The matrix \( \partial R(f)/\partial x_{f,a} \) is a matrix the same size as \( R(f) \), with all columns being zero except the \( n \)th column. Simply applying the derivative shows that the \((m, n)\) element of \( \partial R(f)/\partial x_{f,a} \) is related to the \((m, n)\) element of \( R(f) \) through

\[ \left[ \frac{\partial R(f)}{\partial x_{f,a}} \right]_{m,n} = \delta(n, n') \left( \begin{array}{c} x_{m,n} - x_{f,a} \\ \rho_{m,n} \end{array} \right) \]  

(26)

\[ \times \left( \frac{\ell}{\rho_{m,n}} + \frac{2\pi N_f}{n_f v} \right) [R(f)]_{m,n}. \]

where

\[ \delta(n, n') = \begin{cases} 1, & n = n' \\ 0, & n \neq n' \end{cases}. \]

An analogous technique is used to derive \( \partial \tilde{K}(f)/\partial y_{f,a} \).

For the multi-path parameters we have \( \partial \tilde{K}(f)/\partial \gamma_{\gamma,m,n,p} = \partial H(f)/\partial \gamma_{\gamma,m,n,p} \) and also have \( \partial \tilde{K}(f)/\partial \tau_{\gamma,m,n,p} = \partial H(f)/\partial \tau_{\gamma,m,n,p} \). Accordingly the elements of each matrix are obtained through

\[ \left[ \frac{\partial H(f)}{\partial \gamma_{\gamma,m,n,p}} \right]_{(m,n)} = \delta(m, m')\delta(n, n') \exp(-\frac{j2\pi}{n_f} f_{\gamma,m,n,p}) \]  

(27)

and

\[ \left[ \frac{\partial H(f)}{\partial \tau_{\gamma,m,n,p}} \right]_{(m,n)} = -\delta(m, m')\delta(n, n') \frac{j2\pi}{n_f} f_{\gamma,m,n,p} \]  

\[ \times \exp(-\frac{j2\pi}{n_f} f_{\gamma,m,n,p}). \]  

(28)

Specifying the elements of the Fisher matrix \( F \) yields the CRLB values for all the estimations.

4 Minimization Strategy

The minimization in [11] may be performed through various optimization schemes, most generally categorized as global and local optimizations. For a global optimization different approaches such as deterministic, stochastic or evolutionary and metaheuristic methods may be considered [22-24]. Clearly for an accurate localization, global minimizers of [11] are required. However in general, using global methods to optimize an arbitrary function
In this phase a mutant vector $\mu_{i,G}$ is generated as
\[ \mu_{i,G} = \theta_{r_1,G} + F \left( \theta_{r_2,G} - \theta_{r_3,G} \right), \quad (29) \]
where $r_1, r_2$ and $r_3$ are randomly selected indices among $1, 2, \cdots, N_P$ and $F \in [0, 2]$ is a constant real scalar controlling the difference vector amplification.

### 4.1.2 Crossover
A mixing with the mutant vector to increase the diversity of the population is performed by generating new trial vectors $\upsilon_{i,G}$ of length $D$, defined as
\[ \upsilon_{d,i,G} = \begin{cases} \mu_{d,i,G}, & r(d)_{[0,1]} \leq C_R \text{ or } d = k(i) \\ \theta_{d,i,G}, & \text{otherwise,} \end{cases} \quad (30) \]
with $d = 1, 2, \cdots, D$. Here $C_R \in [0, 1]$ is the crossover constant, $r(d)_{[0,1]}$ is the $d^{th}$ evaluation of a uniform random number generator in $[0, 1]$ and $k(i) \in \{1, 2, \cdots, D\}$ is a randomly chosen index ensuring $\upsilon_{i,G}$ takes at least one of the elements of $\mu_{i,G}$.

### 4.1.3 Selection
At this step a next generation population member $\theta_{i,G+1}$ is produced by a selection among $\theta_{i,G}$ and $\upsilon_{i,G}$. This selection is based on the fitness, and basically, the vector with the lower cost proceeds to the next generation.

### 4.2 A Levenberg-Marquardt Algorithm for the local Minimization
As the local minimization scheme, we suggest using the LMA. Our attention towards this algorithm is based on several advantages. LMA is basically considered as a Newton type method and provides a rather quadratic convergence. Meanwhile this algorithm benefits from stability and uses a trust region approach [30]. The other feature of this method, considered as an advantage over other methods such as the gradient descent, is its suitability for cases where there are different variables of different types as the cost function arguments. In fact LMA is almost independent of variable scaling, while for methods such as the gradient descent, minimizing a cost function dependent on a set of variables with different natures and scales requires appropriate parameter scaling to guarantee a proper convergence [30]. This is a demanding feature for our problem where the $\theta$ vector in general consists of the source locations, attenuations coefficients and the multi-path parameters.

In the LMA which is an iterative algorithm, we start with a $\theta^{(0)}$ as the starting point. At every iteration, having $\theta^{(i)}$ already in hand, $\theta^{(i+1)}$ can be
obtained by solving

\[ (J_\theta^T J_\theta + \lambda^{(i)} I)(\theta^{(i+1)} - \theta^{(i)}) = -J_\theta^T Q. \]

where \( Q \) is the vertical vector of length \( M n f / 2 \) shown in (12) and obtained for values \( \theta^{(i)} \) at that iteration. The parameter \( \lambda^{(i)} \) is the damping factor, obtained at every iteration based on the trust region approach [20,30]. The Jacobian matrix \( J_\theta \) contains the sensitivities of \( Q \) to every element of \( \theta \). In order to run the algorithm we need to know the Jacobian matrix at every iteration, obtaining which is discussed in the Appendix.

4.3 The Hybrid Combination Scheme
For the purpose of combining the DE with the LMA, we propose using a sequential hybridization approach [26]. In this approach, the DE initially starts the minimization by generating consecutively more fitting generations. After a certain number of generations or after getting relatively slow in decreasing the fitness, the best \( \theta \) in the last generation is passed to the LMA algorithm as an initialization. The minimization continues until convergence. An illustration of this algorithm is provided in Fig. 1.

5 Simulation Results
To examine the method developed in the previous section, we consider some localization examples in this section. In the first example we consider a reverberation-free environment to show the efficiency of the method for such cases and provide a comparative study for this scenario. The second example brings more realistic issues such as the multi-path, and sensor synchronization error into the problem and examines the performance of the proposed method for such cases.

Before proceeding with the examples we would like to highlight a fact regarding the relationship between the cost function and the matrix \( \mathbf{K} \). Referring to (15), it can be easily verified that scaling \( \mathbf{K}(f) \) by a scalar does not change the cost function. In other words if the \( \beta_i \) and \( \gamma_{m,n,p} \) values are simultaneously scaled by a scalar value, the cost function remains the same. Therefore, we rewrite the attenuation model in (4) as

\[ \alpha(\rho) = \rho^{-1} + \sum_{\ell=1}^{L} \beta_\ell \rho^{-\ell-1}, \]

which somehow normalizes \( \alpha(\cdot) \) and unifies the representation. Clearly, since the desired unknowns of the problem are the acoustic source coordinates, obtaining a multiple of the attenuation and multi-path coefficients is non-problematic. The true attenuation model to be used in this paper is \( \alpha(\rho) = \rho^{-1.25} \) (see [15]).

5.1 Example 1
For the purpose of this example, we consider the sensors to be placed in the first quarter of the x-y plane as a spiral array of \( M = 40 \) microphones. The spiral is represented in a parametric form as

\[ \begin{bmatrix} x_{M_m} \\ y_{M_m} \end{bmatrix} = \begin{bmatrix} 4 + \frac{s}{\pi} \cos s \\ 4 + \frac{s}{\pi} \sin s \end{bmatrix}, \]

where the angles \( s \) are equally spaced in [2\pi, 4\pi]. Our purpose of choosing such sensor arrangement was to provide a non-symmetric and still reproducible arrangement. The sensor locations are shown in Fig. 2. The sources used in this example are wideband sources with center frequency 500 Hz and 200 Hz bandwidth. The sampling frequency is 4 KHz. The number of samples available from the sources at every sensor is \( n_s = 4000 \) (i.e., the signal duration is 1 second) and the number of frequency bins is taken to be \( n_f = 4100 \). The signal to noise ratio (SNR) at every sensor is 20 dB and the speed of propagation is considered to be the speed of sound as \( v = 345 \text{ m/s} \). In the proposed minimization scheme and more specifically the DE part, we take \( G_{max} = 5 \). Moreover, we set \( F = 0.8, C_R = 1 \) and \( N_P = 40 \). This parameter setting was selected as a general DE setting, however more discussions on determining the DE parameters are available in [19].

The general attenuation model is considered to be \( \alpha(\rho) = \rho^{-1} + \beta_1 \rho^{-2} + \beta_2 \rho^{-3} \), for which the values \( \beta_1 \) and \( \beta_2 \) are in charge of tuning the unknown model. There is no reverberation in the environment (i.e., \( \mathbf{K} = \mathbf{K} \)) and all sensors are synchronized in receiving the signal.

To provide a better understanding of the problem, in Fig. 2 the cost function behavior for a known attenuation model is shown. In Fig. 2a the cost is shown when the source is located at point (4,3) within the sensors convex hull. All positions are in meters. Fig. 2b shows the cost when the source is located at (12,10) outside the sensors region. In both cases the cost functions are rather well behaved functions away from the sensors. Intuitively, for two
Figure 1: A sequential hybridization combing the DE with the LMA

Figure 2: (a) The cost function corresponding to a source located at (4,3) assuming a known attenuation model. (b) The cost function corresponding to a source located at (12,10).
neighboring points in the domain, sudden variation of the cost function with respect to both time delay criteria and attenuation model constraints is unlikely and hence the resulting cost functions are usually expected to be rather slow varying and well behaved away from the sensors.

In Fig. 3 we have shown the iterative procedure of finding a single source, once located at (4, 3) and once at (12, 10). For the first case the source location is estimated to be at (4.002, 3.008) and the attenuation coefficients are estimated to be $\beta_1 = -23.85$ and $\beta_2 = 27.93$. In the second case the source estimation is (11.999, 10.002) and the attenuation coefficients are found to be $\beta_1 = 4.19$ and $\beta_2 = 1.79$. We observe that both localization results accurately match the exact source positions. The attenuation coefficients obtained in both cases are only in charge of fitting the low order model to the true model for the source-sensor ranges in each problem and due to different problems they do not necessarily need to be in the same ranges. By providing this low order attenuation model we provide the flexibility to the problem for accurately estimating the sources.

As a more challenging problem, we consider concurrent localization of the two sources located at (4, 3) and (12, 10). Fig. 4 shows the iterative procedure of finding the sources. The estimated source locations are (4.000, 3.001) and (11.989, 9.993) and the attenuation parameters are estimated to be $\beta_1 = 4.77$ and $\beta_2 = -3.94$. Again an accurate match between the exact source locations and the estimated ones is observable.

We further examine our proposed method through a comparison with the AML method developed in [13]. For this purpose we start reducing the signal samples by reducing the signal duration from 1 to 0.1 seconds and observing the error caused in the source estimation. Here we consider the single source localization for the source being located at (12, 10). Fig. 5 shows the resulting error as the signal duration decreases in both methods. As it is clearly observed, using both time delay and attenuation information helps our method provide better estimates of the source locations even with less available data compared to the AML method which only uses the time delay information. We further examine the performance of both methods for various SNR values. In Fig. 6 the CRLB is calculated for the same single source scenario with the source located at (12, 10). The RMS errors in estimating the $x$ and $y$ components of the source are obtained through 50 independent noise realizations for every SNR value shown in the figure. Again the proposed method shows an acceptable performance regarding the closeness to the CRLB and the superior performance compared to the AML method.

5.2 Example 2

In a more realistic scenario, we examine the performance of the proposed method in a noisy environment where sensor synchronization error and reverberation are likely to happen. The sensor network configuration is shown in Figure 7 where three circular arrays each composed of 25 sensors centered at points (15,5), (215) and (5,28) are considered. The acoustic source is located at (35,25) and the signal specifications are the same as the previous example. For this example $G_{\text{max}}$ is taken to be 20 to benefit more from a global search of a cost function which may not be as well-behaved as the previous example due to bringing more unknown parameters into the problem. The low order attenuation model considered in this example is $\alpha(\rho) = \rho^{-1} + \beta \rho^{-2}$ with $\beta$ as the tuning parameter. Again an SNR of 20 dB is considered at all sensors for all the experiments.

We first examine the case that the sensors are not exactly synchronized to receive the data. For this purpose we rewrite the main component of the signal in (1) as

$$\sum_{n=1}^{N} \alpha(\rho_{m,n}) s_n(t - \tau_{m,n} + \zeta),$$

(34)

where $\zeta$ is a random variable uniformly distributed around zero. Equation (34) basically models the asynchronous measurements of the sensor data. In Table 1 we have provided the localization results for three different synchronization error variances 0.5, 1 and 2 milliseconds. Clearly the phase error is a destructive phenomenon in TDOA localization algorithms, however, considering the localization errors in Table 1, one would observe that exploiting the attenuation information beside the phase information enables our algorithm to perform a rather accurate localization task in case of sensors being out of synchronism.

Furthermore, a more challenging problem is when the reverberation is also taken into account. In theory, for the emitted signal to arrive at every measuring sensor, an individual multi-path filter should be considered. Although the formulation in this paper is general, for the purpose of this example we
Figure 3: (a) The progressive estimates of a single source located at (4, 3). The first jumps and good initials correspond to applying the DE (b) The progressive estimates of a single source located at (12, 10). (c) The evolution of the attenuation model parameters for the single source located at (12, 10)

Figure 4: (a) Concurrent estimates of two sources located at (4, 3) and (12, 10) (b) The corresponding evolution of the attenuation model parameters
Figure 5: The localization error verses the signal duration for our proposed method and the AML method.

have made a reasonable and practical assumption that for all the sensors within each array, the filter representing the multi-path is identical. In general the sensor network may be represented as a collection several clusters each composed of sensors closely placed and each cluster treated as a single receiving node. This assumption prevents dealing with a large collection of unknowns ($\gamma_{m,n,p}$ and $\hat{\tau}_{m,n,p}$) for every source-sensor pair and aggregates them into fewer parameters each assigned to the clusters.

To generate a reverberated signal we use the multi-path FIR filters shown in Figure 8 where three or four shifted scales of the signal are added to it. For the localization purpose, however, we only consider finding the main indirect path. In other words, for every array shown in Figure 7 only one multi-path coefficient $\gamma$ and one multi-path delay $\hat{\tau}$ is to be estimated which totally brings 6 unknowns associated with the multi-path phenomenon into the minimization problem. The remaining minimization unknowns are the source coordinates and the attenuation coefficients as before. The fourth row of Table 1 shows the localization result for this problem. Although the number of unknowns were relatively higher than the previous examples and the cost function is clearly not as well-behaved as before, using DE as the initial minimization scheme provides a suitable starting state for the LMA and this sequential technique helps the algorithm make a rather accurate localization in a noisy and reverberated environment. The fifth row of Table 1 corresponds to the case of having both the multi-path and the synchronization issues, for which the results are still promising. The progressive estimates of the target throughout the minimization are shown in Figure 9.

6 Conclusion
In this paper, we proposed an efficient method for localization of multiple wideband sources based on both signal attenuation and time delay information. The method developed in this paper models the localization problem as a minimization problem and provides an additional flexibility of not being exactly aware of the signal attenuation model. We propose a certain function space for the unknown model, and tune it iteratively along to estimate the signal source locations. The minimization scheme used here is a hybrid algorithm, combining the differential evolution with the Levenberg-Marquardt algorithm. This combination increases the chances of finding a global minima while benefits from the speed and computational advantages of Newton methods. The accuracy and performance of the method is examined through several simulations depicting a noisy environment, a multi-path environment and lack of synchronization among sensors. In the simulations, we compared our approach with the approximate maximum likelihood
Figure 8: The multi-path impulse response associated with each array. Every multi-path model is assumed to hold for all sensors within the corresponding array. The amplitudes are normalized to the amplitude of the main signal component.

Figure 9: The progressive estimates of a single source located at (35, 25). The first jumps and good initials correspond to applying the DE (a) Considering only the multi-path phenomenon in the environment (b) Considering both, the multi-path and sensor synchronization error.
method which show the superiority of the proposed method.

7 Appendix

As mentioned earlier, in order to find columns of the Jacobian, we are required to find \( \partial Q/\partial \theta \), where \( \theta \) is one of the unknown parameters \( x_{S_n}, y_{S_n}, \beta_t, \gamma_{m,n,p} \) or \( r_{m,n,p} \). Since \( Q \) is a vector containing sub-vectors \( Q(f) \) for \( f = 0, 1, \ldots, n_f/2 \), we will only find \( \partial Q(f)/\partial \theta \) and clearly forming \( \partial Q/\partial \theta \) would be aligning the corresponding sub-vectors. We therefore preliminarily derive some related equations. Consider a matrix \( M \), not in general rectangular, elements of which are dependent on a real variable \( \theta \). We assume \( (M^HM)^{-1} \) exists or in other words \( M^I = (M^HM)^{-1}M^H \). Using product rule we have

\[
\frac{\partial MM^I}{\partial \theta} = \frac{\partial}{\partial \theta} M(M^HM)^{-1}M^H = \frac{\partial M}{\partial \theta} (M^HM)^{-1}M^H + M\left(\frac{\partial (M^HM)}{\partial \theta}\right)^{-1}M^H + M^I \frac{\partial M}{\partial \theta} \left(\frac{\partial (M^HM)}{\partial \theta}\right)^{-1}M^H + M^I \frac{\partial M^H}{\partial \theta} \right) \tag{36}
\]

we have

\[
\frac{\partial \tilde{M}}{\partial \theta} = -\tilde{M}^{-1} \frac{\partial \tilde{M}}{\partial \theta} \tilde{M}^{-1}. \tag{37}
\]

Using (37) in (36) regarding the term \( \partial (M^HM)^{\dagger}/\partial \theta \), would result in

\[
\frac{\partial MM^\dagger}{\partial \theta} = (I - M^HM^H) \frac{\partial M}{\partial \theta} M^\dagger + M^HM^H \frac{\partial M^H}{\partial \theta} (I - M^HM^\dagger). \tag{38}
\]

Based on (35), and knowing (38), we now have

\[
\frac{\partial Q(f)}{\partial \theta} = (P(f) + P^H(f))X(f), \tag{39}
\]

where

\[
P(f) = \left(\tilde{K}^{-1}(f)\tilde{K}^H(f) - I\right) \frac{\partial \tilde{K}(f)}{\partial \theta} \tilde{K}^\dagger(f). \tag{40}
\]

To complete the derivation we only need to have \( \frac{\partial \tilde{K}(f)}{\partial \theta} \), which is already discussed in Section 5.2.
