Abstract. The evolution of galaxies in groups may have important implications for the global evolution of star formation rate in the Universe, since many processes which operate in groups may suppress star formation, and the fraction of galaxies bound in groups at the present day is as high as \( \sim 60\% \). We present an analysis of our sample of \( 0.3 \leq z \leq 0.55 \) groups, selected from the CNOC2 redshift survey and supplemented with deep spectroscopy and HST ACS imaging. We find that these groups contain significantly more passive galaxies than the field, with excesses of S0, elliptical and passive spiral galaxy types. The morphological composition is closely matched to that of more massive irregular clusters at a similar epoch. Contrasting with galaxy samples in a variety of environments and epochs, we find that the fraction of passive galaxies (\( EW[OII] \leq 5\AA \)), is strongly evolving in the group environment, with parallel evolution in the (global) field population, whilst little evolution is observed in cluster cores since \( z \sim 1 \).

1 Introduction

Groups of galaxies represent the most common galaxy environment at \( z \sim 0 \), containing as much as \( 60\% \) of the galaxy population at the present day [7]. Due to their relatively low velocity dispersions, groups of galaxies are ideal sites for galaxy-galaxy interactions which are likely to give rise to significant changes in the SFRs, total stellar masses, and morphological appearance of galaxies. Recent studies in the local Universe show that galaxy properties are indeed influenced by the group environment (e.g. [2]). Therefore, understanding the evolutionary processes in groups will probe not only the dependence of galaxy properties on environment, but also trace the importance of this common environment in driving global trends such as the strong decline in volume–averaged star formation since \( z \sim 1 \) (e.g. [4]).

Tracing galaxy evolution in groups requires the existence of higher redshift group catalogues. Distant groups have always been difficult to recognize because of their sparse galaxy populations. The presence of high redshift groups has typically been inferred indirectly via the presence of a radio galaxy or X-ray emitting intragroup medium [11]. However, these selection criteria detect only the richest, elliptical dominated groups. To reconcile this selection bias, large spectroscopic field surveys can be used to study galaxy groups selected purely on the basis of their three dimensional galaxy density. Such catalogues of groups now exist.

2 The CNOC2 group sample at \( 0.3 \leq z \leq 0.55 \)

The second Canadian Network for Observational Cosmology Redshift Survey (CNOC2) consists of \( UBVRCI_C \) photometry and spectroscopy, measuring \( \sim 10^4 \) galaxy redshifts up to \( z \sim 0.6 \) [21]. This provided an powerful opportunity to generate a kinematically selected sample of intermediate redshift galaxy groups. A friends-of-friends percolation algorithm was used to detect groups of galaxies in redshift space [4].

This sample can be used to study the influence of the typical group environment on galaxy properties at intermediate redshift. To this end, we have recently obtained deep Hubble Space Telescope ACS imaging of a sub-sample of 26\textsuperscript{1} CNOC2 groups with redshifts \( 0.3 < z < 0.55 \), when the Universe was \( \sim \frac{2}{3} \) its present age. The original spectroscopy has been supplemented with deeper spectroscopy using the LDSS-2 spectograph on the Magellan 6.5-m telescope [22] and will be further supplemented by deep VLT FORS2 spectroscopy (almost complete at the time of writing), reaching \( R_C \sim 23.2 \) (\( M_\star + 3 \) at \( z = 0.4 \)). Combined with forthcoming/ongoing observations at UV (GALEX), Near Infra-red (SOFI on the ESO NTT) and X-ray (Chandra) wavelengths, we are building a unique catalogue of galaxy groups, combining significant look–back time with the depth required to probe the faint-end of the galaxy luminosity function, and coverage across the electromagnetic spectrum.

Magellan observations have extended the depth of our spectroscopic sample to \( R_C = 22.0 \), down to which we have well-understood selection, and no bias towards emission-line galaxies [22]. Our combined group galaxy sample numbers 282 galaxies in 26 separate groups at \( 0.3 < z < 0.55 \).\textsuperscript{2} Within the area of (deeper) Magellan coverage, our spectroscopic sample also contains 334 serendipitous field galaxies within this redshift range.

\textsuperscript{1}The 26 groups include 20 targeted groups and 6 serendipitous groups.
\textsuperscript{2}For further details of the Magellan spectroscopy and group membership allocation, see Wilman et al. (2005a) [22].
Throughout this paper we assume a $\Lambda$CDM cosmology of $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$ and $H_0 = 75\text{km s}^{-1}\text{Mpc}^{-1}$.

3 Results and Analysis

The observed magnitudes of all galaxies in our sample are extinction corrected based upon the models of Schlegel et al. (1998) [19]. A best-fit SED is computed using observed local SEDs [13] as templates, and the observed $R$-magnitude, $(B-I_c)$ colour and spectroscopic redshift of each galaxy. The rest-frame $b_J$ luminosity ($M_{b_J}$) is computed from the best-fit SED. This band is chosen because it closely matches the CNOC2 spectroscopic selection band ($R_c$) in the observed–frame, and it facilitates comparisons with the 2PIGG local group catalogue.

3.1 Star Formation and Evolution in CNOC2 Groups

To study the relative levels of star formation in statistical galaxy samples, we use the $\text{[OII]}\lambda3727$ emission line which lies centrally in the visible window at $0.3 \leq z \leq 0.55$ and at wavelengths of low sky emission. We note that due to uncertainties in the calibration of star formation rates, we deliberately limit our study to direct comparisons between measurements of the Equivalent Width (EW) of $\text{[OII]}$. Normalisation by the continuum also reduces uncertainties related to absorption by dust and aperture bias.

We are motivated by the clear bimodal distribution in colour and EW[Hα] [2, 3] which show that the fraction of red, passive galaxies is strongly dependent upon local galaxy density. To examine how the fraction of passive galaxies depends upon environment in our sample, we impose an arbitrary division at $\text{EW}[\text{OII}]=5\AA$. We expect the population with $\text{EW}[\text{OII}]<5\AA$ to be dominated by passive galaxies and the population with $\text{EW}[\text{OII}]>5\AA$ to be dominated by star-forming galaxies. This division is sufficient to reveal trends in statistical samples [e.g. 22]. To assess the relative size of each population, we define $f_p$ to equal the weighted$^3$ fraction of galaxies with $\text{EW}[\text{OII}]<5\AA$ (i.e. an estimator of the fraction of passive galaxies).

Figure 1(a) shows how $f_p$, depends upon galaxy $b_J$-band luminosity in the group and field samples. The group galaxy sample is limited to those within $1h_{75}^{-1}\text{Mpc}$ of the luminosity-weighted group centroid. There is a clear enhancement of $f_p$ in the group galaxies with respect to the field, especially in the luminosity range $-22.0 \leq M_{b_J} \leq -19.0$. Combining all galaxies within the luminosity range $-22.5 \leq M_{b_J} \leq -18.5$, the enhancement in groups of $f_p$ is better than $3\sigma$ significance, and this trend is still evident if the most massive two groups (velocity dispersion $\sigma(v)>600\text{ km s}^{-1}$) are excluded from the sample.

We interpret the enhancement of $f_p$ in groups as direct evidence that galaxies in intermediate redshift groups are significantly less likely to have ongoing star formation than field galaxies. This could be a related to either a different formation history in the group environment, intragroup environmental processes accelerating galaxy evolution to the passive state, or a combination of these two effects. We also note that their is a strong luminosity dependence on $f_p$ in both group and field samples, such that a higher fraction of brighter galaxies are passive by $z\sim0.4$. This is consistent with the overall picture that more massive galaxies have formed all their stars at earlier epochs.

In Figure 1(b) we examine evolution in the cluster, group and field environments. For our low redshift sample, we choose the 2dFGRS field survey and the 2PIGG group catalogue [7]. A detailed description of sample selection, and the comparison between CNOC2 and 2dFGRS data can be found in Wilman et al. (2005b) [23]. The cluster core data are taken from Nakata et al. (2005) [15], originating in the 2dFGRS, CNOC1 and high redshift cluster samples of Van Dokkum et al. (2000) [21] and Postman et al. (2001) [18]. These data are limited to within $0.75h_{75}^{-1}\text{Mpc}$ of the cluster centres. To match the Nakata et al. (2005) [15] sample we apply a luminosity limit of $M_{b_J}=-19.65$ to all data. This figure neatly illustrates the strength of evolution observed for $f_p$ in groups and the field whilst galaxies in dense cluster cores were already largely passive by $z \sim 1$.

3.2 Morphological Composition of CNOC2 Groups

With deep HST ACS (Hubble Space Telescope - Advanced Camera for Surveys) F775W filter observations of our CNOC2 groups we have the resolving power to classify galaxy morphologies to well below the magnitude limit of our spectroscopy. In this way we can isolate the morphological transformations which may be driving galaxy evolution in groups at intermediate redshift.

To date, a sub-sample of galaxies from the first 16 ACS fields have been morphologically classified visually by Augustus Oemler Jnr. (AO). $^5$ Galaxies with spectroscopic redshifts in the $0.3 < z < 0.55$ redshift range were

---

$^3$Galaxy weights are computed to account for incompleteness in the sample. See Wilman et al. (2005a) [22] for a derivation of selection functions and weights in this sample.

$^4$Note that whilst in that paper a 10Å division in EW[OII] is used, we maintain consistent use of a 5Å limit.

$^5$We acknowledge that the analysis presented here is merely preliminary, as the classifications will be extended to the full sample, and classifications by more than one author will be used to assess the robustness of the classification process.
Figure 1: (a) The fraction of passive galaxies, $f_p$, in the stacked group within $1h^{-1}\text{Mpc}$ of the group centre (solid line) and the field (dashed line) as a function of galaxy luminosity, $M_{b_1}$. The field symbols are offset slightly in luminosity for clarity. Statistical errors on $f_p$ are computed using a Jackknife method. (b) The fraction of passive galaxies, $f_p$, plotted as a function of redshift in different environments. The group and field data are selected from our 2dF and CNOC2 samples. We overplot the equivalent fractions in cluster cores, selected from the samples of [10]. These data originate in the 2dFGRS, CNOC1 and high redshift cluster samples of [21] and [15]. Cluster data are selected only within the inner $0.75h^{-1}\text{Mpc}$ of the cluster centre and we match the luminosity limit of [10] ($M_{b_1} = -19.65$). This figure shows the strong decline of $f_p$ in the Universe since $z \sim 0.4$ in groups and the field whilst the passive population in the dense core regions of clusters is consistent with having been mostly in place since $z \sim 1$.

To assess the statistical significance of differences between the morphological composition of group and field samples, we bin the galaxies into four broad morphological classes. These are Elliptical, S0, Spiral and Other (mostly Irregular and merger types). In Figure 2 we show the fraction of galaxies of each morphological type, $f_{\text{type}}$ in 3 bins of luminosity ($M_{b_1} < -21.0$, $-21.0 \leq M_{b_1} < -20.0$, $-20.0 \leq M_{b_1} \leq -18.5$). The solid line with the filled circles represents the group galaxy population and the dashed line with the open circles represents the field population. It shows that while spiral galaxies dominate the field galaxy population, there is a significant deficit of spirals in galaxy groups (3σ computed for all galaxies $M_{b_1} \leq -18.5$). In the place of these spirals, there is an excess of early-type galaxies in groups. There is a $2.7\sigma$ excess of ellipticals and a $1.3\sigma$ excess of S0 type galaxies in total. Figure 2 indicates that the elliptical excess is most significant at faint luminosities, where the field elliptical population is less important. However at brighter luminosities, the S0 population seems to become very important in groups. In fact, brighter than $M_{b_1} \leq -20.5$ there are 16 group and no field S0 type galaxies.

A bootstrap-resampling technique is then used to estimate the significance of this excess with respect to $f_{\text{S0}} = 0$ in the field. We find that there is a $\sim 3.5\sigma$ excess of bright S0s in groups. Finally, we also note that bright S0s appear to be particularly predominant in groups with velocity dispersions of $\sim 400 \text{ km s}^{-1}$. Indeed, six of these galaxies are located in just two groups (3 in group 37, $\sigma(v) = 419 \pm 97 \text{ km s}^{-1}$ and 3 in group 39, $\sigma(v) = 454 \pm 88 \text{ km s}^{-1}$), suggesting that the formation of bright S0 galaxies appears to be biased towards a certain type of group environment, as represented by these groups.

A comparison with the $z \sim 0.5$ MORPHS cluster sample of Dressler et. al. (1997) [10] indicates that our groups match the morphological composition of the irregular MORPHS clusters ($\sim 40\%$ spirals, $\sim 40\%$ ellipticals and $\sim 20\%$ S0s). This suggests that the morphological mix of unvirialised clusters is likely to be already in place during the infalling group stage.

Another interesting class of galaxy is the Passive Spiral. These galaxies are still morphologically spiral-type, but with no sign of ongoing star formation (in our case, EW[OII] < 5Å). Passive spirals have typically aroused interest in cluster studies, where they have often been interpreted to be infalling spiral galaxies in which star formation has been somehow truncated without any morphological transformation, up to the point of observation (e.g. [3] [17]). Figure 3(a) shows $f_p$ as a function of luminosity, only for galaxies which are morphologically classified spirals (67 in groups, 68 in the field). At brighter luminosities ($M_{b_1} \leq -20.0$), the population of spiral galaxies is clearly more passive in groups (solid line, filled circles) than the field (dashed line, open circles). This excess is assessed at $3.2\sigma$ significance using a resampling method. Interestingly, the lack of any passive spiral excess in fainter galaxies suggests that interactions with the IGM are unlikely to be

---

For reference, in the local 2dFGRS survey, $M_* = -20.28$ in our cosmology.
Figure 2: The fraction of each morphological type of galaxy, $f_{\text{type}}$, in 3 bins of luminosity: Bright ($M_J < -21.0$), Control ($-21.0 \leq M_J < -20.0$) and Faint ($-20.0 \leq M_J \leq -18.5$). The solid line with the filled circles represents the group galaxy population and the dashed line with the open circles represents the field population. Errors are estimated using the Jackknife technique and field points are offset slightly in $M_J$ for clarity. This figure clearly shows that the CNOC2 groups possess a larger fraction of early galaxy types (elliptical and S0) than the field, in place of spiral galaxies, more common in the field.

Figure 3: The fraction of each morphological type of galaxy, $f_{\text{type}}$, in 3 bins of luminosity: Bright ($M_J \leq -20.0$) spiral galaxies has any dependence upon its group-centric radius, $d_r(b)$ and group-centric radius, normalised by the rms($d_r$) for the parent group (c). It is clear that a larger fraction of spiral galaxies are passive towards the group centre, and that this relation holds when the radial distance is normalised by the typical group-centric radius of each group. This indicates that processes leading to the cessation of star formation in bright spiral galaxies are tightly related to the group environment. However, we note that we find no passive spiral in the two most massive groups ($\sigma(v) > 600$ km s$^{-1}$). Since passive galaxies in local clusters seem to be found predominantly in the cluster outskirts [8], we believe passive spirals are therefore most likely to be found in environments typical of smaller groups and the outskirts of clusters.

### 4 Conclusions

We have presented an analysis of galaxy properties in the group and field environments at intermediate redshift ($0.3 \leq z \leq 0.55$). This is part of an ongoing study of how the group environment influences galaxy evolution. Our main conclusions to date can be summarized as follows:

- Whist (massive) galaxies were largely passive in cluster cores by $z \sim 1$, there has been strong evolution in the fraction of passive galaxies ($f_p$) in groups and the field since $z \sim 0.4$. This must be important when considering the global budget of star formation.
- Galaxies in CNOC2 groups are more likely to be passive or bulge-dominated than in the CNOC2 field.
- However, the morphological composition of the $z \sim 0.4$ group population matches that of the irregular MORPHS clusters at similar redshift.
- Excesses of bright S0s and passive spirals in CNOC2 groups relates the 2 galaxy types and suggests that the S0 formation process may favour groups. These excesses are not found fainter than $\sim M_*$ and so interactions with the IGM are unlikely to be responsible.

**Acknowledgements.**

We acknowledge the CNOC2 survey team for providing an excellent dataset without which this study would not be possible. We are also grateful to those involved in the other studies from which we have compiled Figure 1(b).
Figure 3: (a) The fraction of spiral galaxies which are passive, $f_p$, in groups (solid line, filled circles) and in the field (dashed line, open circles) in 3 bins of luminosity: Bright ($M_{B_J} < -21.0$), Control ($-21.0 \leq M_{B_J} < -20.0$) and Faint ($-20.0 \leq M_{B_J} \leq -18.5$). Errors are estimated using the Jackknife technique. The passive fraction in group spirals is only significantly greater than in the field brighter than $M_{B_J} = -20.0$. (b) The fraction of spiral galaxies brighter than $M_{B_J} = -20.0$ which are passive, $f_p$, in the field (solid horizontal line) and in groups as a function of group-centric radius, $d$, and (c) group-centric radius, normalised by the rms value of the parent group. The likelihood that a spiral galaxy is no longer forming significant numbers of stars is a clear function of its position in the group.
