Abstract

Objective To determine the causative agents of infections and their antimicrobial susceptibility at a tertiary care hospital in Moshi, Tanzania, to guide optimal treatment.

Methods A total of 590 specimens (stool (56), sputum (122), blood (126) and wound swabs (286)) were collected from 575 patients admitted in the medical and surgical departments. The bacterial species were determined by conventional methods, and disc diffusion was used to determine the antimicrobial susceptibility pattern of the bacterial isolates.

Results A total of 249 (42.2%) specimens were culture-positive yielding a total of 377 isolates. A wide range of bacteria was isolated, the most predominant being Gram-negative bacteria: Proteus spp. (n = 48, 12.7%), Escherichia coli (n = 44, 11.7%), Pseudomonas spp. (n = 40, 10.6%) and Klebsiella spp. (n = 38, 10.1%). Wound infections were characterised by multiple isolates (n = 293, 77.7%), with the most frequent being Proteus spp. (n = 44, 15%), Pseudomonas (n = 37, 12.6%), Staphylococcus (n = 29, 9.9%) and Klebsiella spp. (n = 28, 9.6%). All Staphylococcus aureus tested were resistant to penicillin (n = 22, 100%) and susceptible to vancomycin. Significant resistance to cephalosporins such as cefazolin (n = 62, 72.9%), ceftriaxone (n = 44, 51.8%) and ceftazidime (n = 40, 37.4%) was observed in Gram-negative bacteria, as well as resistance to cefoxitin (n = 6, 27.3%) in S. aureus.

Conclusion The study has revealed a wide range of causative agents, with an alarming rate of resistance to the commonly used antimicrobial agents. Furthermore, the bacterial spectrum differs from those often observed in high-income countries. This highlights the imperative of regular generation of data on aetiological agents and their antimicrobial susceptibility patterns especially in infectious disease endemic settings. The key steps would be to ensure the diagnostic capacity at a sufficient number of sites and implement structures to routinely exchange, compare, analyse and report data. Sentinel sites (hospitals) across the country (and region) should report on a representative subset of bacterial species and their susceptibility to drugs at least annually. A central organising body should collate the data and report to relevant national and international stakeholders.

Keywords bacterial infections, antimicrobial resistance, Africa, Western Europe, America

Introduction

Regular review of patterns of infections and their antibacteriogram is key for empirical treatment, which is common in resource-poor settings. Over the past 20 years, the pattern of infections and their susceptibility to antimicrobial agents [1, 2] has changed, likely due to factors such as increased use of antimicrobial agents [3] and rising prevalence of diabetes mellitus [4] which due to socio-demographic changes [1] is becoming a common comorbid condition for patients admitted due to infection [5]. Human immunodeficiency virus (HIV) has also changed the pattern of infections [2]; antiretroviral (ARV) therapies, which boost the immune status of the patients infected with HIV [6], may play a role in the susceptibility to both common and opportunistic infections [7], as

well as other chronic conditions such as cancer and kidney disease.

In Africa, infectious diseases constitute a much higher burden in people of all age groups [8–13] than in Europe and North America. Active surveillance systems on infectious disease control are inadequate in most African countries [14–17], and the absence of data on disease causes and the lack of control measures add to the disease burden [6]. Obtaining adequate and timely data on infectious diseases in African countries is difficult, whereas much more data are available from developed countries. As a result, empirical treatment in Africa regarding pathogenic bacteria might be based on data from clinical laboratories in developed countries [18].

The pattern of bacterial infections in Africa differs from those observed in Western Europe and North America; hence, empirical treatment should be adjusted to fit the different need. In Africa, as elsewhere, regular local data collection about patterns of infections, and their response to antimicrobial agents, coupled with a long-term commitment to providing adequate health information systems, is key to effective planning and policy formulation. The availability of data on disease patterns, etiological agents and their antimicrobial resistance is a prerequisite for the establishment of empirical treatment regimens and for avoiding escalation of the global trend of bacterial resistance to the current antimicrobial regimens [19–21].

This study was conducted to determine the most frequent bacterial species isolated from samples submitted for microbiological examinations at a tertiary care hospital in Moshi, Tanzania. We also determined antimicrobial susceptibility patterns of the isolates and associated comorbid conditions.

Materials and methods

Study design, location and sample collection

This study is a descriptive analysis of culture, bacterial identification and antimicrobial susceptibility testing conducted at Kilimanjaro Christian Medical Centre (KCMC), which hosts a tertiary healthcare facility for the northern zone of Tanzania. The study was conducted from August 2013 to August 2015. Clinical samples were collected from inpatients admitted to the medical or surgical wards of the hospital. Informed consent was obtained from all participants. Specimens including stool (56), sputum (122), blood (56) and wound/pus swabs (286) were collected from 575 patients. Twenty specimens were not included due to insufficient quantity. Blood, stool or sputum samples were collected if the patient was diagnosed to have sepsis or upper respiratory infection, respectively. Blood samples were also collected from patients with fever of unknown cause. Wound or pus swabs were collected from wounds due to burns, surgical procedures, diabetes mellitus, animal bites, motor traffic accidents and other injuries.

Patient hospital files were used to obtain socio-demographics and clinical characteristics of the study participants admitted at KCMC wards. Data were recorded on designated case report forms (CRFs). All samples were transported immediately after collection to the Kilimanjaro Clinical Research Institute (KCRI), to be processed by the microbiology unit of the biotechnology laboratory department.

Culture and identification

Wound/pus swabs and sputum specimens were cultured onto trypticase soy agar with 5% sheep blood (BD BBL™), chocolate agar and McConkey agar plate media (BD BBL™) and incubated at 37 °C with 5% CO2 for 18–24 h. Stool samples were cultured onto McConkey agar and incubated at 37 °C overnight. Blood samples were collected in 40 ml BD BACTEC standard 10 Aerobic/F, followed by incubation in BD BACTEC for a maximum of 5 days. Gram stain was used to differentiate Gram-positive and Gram-negative bacteria from culture. Positive blood cultures were inoculated on blood agar, chocolate agar and McConkey agar and incubated for 18–24 h at 37 °C with 5% CO2. Bacteria were isolated from culture by picking single colonies and subculturing onto purity plate (Blood agar) overnight. From the purity plate, morphology determination and gram stain was made followed by microscopic examination.

Based on Gram staining results, Gram-negative bacteria were identified using API 20E and/or API NE 20 (bioMérieux) for Enterobacteriaceae and other non-fastidious Gram-negatives. Catalase and coagulase tests were used to identify Gram-positive cocci. Optochin susceptibility testing (BD BBL Taxo™ Benex Limited, Shannon County Clare, Ireland) was used to confirm Streptococcus pneumoniae, and BD BBL Streptocard® Enzyme Latex test was used to identify streptococcal group A, B, C, D, F and G.

Antimicrobial susceptibility testing

Antimicrobial susceptibility testing (AST) was performed using disc diffusion on Müller–Hinton II Agar (MHA) according to Clinical Laboratory Standards Institute (CLSI, 2013) guidelines. Gram-negative bacterial isolates were tested for ampicillin 10 μg, amoxicillin-clavulanic acid 30 μg, cefazolin 30 μg, cefazidime 30 μg,
ceftriaxone 30 μg, chloramphenicol 30 μg, ciprofloxacin 5 μg, gentamicin 10 μg, nalidixic acid 30 μg and trimethoprim-sulfamethoxazole 23.75 μg/1.25 μg. Antimicrobials tested for Gram-positive bacterial isolates were chloramphenicol, trimethoprim-sulfamethoxazole (23.75 μg/1.25 μg), erythromycin 15 μg, vancomycin 30 μg, penicillin 10 μg and cefoxitin 30 μg. Interpretation as susceptible, intermediate resistant and resistant was performed according to CLSI 2013. Isolates with intermediate or resistant results were merged into a single group as resistant during data analysis. Considering intermediate group as resistance can be one of the ways of sidestepping uncertain therapeutic effects [22].

Data analysis
Data were double-entered in OpenClinica (OpenClinica LLC, Waltham, MA, USA). Data extracts were exported to STATA 13 (StataCorp LP, Texas 77845, USA). This tool was used for all analyses. Proportions of comorbidities and bacterial isolates were calculated and presented as column or row percentages.

Results
Characteristics of the study participants
Table 1 summarises characteristics of 575 patients with different medical conditions enrolled in the study from August 2013 to August 2015. Five patients were excluded during analysis due to incomplete patient information. The median age (IQR) was 43 (30–57) years; 61% (n = 348) were males, 39% females (n = 227).

Half of the participants were peasants (n = 271, 47.3%), and the predominant education level was primary education (n = 339, 59%); few participants (n = 34, 5.9%) had tertiary education; 71.9% participants (n = 412) had a history of receiving antibiotic treatment prior to admission, and 45.9% of patients were admitted due to wound infection (n = 263), 14.4% due to pneumonia (n = 81), 10.5% due to tuberculosis (n = 60), 8.03% due to septicemia (n = 46), 3.5% due to diarrhoea (n = 20) and 0.7% due to meningitis (n = 4). Coexisting health conditions were diabetes mellitus (n = 122, 21.3%), HIV (n = 81, 14.1%) and cancer (n = 52, 9.1%).

Culture results
A total of 590 specimens were cultured: 286 wound swabs, 126 blood, 122 sputum and 56 stool samples; 42.2% of the cultured specimens had positive growth after overnight incubation: 72.3% of wound swabs

| Cancer                        | 52 (9.1%)     |

Table 1 Socio-demographics and clinical characteristics of the study participants admitted at KCMC (N = 575)

IQR (Interquartile range) ICU, intensive care unit TB, tuberculosis HIV, human immunodeficiency virus. *Widowed: widowed and divorced, gender n = 574, age n = 559, the rest n = 573, two patients had no information, *wound (includes abscess).

(n = 180), 14.1% of sputum samples (n = 35), 7.6% of stools (n = 19) and 6% of blood samples (n = 15).

We obtained 377 bacterial isolates; 43.8% of specimens (n = 109) had more than one isolate, and 77.7% of isolates (n = 293) were obtained from wound swabs, 11% (n = 4), from sputum, 6.1% (n = 23) from stools and 4.2% (n = 16) from blood cultures (Table 2).

There was a wide range of bacterial isolates, the majority being Gram-negative isolates, with Proteus spp (n = 48, 12.7%), E. coli (n = 44, 11.7%), Pseudomonas spp (n = 40, 10.6%) and Klebsiella spp (n = 38, 10.1%) being predominant, together accounting for 170 (45.1%)
Table 2 Bacteria isolates obtained from culture-positive specimens

| Specimen     | Isolates | N (%) |
|--------------|----------|-------|
|              | Total (N) | Wound swab | Sputum | Stool | Blood |

Table 1 summarises bacterial pathogens identified in this study. Where more than one subtypes identified, collectively they were named as species (spp) of that genus to accommodate all groups of bacteria in a single table.

of all isolates. The Gram-positive bacteria were *Staphylococcus aureus* (*n* = 35, 9.3%), coagulase negative *Staphylococcus* spp (*n* = 23, 6.6%) and *Streptococcus* spp (*n* = 17, 4.5%). Wound infections were characterised by multiple isolates (*n* = 293, 77.7%), with the most frequent being *Proteus* spp (*n* = 44, 15%), *Pseudomonas* spp (*n* = 37, 12.6%), *Staphylococcus* (*n* = 29, 9.9%) and *Klebsiella* spp (*n* = 28, 9.6%). *Streptococcus* spp were the most common finding (*n* = 9, 20%) in sputum samples, followed by *Klebsiella* spp (*n* = 7, 15.6%). *E. coli* (*n* = 11, 47.8%) was the predominant isolate in stool samples (Table 2).

**Pattern of infections and aetiological agents**

Table 3 outlines disease conditions found; wound infection (*n* = 277, 45.8%), pneumonia (*n* = 87, 14.4%), tuberculosis (*n* = 64, 10.6%), septicemia (*n* = 52, 8.6%), diarrhoea (*n* = 21, 3.5%) and meningitis (*n* = 4, 0.7%). *S. aureus, Klebsiella* spp, *Proteus* spp, *E. coli* and *Pseudomonas* spp were the most common bacterial pathogens isolated from patients with the above disease presentations. The distribution of these pathogens was diversified in wound infections. Septic wounds were dominated by *Pseudomonas* spp (*n* = 31, 77.5%), *Proteus* spp (*n* = 37, 75.5%), *E. coli* (*n* = 24, 54.3%), *S. aureus* (*n* = 20, 57.1%) and *Klebsiella* spp (*n* = 21, 51.2%). Burn and diabetic wounds had more *Proteus* spp (*n* = 10 (20.4%) and *n* = 15 (30.6%), respectively). Motor traffic and post-surgical wounds had few bacterial isolates.

Table 4a and b summarise the association between co-existing health conditions such as diabetes, cancer and HIV and the burden of commonly isolated bacteria. The prevalence of *Proteus* spp, *Escherichia coli* and *Pseudomonas* spp infections was higher among people with diabetes and cancer, although the associations were not statistically significant (*P* > 0.05). A statistically significant independent association was observed between the prevalence of *Pseudomonas* spp among HIV-negative patients (11%) and HIV-positive patients (3%) (*P* = 0.03). The prevalence of both *Proteus* spp (16%) and *Pseudomonas* spp (13%) among patients with wound infection was higher than in patients without (*P* = 0.03).

**Pattern of resistance to antimicrobial agents**

About three-quarters of the patients (*n* = 412, 71.9%) had a history of antibiotic/antimicrobial treatment before
arriving to the hospital (Table 1). Drugs that were commonly used were ceftriaxone ($n = 173, 46.2\%$), metronidazole ($n = 147, 39.4\%$), cloxacillin ($n = 64, 17.1\%$), ciprofloxacin ($n = 25, 6.6\%$) and co-trimoxazole ($n = 21, 5.5\%$).

Generally, there was high antimicrobial resistance in bacterial isolates in this study; Proteus spp, Klebsiella spp and E. coli exhibited relatively high resistance to all drugs tested among Gram-negative isolates. Ampicillin resistance was frequent among Klebsiella spp ($n = 24, 92.3\%$), Proteus spp ($n = 21, 75\%$) and E. coli ($n = 13, 68.4\%$). Other bacterial spp such as Enterobacter cloacae, Acinetobacter baumannii, Serratia spp, Morganella morganii and Providencia spp were resistant by 100\% to ampicillin. Resistance of Proteus spp, Klebsiella spp and E. coli to cefazolin was ($n = 23, 82.1\%$), ($n = 16, 61.5\%$) and ($n = 11, 57.9\%$), respectively, with all other spp at 100\% resistance. Resistance to third-generation cephalosporins (ceftriaxone and ceftaxime) was well observed for Klebsiella spp ($n = 14, 53.8\%$ and $n = 12, 46.2\%$) and E. coli ($n = 8, 42.1\%$ and $n = 7, 36.8\%$), Table 5a. Among the Gram-positive isolates, S. aureus was the only species, which demonstrated detectable resistance to penicillin ($n = 22, 100\%$), erythromycin ($n = 11, 50\%$), trimethoprim–sulfamethoxazole ($n = 10, 45.5\%$), as well as cefoxitin ($n = 6, 27.3\%$). All S. aureus in this study were sensitive to vancomycin (refer to Table 5b). Table 5c summarises the susceptibility pattern of the six cefoxitin-resistant S. aureus and 16 cefoxitin-susceptible S. aureus. Resistance of cefoxitin-resistant S. aureus to other drugs such as erythromycin, penicillin and trimethoprim–sulfamethoxazole was 100\%, while none were resistant to vancomycin and chloramphenicol. All cefoxitin-susceptible S. aureus isolates were resistant to penicillin (100\%), six (37.5\%) to erythromycin, five (31.3\%) to trimethoprim–sulfamethoxazole and one (6.3\%) to chloramphenicol. None were resistant to vancomycin.

**Discussion**

**Culture results**

KCMC is a referral hospital serving approximately 11 million people in the northern zone of Tanzania. We conducted a 2-year study from August 2013 to August 2015 to determine the pattern of bacterial pathogens associated with different health conditions among patients who were admitted at medical and surgical departments in this hospital.

The culture results revealed a higher positive growth rate on wound swab specimens ($n = 180, 72.3\%$), compared to others. Both Gram-negative and positive species were observed. Our findings are in agreement with other studies in Africa where wound infections tend to manifest with a variety of bacterial pathogens [23, 24]. This is explained by the complexity of wound specimens that will tend to have a variety of bacterial pathogens, depending on the way wounds were acquired. Wounds acquired from a community environment will have more diverse organisms than hospital-acquired wounds [25,

NB: Part C of the table shows susceptibility pattern of the six cefoxitin-resistant S. aureus (probably MRSA) and sixteen cefoxitin-susceptible S. aureus.
In our study, there were few positive blood specimens \( (n = 15, 6\%) \) on culture, a finding which is in agreement with other studies that showed a low positive growth of blood cultures \([27]\). Possibly this is because most septicemia cases we tested were not due to bacterial infections, a finding that has been reported from other studies in Tanzania \([28]\). The use of antibiotic prior to coming to the hospital, which hinders the detection of susceptible organisms \([29]\), may be another reason. This is a practice which is very common in Tanzania and other developing countries \([30–32]\). KCMC being a tertiary care hospital receives patients referred from health facilities in Kilimanjaro region and other parts of Tanzania. The majority of these patients have been treated with antibiotics in the referring hospital. However, the patients could also have self-medicated as antibiotics are easily available and policies to control improper use of antibiotics are non-existent in Tanzania, as in other developing countries \([30, 32–35]\).

**Bacterial spectrum**

The bacterial spectrum observed from this study showed a high diversity of Gram-negative bacilli such as *Proteus* spp \( (12.7\%) \), *E. coli* \( (11.7\%) \), *Pseudomonas* spp \( (10.6\%) \) and *Klebsiella* spp \( (10.1\%) \), with *Staphylococcus aureus* \( (9.3\%) \) being the predominant Gram-positive isolate. The majority of these Gram-negative bacilli were from wound infections rather than from other disease conditions. This predominantly Gram-negative infection pattern, as also observed in other studies \([24, 36, 37]\), is different from that most commonly reported from Western Europe and North America \([38, 39]\). The reasons for this are not entirely known, but recent studies have also shown that higher temperatures are correlated with increased numbers of infections caused by Gram-negative bacterial species \([40]\). Our results do however emphasise that we cannot use knowledge obtained in Western Europe and North America directly for clinical care and empirical treatment in sub-Saharan Africa.

**Infection pattern**

Like any other resource-constrained countries, Tanzania is still experiencing the burden of infectious diseases. In the current study, we observed presence of wound infections \( (n = 263, 45.9\%) \), septicemia \( (n = 46, 8.03\%) \), diarrhoea \( (n = 20, 3.5\%) \), HIV \( (n = 81, 14.1\%) \), and tuberculosis \( (n = 60, 10.5\%) \) and many other respiratory infections. As also indicated in other studies \([13, 41]\), these diseases are still health challenges in low-income countries. We also recognised the presence of non-communicable diseases such as cancer \( (n = 52, 9.1\%) \) and diabetes \( (n = 122, 21.3\%) \). This suggests co-existence of communicable and non-communicable diseases in low-income countries as has been indicated in other studies \([42, 43]\). The increase of diabetes in Tanzania may be the effect of little knowledge about the risk factors associated with the disease \([4]\), which may be related to the majority \( (n = 339, 59.2\%) \) of the participants having only primary level education. There was no relationship between the most frequently isolated bacteria and conditions like diabetes and cancer. However, a non-statistically significant association between diabetes and *Proteus* spp \( (19\%) \) and *E. coli* \( (14\%) \) \( (P = 0.07) \) was observed. The finding was more or less the same with HIV status. It was noted that prevalence of *Proteus* spp \( (16\%) \) and *Pseudomonas* spp \( (13\%) \) was higher in wound infections than in those with no wound infection \( (9\% \text{ and } 6\%, \text{ respectively}) \), and the difference was statistically significant \( (P = 0.03) \). This is in agreement with other studies \([25]\) despite the fact that the design of the studies was different. Again we can generally attest that aetiology of a wound infection is broad, depending on environment and nature of the wound.

**Antimicrobial susceptibility testing**

Proper identification and determination of antimicrobial resistance of the bacterial pathogens is crucial to help physicians to provide proper treatment promptly. The advancement in pharmaceutical industries has lead to discoveries of many antibiotics, which has facilitated physicians’ efforts into providing quality effective medical care. Despite of this increase, prudent use is essential in controlling antimicrobial resistance, which has now become one of the major challenges for medical progress. The current study demonstrated that a majority \( (n = 412, 71.9\%) \) of patients had sought treatment prior to coming to the hospital. It is likely these patients received antibiotics during their previous treatment. The most frequently used drugs were ceftriaxone \( (46.2\%) \), metronidazole \( (39.4\%) \), cefoxitin \( (17.1\%) \), ciprofloxacin \( (6.6\%) \) and co-trimoxazole \( (5.5\%) \). Along with this, the observed resistance patterns of Gram-negative bacterial isolates tested on drugs such as amoxicillin-clavulanic acid ampicillin, gentamicin, trimethoprim-sulfamethoxazole and chloramphenicol were relatively high in ampicillin \( (82.4\%) \) and trimethoprim-sulfamethoxazole \( (60\%) \), and below 50% in the rest. This is probably due to the fact that these drugs are used in Tanzania as first-line antibiotics in treatment of gastrointestinal diseases, respiratory diseases, obstetrical/gynaecological, cardiovascular and nervous system diseases \([44]\). Their easy availability from hospitals causes these drugs to be commonly used for treatment by medical practitioners as well as for
self-medication, factors which play a great role in drug resistance [33, 34, 45]. The finding is in agreement with
other two studies in Tanzania which indicated resistance of
E. coli and Klebsiella to trimethoprim-sulfamethoxa-
zole, ampicillin, amoxicillin–clavulanic acid and gentam-
icin (100%, 96%, 88%, 60%) and (85%, 95%, 70%,
70%), respectively [46, 47]. Resistance ranging from
9.1% to 78% also has been noted to ciprofloxacin and
nalidixic acid. These are categorised as second-line drugs
in Tanzania, yet they show a high frequency of resis-
tance. As ceftriaxone is a third-generation cephalosporin,
we expected its use to be controlled, yet it was the most
used. Moreover, convincing percentages of resistant
strains of E. coli and Klebsiella to first and third-genera-
tions of cephaplosporins have been broadly noted, ranging
from 36.8% to 61.5%. This finding suggests existence of
extended spectrum beta lactamase (ESBL) bacteria, as has
been addressed in other studies in Tanzania [23] where
64.3% of E. coli and 80% of Klebsiella pneumoniae
were ESBL producers. The presence of ESBL producers
reduces treatment options, resulting in higher morbidity
and mortality due to severe infections and sepsis.

Staphylococcus aureus was the predominant spp among
Gram-positive isolates. It accounted for 6 (27.3%) of the
observed resistances to cefotxin and other antibiotics
such as erythromycin, trimethoprim–sulfamethoxazole
and penicillin G, a characteristic that we would postulate
to indicate methicillin-resistant Staphylococcus (MRSA)
clones, as has been suggested in other studies [48].

Conclusion
The study has revealed a wide range of causative agents,
with an alarming rate of resistance to the commonly used
antimicrobial agents. Furthermore, the bacterial spectrum
differs from those observed in high-income countries. This
highlights the imperative of regular generation of data on
aetiological agents and their antimicrobial susceptibility
patterns especially in infectious disease endemic settings.
The key steps would be to ensure the diagnostic capacity at
a sufficient number of sites and routine exchange, com-
parison, analysis and reporting of data. As the minimum, sen-
tinel sites (hospitals) across the country and region should
report on a representative subset of bacterial species and
their susceptibility to drugs at least once a year. A central
organising body should collate the data and report to all
relevant national and international stakeholders [49].

Acknowledgements
We thank the study participants for volunteering to take
part in the study, KCMC management for allowing the
study to take place at the hospital, KCRI and DTU for
granting access to their research facilities, and DANIDA
for funding the study. We would also like to thank the
KCRI microbiology team for their time and effort.
