Alkamides belong to a class of small lipid signals of wide distribution in plants, which are structurally related to the bacterial quorum-sensing signals \(N\)-acyl-\(L\)-homoserine lactones. Arabidopsis (\textit{Arabidopsis thaliana}) seedlings display a number of root developmental responses to alkamides, including primary root growth inhibition and greater formation of lateral roots. To gain insight into the regulatory mechanisms by which these compounds alter plant development, we performed a mutant screen for identifying Arabidopsis mutants that fail to inhibit primary root growth when grown under a high concentration of \(N\)-isobutyl decanamide. A recessive \(N\)-isobutyl decanamide-resistant mutant (\textit{decanamide resistant root [drr1]}) was isolated because of its continued primary root growth and reduced lateral root formation in response to this alkamide. Detailed characterization of lateral root primordia development in the wild type and \textit{drr1} mutants revealed that \textit{DRR1} is required at an early stage of pericycle cell activation to form lateral root primordia in response to both \(N\)-isobutyl decanamide and \(N\)-decanoyl-\(L\)-homoserine lactone, a highly active bacterial quorum-sensing signal. Exogenously supplied auxin similarly inhibited primary root growth and promoted lateral root formation in wild-type and \textit{drr1} seedlings, suggesting that alkamides and auxin act by different mechanisms to alter root system architecture. When grown both in vitro and in soil, \textit{drr1} mutants showed dramatically increased longevity and reduced hormone- and age-dependent senescence, which were related to reduced lateral root formation when exposed to stimulatory concentrations of jasmonic acid. Taken together, our results provide genetic evidence indicating that alkamides and \(N\)-acyl-\(L\)-homoserine lactones can be perceived by plants to modulate root architecture and senescence-related processes possibly by interacting with jasmonic acid signaling.

Plant growth and development require the integration of a variety of environmental and endogenous signals, which together with the intrinsic genetic program determine plant form and longevity. Lipids have long been recognized as signals that have the capacity to trigger profound physiological responses. In animals, ceramides and sphingosines are lipids that have proapoptotic and antiproliferative actions (Wymann and Schneider, 2008). In plants, ceramides, sphingosines, and phosphatidic acid are involved in mediating plant growth, development, and responses to environmental stimuli (Worrall et al., 2003; Wang, 2004).

In the past few years, additional small lipids have been found to act as plant signals, including alkamides and \(N\)-acyl-ethanolamines (NAEs). Alkamides comprise at least 200 amides with varied acyl chain lengths and saturation grades (for review, see López-Bucio et al., 2006; Morquecho-Contreras and López-Bucio, 2007). These compounds have been found to alter root and shoot system architecture in \textit{Arabidopsis thaliana}; Ramírez-Chávez et al., 2004; Campos-Cuevas et al., 2008). NAEs represent compounds with aminoalcohol linked as an amide to the fatty acid. They are likely produced from the hydrolysis of \(N\)-acyl-phosphatidylethanolamines, a minor constituent of cell membranes, by phospholipase D (Chapman, 2004). NAEs have been found to accumulate in seeds of some higher plants, including cotton (\textit{Gossypium hirsutum}), corn (\textit{Zea mays}), \textit{Arabidopsis}, soybean (\textit{Glycine max}), tomato (\textit{Solanum lycopersicum}), and pea (\textit{Pisum sativum}), and their levels decline during germination (Wang et al., 2006).

Many gram-negative bacteria produce alkamide-related substances termed \(N\)-acyl-\(L\)-homoserine lactones (AHLs). These compounds participate in

cell-to-cell signaling that is usually referred to as quorum sensing (Pearson et al., 1994). The AHL signals contain a conserved HL ring and an N-linked acyl side chain. The acyl-chain moiety of naturally occurring AHLs can differ in length and substitution at position C3, which is either unmodified or carries an oxo or hydroxyl group (Pearson et al., 1994; Parsek et al., 1999). These molecules are freely diffused through the bacterial membrane, which is to some extent dependent upon the length of the acyl side chain and the nature of any C3 substitutions and distribute within the rhizosphere (Pearson et al., 1999; Schuhgetter et al., 2006; Scott et al., 2006). Evidence has accumulated indicating that plants are able to perceive AHLs. The application of AHLs to Medicago truncatula and Arabidopsis plants resulted in differential transcriptional changes in roots and shoots, affecting the expression of genes potentially involved in development (Mathesius et al., 2003; Von Rad et al., 2008). Ortíz-Castro et al. (2008) evaluated Arabidopsis growth responses to a variety of saturated AHLs ranging from four to 14 carbons in length, focusing on alterations in postembryonic root development. The compounds affected primary root growth, lateral root (LR) formation, and root hair development. While this information clearly indicates that plants are able to sense a variety of small lipid signals, including alkamides, NAEs, and AHLs, which modulate root architecture, the genetic mechanisms involved in signal perception to these compounds are unknown.

The Arabidopsis root system is an excellent model to dissect the genetic and developmental processes that determine plant architecture. It mainly consists of an embryonic primary root and postembryonic developed LRs (López-Bucio et al., 2005). LR formation is influenced by a wide range of environmental cues, such as nutrients and water availability in the soil (López-Bucio et al., 2003; Malamy, 2005; Nibau et al., 2008). The plasticity of LR formation is of critical importance, allowing plants to compete for resources and adapt to constantly changing growth conditions. LRs originate from pericycle founder cells located opposite to xylem poles, which undergo several rounds of anticlinal divisions to create a single-layered primordium composed of up to 10 small cells of equal length (termed stage I; Dolan et al., 1993; Malamy and Benfey, 1997; Dubrovsky et al., 2001). Further anticlinal and periclinal divisions create a dome-shaped primordium (spanning stages III–VII), which eventually emerges from the parental root (Malamy and Benfey, 1997; Casimiro et al., 2003; Péret et al., 2009).

The phytohormone auxin (indole-3-acetic acid [IAA]) plays an important role during each stage of LR formation (De Smet et al., 2006; Fukaki et al., 2007; Dubrovsky et al., 2008; Fukaki and Tasaka, 2009). Application of IAA or synthetic auxins such as 2, 4-dichlorophenoxyacetic acid or naphthalenacetic acid (NAA) stimulates LR formation (Celenza et al., 1995; Woodward and Bartel, 2005), whereas polar auxin transport inhibitors such as N-(1-naphthyl)-phthalic acid and 2,3,5-triiodobenzoic acid prevent LR formation (Casimiro et al., 2001; Himanen et al., 2002). Consistently, Arabidopsis mutants with increased auxin levels, such as rooty and its alleles aberrant lateral root formation1 and superroot1, have increased numbers of LRs (Boerjan et al., 1995; Celenza et al., 1995; King et al., 1995), while mutants with defective auxin transport, perception, or signaling, including aux1, axr1, and tir3/doc1/big, show reduced LR formation (Lincoln et al., 1990; Gil et al., 2001; Swarup et al., 2001). In contrast to auxin, less is known about the action of alkamides, AHLs, and other related small lipid signals on LR formation and whole plant development.

To identify the genetic components responsible for the root architectural responses to alkamides, we performed a visual screening for Arabidopsis mutants that under high N-isobutyl decanamide concentration do not manifest primary root growth reduction. We isolated an N-isobutyl decanamide-resistant mutant (decanamide resistant root [drr1]) defective in a single recessive trait. Detailed cellular and developmental studies of wild-type and drr1 plants indicate that drr1 mutants show resistance to primary root growth inhibition and LR growth promotion induced by both an alkamide (N-isobutyl decanamide) and a bacterial quorum-sensing signal (N-decanoyl-l-homoserine lactone [C10-AHL]). We further show that DRR1 is a crucial component of the regulation of plant senescence, which likely links alkamide and jasmonic acid (JA) in modulating plant longevity and LR development.

RESULTS

Isolation of drr1, an Arabidopsis Mutant with Altered Primary Root Growth Response to N-Isobutyl Decanamide

From a group of similar chain length alkamides and NAEs, López-Bucio and coworkers (2007) identified N-isobutyl decanamide, a C10 saturated alkamide that is naturally produced in Acmella radicans (Rios-Chávez et al., 2003) and Cissampelos glaberrima (Lauroerio-Rosario et al., 1996), as the most active compound in inhibiting primary root growth and stimulating LR formation in Arabidopsis.

To investigate the genetic basis of plant responses to alkamides, we screened 25,000 lines from T-DNA insertion mutant collections (Krysan et al., 1999) by inspecting the root architecture of plants grown over the surface of 0.2× Murashige and Skoog (MS) agar plates supplied with 30 μM N-isobutyl decanamide. A mutant line was isolated that, in contrast to the wild type, was able to sustain primary root growth under this inhibitory concentration of the alkamide (Fig. 1A). The mutant was backcrossed to wild-type plants (Wassilewskija [Ws] ecotype) three times prior to detailed phenotypical analysis. In F2 progeny from these crosses, in plants grown in medium supplied
with 30 μM N-isobutyl decanamide, the line segregated the mutant phenotype in a 1:3 ratio (Table I). These results indicate that the primary root growth resistance to the alkamide resulted from a recessive single-gene mutation. We named this locus \textit{drr1}. To further study the developmental alterations induced by \textit{N}-isobutyl decanamide in wild-type and \textit{drr1} plants, we grew ecotype Ws and \textit{drr1} plants side by side on vertically oriented agar plates with varied alkamide contents. Wild-type plants grown in 0.2× MS medium without \textit{N}-isobutyl decanamide showed a typical root system, consisting of a long primary root with many LRs forming in a gradient from the root/shoot junction to the primary root tip (Fig. 1B). In the same medium, \textit{drr1} mutants developed a long primary root lacking visible LRs (Fig. 1B), thus indicating that \textit{DRR1} is important for normal LR development under normal growth conditions. In wild-type plants treated with 20, 25, or 30 μM \textit{N}-isobutyl decanamide, there was a dose-dependent inhibitory effect of the alkamide on primary root growth, which correlates with an increase in LR formation. In these plants, multiple LRs developed, giving rise to a highly exploratory root system with different architecture from that observed in plants grown in medium without \textit{N}-isobutyl decanamide (Fig. 1, C–E). In contrast, alkamide-treated \textit{drr1} mutants showed longer primary roots and reduced LR formation when compared with wild-type plants in most concentrations of \textit{N}-isobutyl decanamide tested (Fig. 1, C–E).

\textit{drr1} Mediates the Root Architecture Responses of \textit{Arabidopsis} to \textit{N}-Isobutyl Decanamide

To more clearly define the alterations in the root architectural response to \textit{N}-isobutyl decanamide caused by mutation in \textit{DRR1}, we performed temporal and single-point measurements of primary root length, LR number per plant, and LR density in wild-type and \textit{drr1} mutants treated with varied concentrations of \textit{N}-isobutyl decanamide. Primary root growth was similar in wild-type and \textit{drr1} plants in concentrations of up to 15 μM \textit{N}-isobutyl decanamide, while in concentrations of 20, 25, and 30 μM of this compound, \textit{drr1} primary roots were significantly longer than wild-type plants (Fig. 2A). \textit{N}-Isobutyl decanamide increased the number of emerged LRs in wild-type plants, while \textit{drr1} plants were resistant to this effect (Fig. 2B). The density of emerged LRs dramatically increased in response to alkamide treatment in wild-type plants, but the mutants again showed reduced responses. The most contrasting responses between wild-type and \textit{drr1} plants were observed in 25 μM \textit{N}-isobutyl decanamide, in which wild-type plants showed a highly branched root system harboring second- and third-order LRs (Fig. 1, C–E), with a 6-fold increased density of LRs (Fig. 2C). This alkamide concentration, \textit{drr1} mutant plants produced less than 15% of the LRs observed in wild-type plants. Interestingly, although \textit{drr1} mutants produced

| Generation | Phenyvote of Progeny | Ratio Obtained, Wild Type: \textit{drr1} | Ratio Tested, Wild Type: \textit{drr1} | \( \chi^2 \) |
|------------|----------------------|------------------------------------------|-----------------------------------------|-----------|
|            | Many LRs (Wild Type) | Few LRs (\textit{drr1})                 |                                         |           |
| F1         | 128                  | 0                                        | 2.81:1                                  | 3:1       | 0.84 |

consistently fewer LRs compared with the wild type in most N-isobutyl decanamide treatments, exposure to 30 μM N-isobutyl decanamide caused an 8-fold increase in LR number and a 2-fold increase in LR density (Fig. 2, B and C), indicating that the mutants are not completely insensitive to the alkamide.

**drr1 Mutants Are Resistant to Inhibitory Effects of N-Isobutyl Decanamide on Cell Division in Primary Root Meristems**

An important factor determining primary root growth reduction in wild-type seedlings grown in high N-isobutyl decanamide concentrations is the reduction in cell division in the root meristem (López-Bucio et al., 2007). To analyze the cell division responses of *drr1* mutants to alkamide treatment, we crossed *drr1* with a transgenic plant harboring the *CycB1:uidA* construct, which is expressed only in cells in the G2/M phase of the cell cycle and is a marker of mitotic activity (Colón-Carmona et al., 1999). *CycB1:uidA* seedlings and *drr1* seedlings were grown in 0.2× MS agar medium supplied with the solvent or with 20, 25, and 30 μM N-isobutyl decanamide. In both wild-type *CycB1:uidA* and *drr1* mutant seedlings supplied with the solvent only, a patchy pattern of single cells expressing *CycB1:uidA* was observed in the primary root meristem (Fig. 3, A and B). In wild-type plants subjected to treatment with 30 μM N-isobutyl decanamide, GUS expression in the primary root tip decreased and root hairs were formed in close proximity to the root meristem (Fig. 3C). Interestingly, *CycB1:uidA* expression in the primary root apex of *drr1* seedlings treated with the alkamide was not as much inhibited as in the wild type, and their root meristems were anatomically similar to those of solvent only-treated seedlings (Fig. 3D). Root hair formation close to the root meristem was not observed in *drr1* seedlings treated with the alkamide (Fig. 3D). Next, we quantified the length of the primary root meristems in wild-type and *drr1* plants at 4 and 12 d after germination. At these developmental stages, increased concentrations of N-isobutyl decanamide decreased the length of the meristem in wild-type plants, while *drr1* mutants were resistant to this effect (Fig. 3E).

**drr1 Is Defective in N-Isobutyl Decanamide-Induced LR Primordia Development**

LR formation is a major determinant of root system architecture. Next, we investigated the effects of N-isobutyl decanamide on lateral root primordia (LRP) development and LR emergence in wild-type and *drr1* plants. LRP originating in the primary root and emerged LRs were counted at 6 d after germination in plants grown in 0.2× MS agar medium supplied with the solvent only or with 30 μM N-isobutyl decanamide. The developmental stage of each LRP was classified according to Malamy and Benfey (1997; see “Materials and Methods”). In solvent-treated wild-type plants,
most LRP remained at an early developmental stage (stage I). Interestingly, N-isobutyl decanamide treatment increased both the number of LRP at stage I and the density of emerged LRs (Fig. 4). Solvent-treated drr1 mutants showed similar LRP density to wild-type plants (Fig. 4A) but dramatically decreased density of emerged LRs (Fig. 4B), indicating that the mutant is not inherently defective in LRP initiation but rather shows a retardation in the maturation of LRP. When treated with N-isobutyl decanamide, drr1 mutant seedlings did not show an increase in stage I LRP or in LRP emergence observed in wild-type plants (Fig. 4), indicating the DRR1 locus is involved in alkamide responses in the pericycle and during LRP development. Although alkamide treatment significantly increased the density of emerged LRs in drr1 mutants, drr1 always showed lower LR density than wild-type plants in the different growth conditions (Fig. 4B). These results indicate that N-isobutyl decanamide modifies root system architecture both by inducing more pericycle cells to form stage I LRP and by accelerating the emergence of LRP from the primary root to form mature LRs. Mutations in drr1 interfere with both of these processes.

**drr1** Is Defective in Root Architectural Responses to C10-AHL, a Quorum-Sensing Signal from Bacteria

Previous studies documented that AHLs, a class of alkamidine-related quorum-sensing signals from bacteria, modulate root system architecture in Arabidopsis (Ortíz-Castro et al., 2008; Von Rad et al., 2008). To determine if **drr1** is involved in AHL responses, we tested the primary root growth and LR responses of **drr1** seedlings to C10-AHL over a range of concentrations of this compound as compared with wild-type plants. **drr1** had a level of resistance to primary root growth inhibition by C10-AHL over most concentrations tested (Fig. 5A). At 30 μM C10-AHL in wild-type plants, about 60% inhibition of growth occurred, whereas in the mutant, it was about 30%. As previously reported (Ortíz-Castro et al., 2008), C10-AHL stimulated LR formation (Fig. 5B). A dose-dependent effect increasing LR density was observed (Fig. 5C), confirming the positive role of AHLs in LR induction. In contrast, **drr1** mutants showed reduced LR formation when compared with wild-type seedlings over most concentrations of C10-AHL tested (Fig. 5, B and C).

**drr1** Shows Normal Auxin Responses

Several auxin-related mutants have been characterized in screens for primary root growth resistance to inhibitory amounts of IAA, which display alterations in LR formation (Rogg et al., 2001; Swarup et al., 2001; Fukaki et al., 2002). To determine if **drr1** operates in a genetically defined auxin pathway, wild-type Arabidopsis seedlings (ecotype Columbia [Col-0] and Ws), **drr1** seedlings, and the auxin-related mutants aux1-7 and axr2 were evaluated in primary root growth response assays to IAA. First, to confirm the auxin resistance of auxin-related mutant lines, homozygous aux1-7 and axr2-1 seedlings were screened for resistance to IAA based on primary root growth. In these experiments, aux1-7 and axr2 were resistant to the inhibition of primary root elongation by IAA when compared with wild-type Col-0 seedlings (Fig. 6A). These mutants also failed to form abundant root hairs at the root tip region in response to increasing IAA concentration in the medium, a phenotype associated with increased auxin resistance (Fig. 6B). In contrast, the auxin response in **drr1** mutants was equally sensitive to IAA than the wild-type (Ws ecotype) both in primary root growth assays (Fig. 6A) and toward induction of root hair formation close to the root tip (Fig. 6B). Because **drr1** mutants showed normal root responses to IAA, we conclude that auxin signaling is unaffected in the mutant.

To better understand the role played by auxin in LR formation in wild-type and **drr1** plants, we tested the effects of NAA to activate LR formation in a transfer assay. In these experiments, wild-type and **drr1** plants were first germinated and grown for 7 d in 0.2× MS agar medium. At day 7 after germination, plants were

---

**Figure 5.** Effects of C10-AHL on the root system architecture of wild-type (Ws) and **drr1** plants. A, Primary root length. B, Number of emerged LRs per plant. C, LR density expressed as the number of LRs per centimeter. Data were recorded at 14 d after germination. Values shown are means ± SD (n = 20). Different letters represent means statistically different at the 0.05 level. The experiment was repeated three times with similar results.
transferred to 0.2× MS liquid medium supplied with the solvent or varied concentrations of NAA for an additional 4-d period. At this stage, the number and density of LRs were determined. As shown in Figure 7, NAA treatment caused a dose-response effect in LR formation (Fig. 7A), which was similar between wild-type and dr1 plants. Both wild-type and dr1 plants produced highly branched root systems with normal LR growth (Fig. 7, B–I). These results indicate that dr1 seedlings are not inherently defective in pericycle cell activation to form LRs and are able to correctly sense and respond to auxins.

To study the role of DRR1 in plant growth and development, we compared the phenotype of wild-type and homozygous dr1 plants of the same age that were first germinated and grown for 10 d on 0.2× MS agar medium and then transferred to soil. Wild-type and dr1 plants were grown side by side during their entire life cycle. The young and adult phenotypes of plants are shown in Figure 8. During the first 28 d after transfer, a general delay in the growth of dr1 mutants was observed, as illustrated by their delay in stem formation (Figs. 8, A and B, and 9A) and significantly decreased rosette size during early stages of vegetative growth (Fig. 9B). At 28 d after transfer, the rosette leaves of wild-type plants had already turned yellow and stem growth ceased, but dr1 leaves remained

green, and 7 d later, the stems just started to be formed (Figs. 8, A–C, and 9, A and B). At 35 d after transfer, wild-type leaves had turned completely yellow and showed signs of death with drying (Fig. 8C). In contrast, the \textit{drr1} mutant leaves retained a significant amount of chlorophyll and maintained the integrity of the leaf shape (Fig. 8C). The extension of leaf longevity at a whole plant level dramatically increased in \textit{drr1} mutants with time. Delayed flowering was accompanied by the generation of new leaves, increased rosette size, and greater stem length in \textit{drr1} mutants when compared with wild-type plants (Figs. 8, D and E, and 9, A–C). \textit{drr1} sustained chlorophyll production for a longer time period (Fig. 9D). In addition, the shoot architecture of \textit{drr1} mutants was different from that observed in wild-type seedlings, producing only one primary stem with reduced branches, which suggests increased apical dominance in the mutants (Fig. 9, E and F). Aside from the delayed senescence and altered shoot architecture, \textit{drr1} mutants produced fertile flowers that yielded fruits with fully viable seeds (Fig. 8D). We determined that the longevity in \textit{drr1} mutants was extended by approximately 2-fold when compared with wild-type plants, which correlates with a 3- to 4-fold increase in the number of visible leaves and overall increased plant size (Fig. 9, A–C).

The \textit{drr1} Mutant Shows Delayed Senescence Symptoms in JA- and Alkamide-Induced Senescence

Leaf senescence is modulated by JA (Schommer et al., 2008). Therefore, the possibility was open that the \textit{drr1} mutant could be deficient in the JA-induced senescence program. We compared the effects of JA and \textit{N}-isobutyl decanamide in wild-type and \textit{drr1} plants in a senescence-induced assay for detached leaves (Fig. 10). In this assay, after 6 d of incubation in water, wild-type detached leaves gradually lost chlorophyll content (Fig. 10, A and C). A deficient senescence program for detached \textit{drr1} plants incubated in water was evident (Fig. 10, B and D). In response to treatments with JA and \textit{N}-isobutyl decanamide, wild-type leaves showed severe senescence symptoms that were reduced in \textit{drr1} mutants (Fig. 10, E–I). Taking together the increased \textit{drr1} longevity in soil and the delaying response to hormone-induced senescence, we conclude that \textit{DRR1} plays an important role in the senescence process modulated by JA and \textit{N}-isobutyl decanamide as well as in age-dependent senescence.

\textit{drr1} Is Altered in Jasmonate-Mediated LR Induction

Jasmonates are signals involved in root system architecture modulation (Wasternack, 2007). The in-
hibitory effect of methyl jasmonate (MeJA) on primary root growth has been well recognized and widely employed as a useful trait to identify jasmonate-related mutants in Arabidopsis. Recently, it has been reported that MeJA also promotes LR formation (Sun et al., 2009). The MeJA dose response of \textit{drr1} in primary root growth and LR formation was compared with \textit{jar1}, a MeJA-insensitive mutant, and wild-type seedlings of the Ws and Col-0 ecotypes; the Col-0 ecotype provided the genetic background for \textit{jar1} and therefore was included as an additional control. When compared with Ws and Col-0 plants, the \textit{jar1} mutant showed strong resistance to MeJA-induced primary root growth inhibition over most concentrations tested (Fig. 11A). The primary root growth inhibition in \textit{drr1} was essentially the same as in Ws seedlings (Fig. 11A). Interestingly, MeJA, at concentrations of 30 to 45 \(\mu\text{M}\), increased emerged LRs in wild-type seedlings and in \textit{jar1} mutants by 70% to 150% (Fig. 11B; Supplemental Fig. S1). In the absence of MeJA, LR formation in \textit{drr1} was significantly reduced compared with wild-type and \textit{jar1} plants. However, \textit{drr1} mutants failed to produce increased numbers of LRs when grown on medium containing a range of concentrations of MeJA (Fig. 11B; Supplemental Fig. S1). Our data reveal that \textit{drr1} encodes a novel genetic locus modulating the effects of MeJA on LR formation.

Figure 9. Age-dependent senescence symptoms and other developmental traits of wild-type (Ws) and \textit{drr1} plants grown in soil. A, Age-dependent stem size. B, Rosette diameter. C, Number of visible rosette leaves. D, Chlorophyll content in rosette leaves at 28 d after transfer to soil. E, Stem number. F, Number of stem branches. Plants were grown with a 16-h-light/8-h-dark cycle at 22°C in a growth chamber, and developmental traits were monitored during their entire life cycle. Values shown are means \(\pm\) SD (\(n=18\)). Different letters represent means statistically different at the 0.05 level. The experiment was repeated twice with similar results. nd, Not determined.
DISCUSSION

drr1 Mutants Define a Locus Involved in Root Architectural Responses to Both Alkamides and AHLs

This report describes the identification and characterization of an Arabidopsis mutant that was defective in its root response to N-isobutyl decanamide but with additional characteristics, which suggest that alkamides play a role in plant longevity. Our characterization of root architectural responses in the wild type and drri to N-isobutyl decanamide provided insights into the genetic mechanisms mediating the responses to alkamides. While N-isobutyl decanamide inhibited primary root growth and promoted LR formation in wild-type seedlings, resistance to the repressive effect of this alkamide on primary root growth and the failure to increase LR formation typified the drri phenotype (Figs. 1 and 2).

Detailed cellular analysis of wild-type and drri plants showed that the mutants sustained almost normal root meristematic activity when grown under inhibitory concentrations of N-isobutyl decanamide, as revealed by cell counts and CycB1:uidA expression in the primary root meristem (Fig. 3). Interestingly, the typical increase in LR primordia initiation and LR emergence observed in wild-type plants treated with the alkamide was reduced in drri (Fig. 4). Several types of reported experimental evidence suggested that conditions that reduce primary root meristem activity, including destruction of the primary root meristem by cell ablation and physical decapitation of the root tip, elicit an increase in LR number (Tsugeki and Fedoroff, 1999). Our findings that drri mutants grown in medium lacking alkamides sustain normal primary root growth but reduced LR formation (Figs. 1 and 2) indicate that LR proliferation in response to N-isobutyl decanamide is not a direct consequence of

Figure 10. Hormone-dependent senescence symptoms in the drri mutant. Detached leaves of wild-type (Ws) and drri plants were incubated in 2-mL water solutions supplied with the indicated concentrations of compounds. The plates were included in a growth chamber (Percival ARR95L) under dark conditions, and representative photographs of leaves subjected to the different treatments were taken 6 d later (A–H) and chlorophyll determination was performed (I). The experiment included at least three independent samples of five leaves each and was replicated three times with similar results. [See online article for color version of this figure.]

Figure 11. Effects of JA on primary root growth and LR development in wild-type (Ws and Col-0) and mutant (drr1 and jar1) lines. A, Primary root length. B, Number of emerged LRs per plant. Data were recorded at 12 d after germination. Values shown are means ± sd (n = 20). Different letters represent means statistically different at the 0.05 level. The experiment was repeated three times with similar results.
primary root growth inhibition but rather suggest a positive effect of the alkamide on pericycle cells to produce more LRP (Fig. 4).

Many bacterial species use small molecule signaling to communicate with each other and to coordinate their growth activities, a process commonly referred to as quorum sensing (Taga and Bassler, 2003; Reading and Sperandio, 2006). Diverse gram-negative bacteria produce AHLs, and these compounds contain a conserved HL ring and an N-linked acyl side chain. Our previous work indicated that saturated medium (C8–C14)-chained AHL compounds showed a dose-dependent effect on root architecture, inhibiting primary root growth and promoting LR formation (Ortiz-Castro et al., 2008). In this work, we used the drr1 mutant to determine whether alkamides and AHLs could be perceived by similar genetic mechanisms. We show that C10-AHL inhibited primary root growth and promoted LR formation in Arabidopsis wild-type seedlings (Fig. 5). drr1 mutants showed reduced sensitivity to both N-isobutyl decanamide and C10-AHL, indicating a potential genetic interaction in plant responses to alkamides and AHLs in roots. These results also suggest that plants have evolved the capacity to sense AHLs in order to activate developmental responses.

Several reports indicate that bacteria commonly associated with plants are capable to produce a variety of AHLs (Cha et al., 1998; Elasri et al., 2001; Khmel et al., 2002; D’Angelo-Picard et al., 2005). Several strains of Pseudomonas have been studied for their ability to colonize plant-related niches, such as the rhizosphere (i.e. P. aeruginosa, P. fluorescens, and P. putida), where they can act as plant growth-promoting rhizobacteria by antagonizing plant-deleterious microorganisms and through the production of traits that directly influence plant disease resistance and growth (Venturi, 2006). The rhizospheric P. putida plant beneficial strain WCS358 and IsoF produce 3-oxo-C12-AHL, whereas in the rhizosphere-colonizing biocontrol P. fluorescens strain F13, the production of three AHL molecules, including C10-AHL, has been reported (Laue et al., 2000; Venturi, 2006). Interestingly, C10-AHL and C12-AHL seem to be also produced in the nitrogen-fixing bacterial symbiont Sinorhizobium meliloti (Marketon et al., 2002; Teplitzki et al., 2003). The marked resistance of drr1 to C10-AHL on root development opens new possibilities to identify novel genetic determinants involved in plant-bacteria interactions. Furthermore, the drr1 mutant can be used as a tool to identify novel plant growth-promoting bacterial strains, which could modulate root system architecture through AHL production.

Two recent reports suggested that auxin signaling might be involved in plant responses to AHLs (Mathesius et al., 2003; Von Rad et al., 2008). Auxins are signaling molecules that regulate the asymmetric pericycle cell divisions and thereby influence the patterning of newly initiated LRP. Thus, the possibility was open that altered auxin responses could be responsible for reduced LR formation in drr1 mutants. Our results, however, showed that drr1 mutants are not resistant to IAA or NAA treatments in terms of primary root growth inhibition or LR formation (Figs. 6 and 7), indicating that DRR1 might not be directly connected to the auxin response pathway to modulate plant growth and development. These results are in agreement with our previous research showing that both alkamides and AHLs modulate root system architecture, likely through auxin-independent signaling mechanisms (Ramirez-Chavez et al., 2004; Campos-Cuevas et al., 2008; Ortiz-Castro et al., 2008).

### DRR1 Plays a Role in Senescence-Related Processes

Senescence is a developmental process that limits the longevity of an organism. Genetic studies of longevity mutants have also suggested that some common mechanisms, such as alterations in energy metabolism and oxidative damage, might play a role in determining life span in animals as divergent as nematodes, Drosophila, and mammals (Lin et al., 1998; Parkes et al., 1998). Plants also undergo a distinctive senescence process at the organ and/or organism level. A number of studies have provided evidence suggesting that leaf senescence is an active process controlled by a genetic program (Woo et al., 2001, 2002, Schommer et al., 2008). However, our understanding of how senescence and longevity are controlled at the whole plant level remains quite limited. Our results suggest that LR development and age-dependent plant senescence are directly connected through DRR1. Obvious alterations were seen in drr1 plants grown in soil under long days (16-h-light/8-h-dark conditions). In drr1 plants, leaf senescence was delayed by about 4 to 5 weeks when compared with wild-type plants (Figs. 8 and 9). The extended longevity of leaves was related to an extended growth period as well as to slower onset and/or progression of senescence after the maturation stage. The reduced growth observed at early stages of development in drr1 mutants opens the possibility that it may contribute to extended longevity. Consistent with this hypothesis, we observed that reduced LR formation was not caused by the failure of the pericycle to produce these structures but by the retarded development of LRP to emerge from the primary root (Fig. 4).

In this way, the drr1 mutation shows a senescence character that differs from the delayed leaf senescence phenotype described in the oreesara (ore) and teosinte branched/cycloidea/PCF (tcp) mutants previously (Woo et al., 2001, 2002; Schommer et al., 2008). In ore mutants, the retarded senescence phenotype seems to be specifically observed in leaves. For instance, the leaf longevity in ore9-1 was extended only by about 27%, without affecting other developmental traits such as flowering time and/or plant size (Woo et al., 2001). To our knowledge, no LR phenotypes have been reported for leaf senescence mutants such as the ore and tcp lines. Interestingly, the drr1 mutants also show that...
plants that bolt and senesce late produce more leaves and increase in size (Figs. 8 and 9), which could lead to potential agricultural applications. Together, our findings suggest that DRR1 may function normally as a positive regulator of senescence in Arabidopsis, limiting longevity at the whole plant level. Because the drr1 mutation affects a wide variety of age-dependent developmental and senescence responses (Fig. 10), DRR1 may function upstream in the regulatory cascade of senescence pathways.

drr1 Mutants Reveal Cross Talk between Alkamides and Jasmonate in LR Formation

Cross-resistance of mutants to multiple hormones is well documented (Wilson et al., 1990; Hobbie and Estelle, 1994; Tiryaki and Staswick, 2002) and suggests that the action of hormones is coordinated by common intermediates or modulators. Several phytohormones are involved in leaf senescence, including ethylene, cytokinin, and JA (Schommer et al., 2008). High concentrations of N-isobutyl decanamide have been found to induce callus formation in leaves and in roots (López-Bucio et al., 2007). Although not explicitly tested here, preliminary information shows that drr1 plants are also resistant to callus formation (data not shown). The proliferative growth activity elicited by N-isobutyl decanamide on callus formation in leaves and LR formation in roots was previously shown to be decreased or even absent in Arabidopsis mutants lacking one, two, or three of the putative cytokinin receptors CRE1, AHK2, and AHK3 (López-Bucio et al., 2007). The triple cytokinin receptor mutant cre1-12/ahk2-2/ahk3-3 was particularly insensitive to high alkamide concentrations in terms of developmental alterations, indicating that N-isobutyl decanamide requires, at least in part, a functional cytokinin-signaling pathway to control meristematic activity and differentiation processes. However, the primary root growth response of the drr1 mutants to kinetin, a highly active cytokinin in modulating root development, was similar to that observed in wild-type plants (Supplemental Fig. S2A), indicating that drr1 is not resistant to root inhibition by cytokinin. However, we cannot exclude the possibility that cross talk between alkamide and cytokinin responses may account for the increased longevity and/or reduced senescence of drr1 mutants. Abscisic acid and ethylene are two growth regulators also involved in senescence; DRR1 mutation rendered the drr1 seedlings more sensitive to the primary root growth inhibitory effect of low abscisic acid concentrations than wild-type seedlings (Supplemental Fig. S2B), whereas the ethylene precursor 1-aminoacyclopropane-1-carboxylic acid similarly inhibited growth (Supplemental Fig. S2C).

The plant hormone JA plays a key role in the environmental stress responses and developmental processes of plants. A recent report has revealed an important role of JA in LR development. In such work (Sun et al., 2009), it was shown that exogenous MeJA promotes LR formation in Arabidopsis wild-type plants but not in anthranilate synthase1 mutants, leading to the proposal that localized auxin biosynthesis in response to jasmonate could be important for fine-tuned modulation of LR formation. Our detailed morphological comparison among wild-type, drr1, and jar1 plants indicated that, when grown on JA-free medium, LR development in drr1 was significantly lower than in wild-type or jar1 plants. Interestingly, while JA application led to increased LR numbers in wild-type and jar1 plants, it failed to activate LR formation in drr1 (Fig. 11; Supplemental Fig. S1). Comparison of the primary root response to JA also showed that drr1 behaves essentially different from jar1, which was very insensitive to primary root growth inhibition by JA but responded similarly to wild-type plants in LR induction by this compound. Therefore, drr1 shows alkamide resistance in terms of primary and LR growth, whereas it has resistance to jasmonate in LR formation only. Taking into account these results, it is tempting to speculate that further cross talk of alkamide signaling with phytohormones such as cytokinins or jasmonates might vary in different tissues or in a developmental context, possibly explaining why drr1 mutants exhibit no defects in primary root growth inhibition assays to these phytohormones.

In summary, we have provided evidence that alkamide and AHL signaling are under genetic control in Arabidopsis and that normal responses to these signals are important for plant development. Elucidation of the genetic identity of the DRR1 product is critical to understand the molecular mechanisms underlying the distinct effects of these and other small lipid signals on root architecture adjustment and their role in plant longevity.

MATERIALS AND METHODS

Plant Material and Growth Conditions

Arabidopsis (Arabidopsis thaliana) wild-type plants (Col-0 and/or Ws ecotypes), the transgenic line CoCB1uidA (Colón-Carmona et al., 1999), and the mutant lines jar1 (Tiryaki and Staswick, 2002), axr2-1 (Timpte et al., 1994), and aux1-7 (Picket et al., 1990) were used for all experiments. Seeds were surface sterilized with 95% (v/v) ethanol for 5 min and 20% (v/v) bleach for 7 min. After five washes with sterile distilled water, seeds were germinated on agar plates containing 0.2× MS medium (Murashige and Skoog, 1962). MS medium (MS basal salts mixture; catalog no. M5524) was purchased from Sigma. The suggested formulation is 4.3 g L⁻¹ salts for a 1× concentration of medium; we used 0.9 g L⁻¹, which we consider and refer to as 0.2× MS. This medium lacks amino acids and vitamins. Phytagar (micro-propagation grade) was purchased from Phenotypech. Plants were placed in a plant grown chamber (Percival Scientific AR-95L) with a photoperiod of 16 h of light and 8 h of darkness, light intensity of 100 μmol m⁻² s⁻¹, and temperature of 22°C.

Mutant Isolation Procedure

T-DNA lines (Ws; Krysan et al., 1999) were provided by the Ohio Arabidopsis Seed Stock Center. Seeds were surface sterilized and plated on 0.2× MS medium supplied with 30 μM N-isobutyl decanamide. A number of approximately 25,000 T-DNA lines were screened for reduced LR formation.
by placing seeds on nutrient agar plates (20–25 seeds per plate). The seeds were distributed in two rows on the agar surface at a density of one seed per centimeter, stratified at 4°C for 48 h, and then incubated at 22°C. Fourteen days after germination, N-isobutyl decanamide-treated plants have a short primary root and a large number of LRs are formed. Putative mutants with long primary roots and a reduced number of LRs were selected, transferred to soil, and allowed to self-fertilize. Homozygous M3 seeds were re-screened for sustained primary root growth in medium supplied with 30 μM N-isobutyl decanamide, transferred to soil, and backcrossed three times to the wild type (Ws) to remove unlinked mutations.

**Genetic Analysis of drr1 Mutants**

To determine the segregation pattern of the drr1 phenotype, 990 F2 seedlings derived from the cross drr1 × Ws were analyzed in MS 0.2× agar medium supplied with 30 μM N-isobutyl decanamide. A typical 3:1 recessive segregation was observed for the wild-type/drr1 phenotype. Cosegregation of primary root growth resistance and increased longevity was further confirmed in drr1 seedlings grown in soil.

**Hormone Treatments**

For all experiments, MS 0.2× nutrient medium was supplemented with N-isobutyl decanamide, C10-AHL, or the indicated phytohormones. Ethanol-dissolved compounds were added to cooled (50°C) molten medium and poured onto plates. Control plates were supplied with the greatest concentration of solvent used in the treatments. For hormone-induced senescence, leaves at 22 d after leaf emergence were detached and floated on sterilized water in the presence or absence of 35 μM JA or 35 μM N-isobutyl decanamide for 6 d. All treatments were performed at 22°C under dark conditions. Chemicals were purchased from Sigma Chemical.

**Analysis of Growth and Statistical Analysis**

Growth of primary roots was registered using a rule. LR number and LR density were determined by counting the LRs present in the primary root from the tip to the root/stem transition. LR density was determined by dividing the LR number by the primary root length and expressed as LR density per centimeter. The length of the meristem was determined as the distance between the quiescent center and the cell file where cells started to elongate. For all experiments, the overall data were statistically analyzed in the SPSS 10 program (SPSS). Univariate and multivariate analyses with a Tukey’s posthoc test were used for testing differences in growth and root developmental responses in wild-type and mutant lines. Different letters are used to indicate means that differ significantly (P < 0.05).

**Determination of Developmental Stages of LRP**

LRP were quantified at day 4 after germination. Seedling roots were first cleared to enable LRP at early stages of development to be visualized and counted. Each LR primordium was classified according to its stage of development as reported by Malamy and Beney (1997). The developmental stages are as follows. Stage I, LRP initiation; in the longitudinal plane, approximately eight to 10 “short” pericycle cells are formed. Stage II, the formed LR primordium is divided into two layers by a periclinal division. Stage III, the outer layer of the primordium divides periclinally, generating a three-layer primordium. Stage IV, LR primordium with four cell layers. Stage V, the LR primordium is midway through the parent cortex. Stage VI, the LR primordium has passed through the parent cortex layer and has penetrated the epidermis. It begins to resemble the mature root tip. Stage VII, the LR primordium appears to be just about to emerge from the parent root.

**Chlorophyll Determination**

We used leaves from wild-type (Ws) and drr1 plants germinated and grown on 0.2× MS medium and then transferred to soil for 35 d. Wild-type leaves were yellowed as a result of age-dependent senescence; drr1 leaves remained green at this stage. We used a hand-held chlorophyll meter (CCM-200; Opti-Sciences) to calculate a chlorophyll content index based on absorbance measurements at 660 and 940 nm on 15 independent leaves. Five separate measurements with the hand-held meter were made on each leaf. Chlorophyll content was finally determined as described previously (Richardson et al., 2002).

**Histochemical Analysis of GUS Activity**

Transgenic plants that express the uidA reporter gene (Jefferson et al., 1987) were stained in 0.1% 5-bromo-4-chlorium-3-indolyl-β-D-glucuronic acid in phosphate buffer (NaH₂PO₄ and Na₂HPO₄, 0.1 M, pH 7) with 2 mM potassium ferrocyanide and 2 mM potassium ferricyanide for 12 h at 37°C. Plants were cleared and fixed as described previously by Malamy and Beney (1997). The processed roots were included in glass slips and sealed with commercial nail varnish. For each marker line and for each treatment, at least 10 transgenic plants were analyzed.

**Microscopy**

The Arabidopsis root system was analyzed with a stereoscopic microscope (MZ6; Leica Microsystems). Total LRs were counted at 30× magnification. Primary root meristems were analyzed in semipermanent preparations of cleared roots using a composed microscope (Axioskop Zeiss Plus; Carl Zeiss) at 100× or 400× magnification. Images were captured with a Cyber-shot DSC-S75 digital camera (Sony Electronics) adapted to the microscope and processed with the Axio Vision 4.1C software (Carl Zeiss).

**Supplemental Data**

The following materials are available in the online version of this article.

**Supplemental Figure S1.** drr1 shows defective LR formation in response to JA treatment.

**Supplemental Figure S2.** Effects of kinetin, abscisic acid, and ethylene on primary root growth in wild-type and drr1 plants.

**ACKNOWLEDGMENTS**

We thank Peter Doerner, Angel Arturo Guevara-García, and Plinio Guzmán for kindly providing us with seeds of transgenic and mutant lines. We gratefully acknowledge Jorge Molina-Torres and Enrique Ramírez-Chávez for kindly providing us N-isobutyl decanamide.

Received October 24, 2009; accepted January 20, 2010; published January 27, 2010.
