Abstract
We perform the first reflection study of the soft X-ray transient and Type 1 burst source XTE J1709-267 using NuSTAR observations during its 2016 June outburst. There was an increase in flux near the end of the observations, which corresponds to an increase from \( \sim 0.04 \text{L}_{\text{Edd}} \) to \( \sim 0.06 \text{L}_{\text{Edd}} \) assuming a distance of 8.5 kpc. We have separately examined spectra from the low- and high-flux intervals, which are soft and show evidence of a broad Fe K line. Fits to these intervals with relativistic disk reflection models have revealed an inner-disk radius of \( 13.8^{+3.0}_{-1.8} \text{R}_e \) (where \( \text{R}_e = GM/c^2 \)) for the low-flux spectrum and \( 23.4^{+15.6}_{-13.4} \text{R}_e \) for the high-flux spectrum at the 90% confidence level. The disk is likely truncated by a boundary layer surrounding the neutron star (NS) or the magnetosphere. Based on the measured luminosity and the accretion efficiency for a disk around an NS, we estimate that the theoretically expected size for the boundary layer would be \( \sim 0.9–1.1 \text{R}_e \) from the NS’s surface, which can be increased by spin or viscosity effects. Another plausible scenario is that the disk could be truncated by the magnetosphere. We place a conservative upper limit on the strength of the magnetic field at the poles (assuming \( a_g = 0 \) and \( M_{\text{NS}} = 1.4M_\odot \)) of \( B \leq 0.75 - 3.70 \times 10^{15} \text{ G} \), though X-ray pulsations have not been detected from this source.

Key words: accretion, accretion disks – stars: individual (XTE J1709-267) – stars: neutron – X-rays: binaries

1. Introduction
XTE J1709-267 is a recurrent soft X-ray transient and Type 1 burst source that has a recurrence time of 2–3 years (Markwardt & Swank 2004; Remillard 2007; Negoro et al. 2010, 2013; Sanchez-Fernandez et al. 2012). The source was first discovered to be in outburst in 1997 (Marshall et al. 1997) and is associated with the globular cluster NGC 6293 (Jonker et al. 2004b). It is located at a distance of 8.5 kpc (Lee & Carney 2006). The typical 2–10 keV flux during outburst is \( \sim 2 \times 10^{-5} \text{ erg cm}^2 \text{ s}^{-1} \) (Marshall et al. 1997; Cocchi et al. 1998; Jonker et al. 2003; Jonker et al. 2004a, 2004b; Markwardt & Swank 2004; Remillard 2007; Degenaar et al. 2013).

Broad iron line profiles have been seen in low-mass X-ray binaries (LMXBs) that contain a neutron star (NS) as the primary accreting compact object (e.g., Bhattacharyya & Strohmayer 2007; Cackett et al. 2008, 2009, 2010; Papitto et al. 2008; Di Salvo et al. 2009; Egron et al. 2013; Miller et al. 2013). The effects of the gravitational redshift and Doppler shift/boosting are imprinted on these emission lines. These relativistic effects become stronger closer to the compact object (Fabian et al. 1989). Hence, the profile of the Fe Kα line gives a direct measure of the position of the inner disk. Furthermore, since the disk must be truncated at or before the surface of the star, the Fe Kα line can be used to set an upper limit for the radius of the NS (Cackett et al. 2008, 2010; Reis et al. 2009; Miller et al. 2013; Degenaar et al. 2015).

Two likely scenarios for disk truncation above \( \sim 1\% \text{L}_{\text{Edd}} \) are (1) a pressure balance between the accreting material and the NS’s magnetic field and (2) the boundary layer extending from the surface of the NS, thereby impeding the disk. Thus, studies of disk reflection can also be used to set an upper limit on the magnetic field strength (Cackett et al. 2009; Papitto et al. 2009; Miller et al. 2011; Degenaar et al. 2014, 2016; King et al. 2016; Ludlam et al. 2016) or the extent of the boundary layer (Ibragimov & Poutanen 2009; Chiang et al. 2016; King et al. 2016; Ludlam et al. 2016).

MAXI/GSC registered that XTE J1709-267 had renewed activity in 2016 May 31 (Nakahira et al. 2016). We obtained two \( \sim 20 \text{ ks} \) observations with NuSTAR (Harrison et al. 2013) during this outburst while the source was in the soft state. We detect a broad Fe Kα line that we model as relativistic reflection to determine the extent of the inner accretion disk and measure the inclination. There are no previous Fe K detections for this source, making this the first detailed reflection analysis.

2. Observations and Data Reduction
NuSTAR observations of XTE J1709-267 were taken on 2016 June 8 (Obsids 90201025002 and 90201025003). There are two detectors aboard NuSTAR that collect data: focal plane module A (FPMA) and focal plane module B (FPMB). Light curves and spectra were created using a 120° circular extraction region centered around the source using the NUPRODUCTS tool from NUSTARDAS v1.5.1 with CALDB 20160421. A background was generated and subtracted using another region of the same dimension away from the source. There were no Type 1 X-ray bursts present in the light curves, but there was an increase in count rate near the end of the second observation (see Figure 1). We created gti files in order to separate the observation by low and high count rates. Preliminary modeling of the spectra with a simple continuum multiplied by a cross-normalization constant was performed to determine how well the detectors agree with each other. We fixed the constant to unity for the FPMA and allowed it to float for the FPMB. The floating constant was found to be within 0.95–1.05 in each
case. We proceeded to combine the two source spectra, background spectra, and ancillary response matrices via ADDASCASPEC. We used ADDRMF to create a single redistribution matrix file. We then combined the two observations of the same count rate as per King et al. (2016), which resulted in a total combined exposure time of ~62 ks for the spectrum for the lower-flux regime and ~15 ks for the spectrum generated from the higher flux. We hereafter refer to these spectra as the low and high spectra. The spectra were grouped using GRPPHA to have a minimum of 25 counts per bin.

3. Spectral Analysis and Results

We used XSPEC version 12.9.0 (Arnaud 1996) in this work with all errors quoted at the 90% confidence level. Errors were calculated from a Monte Carlo Markov chain of a length of 100,000. We performed fits over the 3.0–300.0 keV energy range. Above 30 keV, the spectra are background dominated. We accounted for the equivalent neutral hydrogen column density along the line of sight via TBNEWER. We fixed the absorption column to the Dickey & Lockman (1990) value of 0.237 \times 10^{22} \text{ cm}^{-2} (consistent with previous spectral studies of this source; e.g., Jonker et al. 2003, Degenaar et al. 2013), since NuSTAR lacks the lower-energy bandpass to constrain this on its own.

Initial fits were performed with an absorbed single-temperature blackbody component (BBODYRAD) to model the corona or boundary layer and a multi-temperature blackbody (DISKKBB) to account for the accretion disk emission. This combination of models gave a particularly poor fit in each case ($\chi^2_{\text{low}}$/dof = 1873.69/672 & $\chi^2_{\text{high}}$/dof = 954.38/670), partly owing to the presence of strong disk reflection features in the spectrum. We added a power-law component with the photon index bound at an upper limit of 4.0, which has been observed in astrophysical sources such as black hole (BH) X-ray novae (Sobczak et al. 2000; Park et al. 2004). The addition of a power-law component improved the overall fit for the low-flux case by $\Delta\chi^2_{\text{low}} = 350$ for 4 dof (an 11σ improvement). This continuum model is in agreement with the framework laid out by Lin et al. (2007) for NS transients in the soft state, though they use a broken power-law component instead. The additional power-law component was not statistically necessary in the high-flux state; therefore, we did not use it in that case. The reflection is still unaccounted for by these models. Figure 2 shows an asymmetric Fe K emission line, commonly associated with relativistic disk reflection. The red wing extends down to ~5 keV, while the blue wing drops at ~7 keV.

The REFLIONX (Ross & Fabian 2005) model describes reflection from an ionized disk. We included a modified version that assumes the disk is illuminated by a blackbody rather than a power law. To account for relativistic Doppler shifts and gravitational redshifts, we convolved REFLIONX with RELCONV (Dauser et al. 2010). The parameters of REFLIONX are as follows: ionization parameter ($\xi$), temperature of the incident blackbody in keV ($kT$), iron abundance ($A_{\text{Fe}}$), redshift ($z$), and...
normalization. The parameters of RELCONV are as follows:\hfill
inner emissivity index \(q_{\text{in}}\), outer emissivity index \(q_{\text{out}}\),\hfill dimensionless spin parameter \(a_* (a_* = c_f / GM^2)\) in the model RELCONV to 0 in the subsequent fits since NSs in LMXBs have \(a_* \lesssim 0.3\) (Galloway et al. 2008; Miller et al. 2011). Corrections for frame-dragging for \(a_* < 0.3\) give errors \(\ll 10\%\) (Miller et al. 1998) since the position of the ISCO is nearly constant for values of low spin. Therefore, this did not hinder our estimate of the inner-disk radius. Further, the outer-disk radius was fixed to 400 \(R_g\) (where \(R_g = GM/c^2\)).

Lastly, we tied the outer emissivity index \(q_{\text{out}}\) to the inner emissivity index \(q_{\text{in}}\) to create a constant emissivity index. We were unable to constrain the inner-disk radius versus the inclination space when allowing the emissivity index to be a free parameter. We fixed \(q = 3\), as would be expected for a disk in a flat, Euclidean geometry illuminated by a point source (see Wilkins & Fabian 2012 for a review). Additionally, different plausible geometries for illuminating the disk around NSs, such as boundary layers or hot spots, appear to produce the same \(r^{-3}\) emissivity profile (D. Wilkins 2017, private communication). Since the accretion disks surrounding NSs do not undergo extreme relativistic effects, such as those around maximally spinning BHs, we did not expect steeper emissivity profiles. A shallower profile like \(r^{-2}\) has been postulated based on self-consistent MHD simulations for extended coronal emission surrounding a BH and relies solely on mass, the spin, and the mass accretion rate (Kinch et al. 2016). However, the shallower profile may strongly depend on the specific set of parameters that were input into the simulation \((M_{\text{BH}} = 10 M_\odot, a_* = 0, \text{and the mass accretion rate at 1\% of the Eddington limit})\), and thus may not be directly translatable to NSs.

The overall model we used for the low-flux spectrum was TBNEWER('DISKBB+BBODY+POW+RELCONV\#REFLIONX'). This model provided a better fit with \(\chi^2_{\text{low}}/\text{dof} = 622.6/663\). This is a \(\sim 21\sigma\) improvement over the model that does not take disk reflection into account for each case. The overall model we used for the high-flux spectrum was TBNEWER('DISKBB+BBODY+RELCONV\#REFLIONX'). This model provided an improvement of \(\geq 15\sigma \left(\chi^2_{\text{high}}/\text{dof} = 652.51/665\right)\). The parameters and values can be seen in Table 1. Figure 3 shows the best-fit spectra.

For the low-flux case, the DISKBB component has a temperature of \(kT = 1.64_{-0.03}^{+0.04}\) keV and a normalization \(= 4.9 \pm 0.4 \text{ km}^2/100 \text{ km}^2\). The BBODYRAD component has a temperature of \(kT = 2.44_{-0.02}^{+0.03}\) keV and a normalization \(= 0.36_{-0.07}^{+0.07} \text{ km}^2/100 \text{ km}^2\). The blackbody and disk blackbody normalizations are implausibly small, but this is understood to be the result of spectral hardening in atmospheres above pure blackbody emission (London et al. 1986; Shimura & Takahara 1995; Merloni et al. 2000). The power law may or may not be physical but is still needed at the 8\(\sigma\) level. It has a steep photon index of \(\Gamma = 3.99_{-0.30}^{+0.39}\) with a normalization of \(0.32_{-0.05}^{+0.05} \text{ cm}^{-2} \text{s}^{-1} \text{ keV}^{-1}\). The inner-disk radius is truncated at \(R_{\text{in}} = 13.8_{-1.8}^{+1.0} R_g\), and the inclination was found to be \(25.2_{-2.6}^{+2.6}\)°.

For the high-flux case, the DISKBB component has a temperature of \(kT = 1.76_{-0.04}^{+0.05}\) keV and a normalization \(= 1 \pm 1 \text{ km}^2/100 \text{ km}^2\). The BBODYRAD component has a temperature of \(kT = 2.44 \pm 0.04\) keV and a normalization of \(0.7_{-0.3}^{+0.5} \text{ km}^2/100 \text{ km}^2\). The inner-disk radius is truncated further out at \(R_{\text{in}} = 23.4_{-15.6}^{+15.6} R_g\), though it is consistent with the value found in the low-flux state at the 3\(\sigma\) level. The inclination is \(29_{-10}^{+10}\)°, which also agrees with what is found in the low-flux spectrum.

We found the iron abundance to be \(A_{\text{Fe}} = 0.5\)\text{–}1.6. The low abundance for this source is likely due to its association with a globular cluster. Globular clusters tend to host older populations of stars and therefore have lower metallicity. Lee & Carney (2006) find the metallicity in NGC 6293 is \(\sim 1/100\) of the solar abundance. We were unable to explore a lower iron abundance due to the hard lower limit of the model \((A_{\text{Fe}} = 0.5)\); however, anomalously high iron abundances have been observed in many other reflection studies (e.g., Walton et al. 2014, 2016; García et al. 2015; Parker et al. 2015, 2016; Fürerst et al. 2016). It is possible that this high \(A_{\text{Fe}}\) measurement correctly describes the atmosphere of the accretion disk and not the overall abundances within the accretion flow, due to the ionization structure skewing the relative abundances there. Furthermore, the overabundance found in our fits may be the result of effects from dense gas in the disk that is not accounted for by current models. This would cause the abundance to increase to replicate the continuum for a lower-density disk that is allowed by the atomic data set within current reflection models (see García et al. 2016 for more details).

| Component | Parameter | Low | High |
|-----------|-----------|-----|------|
| TBNEWER   | \(N_0 (10^{22})\) | 0.237 | 0.237 |
| DISKBB    | \(kT\) | 1.64_{-0.03}^{+0.04} | 1.76_{-0.04}^{+0.05} |
| BBODYRAD  | \(kT\) | 1.64_{-0.03}^{+0.04} | 1.76_{-0.04}^{+0.05} |
| POW LAW   | \(\Gamma\) | 2.3_{-0.3}^{+0.5} | 2.4_{-0.4}^{+0.5} |
| RELCONV   | \(q_{\text{in}}\) | 3.0 | 3.0 |
| REFLIONX  | \(R_g (\text{ISCO})\) | 13.8_{-1.8}^{+1.0} | 23.4_{-15.6}^{+15.6} |
|           | \(R_{\text{out}} (R_g)\) | 400 | 400 |
| \(\chi^2_{\text{dof}}\) | | 622.6 (663) | 652.5 (665) |

**Note.** Errors are quoted at the 90\% confidence level. The absorption column density was fixed to the Dickey & Lockman (1990) value and is given in units of \(\text{cm}^{-2}\). The power-law index was bounded by an upper limit of 4.0. The REFLIONX model used was modified for a blackbody illuminating the accretion disk. The blackbody temperature was tied to the temperature used to model the continuum emission. The iron abundance \(A_{\text{Fe}}\) had a hard lower limit of 0.5. Flux is given in units of \(10^{-9} \text{ erg cm}^{-2} \text{ s}^{-1}\). Luminosity was calculated at a distance of 8.5 kpc and is given in units of \(10^{37} \text{ erg s}^{-1}\). For reference, 1 ISCO = 6 \(R_g\) for \(a_* = 0\).

Ludlam et al.

Figure 3. XTE J1709-267 low (top) and high (bottom) spectrum fit at 3.0–30.0 keV with DISKBB (red dashed line), BLACKBODY (purple three-dot-dash line), and the modified version of REFLIONX (blue dotted-dash line), which assumes an input blackbody spectrum. For the low-flux spectrum, an additional power-law component (orange dotted line) was needed. The lower panel shows the ratio of the data to the model. Table 1 lists the parameter values. The data were rebinned for plotting purposes.

Figure 4. Contour plot for inner-disk radius vs. inclination at the 68%, 90%, and 99% confidence levels for the low-flux (black) and high-flux (red) portions of the observations. The best-fit values are denoted with a cross for the low flux and a circle for the high flux.

4. Discussion

We have performed a spectral analysis of the soft X-ray transient XTE J1709-267 during its 2016 outburst. This is the first report and analysis of a broad Fe-Kα line in this source. Our observations capture a change in flux emitted from the source, which we separate into low- and high-flux spectra. We find the disk to be truncated at $13.8^{+3.0}_{-1.8} R_g$ (90% confidence level) in the lower-flux spectrum. The disk appears to move outward to $23.4^{+5.6}_{-5.0} R_g$ during the higher-flux state but is consistent with the low-flux results at the 3σ level. The unabsorbed 0.5–50.0 keV flux at the time of observation started at $2.0 \times 10^{-9}$ erg cm$^{-2}$ s$^{-1}$ and increased to $2.6 \times 10^{-9}$ erg cm$^{-2}$ s$^{-1}$, which is consistent with the typical flux observed during outbursts (Marshall et al. 1997; Cocchi et al. 1998; Jonker et al. 2003, 2004a, 2004b; Markwardt & Swank 2004; Remillard 2007; Degenaar et al. 2013). Additionally, we find a low inclination of $22^\circ-39^\circ$. There are no previous estimates of the inclination for this system. The disk is likely truncated by a boundary layer surrounding the NS or the magnetosphere.

Popham & Sunyaev (2001) lay out the Newtonian framework for boundary layer behavior for different mass accretion rates. We estimate the mass accretion rate for XTE J1709-267 to be $1.5 \times 10^{-9} M_\odot$ yr$^{-1}$ for the lower-flux portion and $1.9 \times 10^{-9} M_\odot$ yr$^{-1}$ for the higher flux from the 0.5–50.0 keV unabsorbed luminosity and with an efficiency of $\eta = 0.2$ (Sibgatullin & Sunyaev 2000). Using Equation (25) in Popham & Sunyaev (2001), we estimate that the boundary layer extends from the surface of the NS out to $\sim 0.9$–1.1 $R_g$ (assuming $1.4 M_\odot$). Additional factors, such as the spin and viscosity in the layer, can extend this region to be consistent with the inner edge of the accretion disk that we measured from our reflection analysis in low flux. However, this would not be consistent with the larger inner-disk radius from the high-flux spectrum.

XTE J1709-267 had a relatively low Eddington fraction ($\sim 0.04$–0.06) during the time of observation. The truncation of the disk could be due to a pressure balance between the magnetic field and accretion in the disk. We can place an upper limit on the strength of the field using the upper limit of $R_m = 16.8 R_g$ from the low-flux spectrum. Assuming a mass of $1.4 M_\odot$, taking the distance to be 8.5 kpc, and using the unabsorbed flux from 0.5 to 50.0 keV of $2.0 \times 10^{-9}$ erg cm$^{-2}$ s$^{-1}$ as the bolometric flux, we can determine the magnetic dipole moment $\mu$ from Equation (1) of Cackett et al. (2009), which was adapted from Ibragimov & Poutanen (2009). If we assume an angular anisotropy $f_{\text{ang}}$ and conversion factor $k_A$ of unity, as well as an accretion efficiency of $\eta = 0.2$, then $\mu \approx 3.7 \times 10^{26}$ G cm$^3$. This corresponds to a magnetic field strength of $B \approx 7.5 \times 10^8$ G at the magnetic poles for an NS of 10 km. The magnetic field strength at the pole is twice as strong as that at the equator. This is within the range for...
magnetic field strength for accreting millisecond pulsars \((10^5-10^{10} \text{ G}; \text{ Mukherjee et al. } 2015\)). The high-flux solution gives a maximum magnetic field strength of \(B > 10^9 \text{ G}\) \((3.7 \times 10^9 \text{ G})\). However, no X-ray pulsations have been detected from this source, so there are no indications that the magnetic field has truncated the disk and channeled material to the magnetic poles.

Recent analyses of a similar nature have been done for \textit{NuSTAR} studies of the transient NS LMXBs 1RXS J180408.9-34205 (RXS J1804) and Aquila X-1 (Aql X-1). Ludlam et al. (2016) found the inner disk of RXS J1804 to be \(R_{\text{in}} \lesssim 11.1 R_g\) in the hard state. They find that a magnetic field strength of \(B \lesssim 0.3-1.0 \times 10^9 \text{ G}\) at the poles or a boundary layer that is about as large as the stellar radius is needed to truncate the disk at 11.1 \(R_g\). Degenaar et al. (2016) found similar estimates of the magnetic field strength \((B \lesssim 2 \times 10^8 \text{ G})\) and inner-disc radius \((R_{\text{in}} \lesssim 1.5 \text{ ISCO})\) while RXS J1804 was in the soft state. King et al. (2016) found a truncated disk at \(R_{\text{in}} = 15 \pm 3 R_g\) around Aql X-1. They estimate a boundary layer of \(R_B = 7.8 R_g\) (King et al. 2016) could be surrounding Aql X-1 giving the efficiency and mass accretion rate. However, if the disk were truncated not by a boundary layer but by the magnetosphere, they would obtain an upper limit on the magnetic field of \(B < 5 \pm 2 \times 10^8 \text{ G}\) (King et al. 2016). Both RXS J1804 and Aql X-1 had at least one Type 1 X-ray burst during their observation, suggesting that material was still reaching the surface.

5. Summary

Using \textit{NuSTAR}, we perform the first reflection study of the soft X-ray transient XTE J1709-267 during its 2016 June outburst. Our observations catch the source during a change in luminosity. We observe the source at a distance in a change in luminosity from 0.04 to 0.06 \(L_{\text{Edd}}\). We find the disk is truncated prior to the NS surface at a distance of \(13.8^{+3.0}_{-1.8} R_g\) at 0.04 \(L_{\text{Edd}}\) and up to \(23.4^{+15.6}_{-5.4} R_g\) at 0.06 \(L_{\text{Edd}}\). The disk is likely truncated by a boundary layer surrounding the NS. We estimate that the boundary layer extends from the surface out to \(\sim 0.9-1.1 R_g\) based on the mass accretion rate and efficiency of the disk. However, though viscosity and spin effects can increase the extent of the boundary layer, at a low Eddington fraction the boundary layer is not likely to halt the accretion disk at a large radius (i.e., at the large radius implied by the high-flux solution). An alternative explanation is that the disk is truncated by the magnetosphere. Conservative estimates place an upper limit on the magnetic field strength of \(B \lesssim 0.75 - 3.70 \times 10^9 \text{ G}\) at the magnetic poles, though XTE J1709-267 is not a known X-ray pulsar.

We thank the referee for their thoughtful comments that have led to the improvement of this work. R.M.L. would like to thank Fiona Harrison for the approval of the DDT that made this work possible. This research has made use of the NuSTAR Data Analysis Software, jointly developed by the ASI Science Data Center (Italy) and Caltech (USA). N.D. is supported by an NWO Vidi grant and a Marie Curie Intra-European Fellowship. E.M.C. gratefully acknowledges support from the National Science Foundation through CAREER award number AST-1351222.
