Abstract

We present our results on the $\gamma$-ray emission from interaction-powered supernovae (SNe), a recently discovered SN type that is suggested to be surrounded by a circumstellar medium (CSM) with densities $10^7 - 10^{12}$ cm$^{-3}$. Such high densities favor inelastic collisions between relativistic protons accelerated in the SN blast wave and CSM protons and the production of $\gamma$-ray photons through neutral pion decays. Using a numerical code that includes synchrotron radiation, adiabatic losses due to the expansion of the source, photon-photon interactions, proton-proton collisions and proton-photon interactions, we calculate the multi-wavelength non-thermal photon emission soon after the shock breakout and follow its temporal evolution until 100-1000 days. Focusing on the $\gamma$-ray emission at $> 100$ MeV, we show that this could be detectable by the Fermi-LAT telescope for nearby ($\lesssim 10$ Mpc) SNe with dense CSM ($> 10^{11}$ cm$^{-3}$).

1 Introduction

The interaction of the shock waves of young supernovae (SNe) with the circumstellar medium (CSM) is the main driving power of the observed thermal and non-thermal emission that is detected predominantly in radio and X-rays. The shocked CSM is heated to high temperatures ($\sim 10^7$ K), while the shock-accelerated electrons (primaries) emit synchrotron radiation that typically peaks in the radio bands. Together with electrons, protons of the CSM are also accelerated at the shock to multi-TeV/PeV energies (for a review see Blasi (2013)). Inelastic proton-proton ($pp$) collisions between the accelerated and non-relativistic protons of the shocked CSM lead to the production of pions ($\pi^+, \pi^-, \pi^0$), which further decay into lighter particles including $e^-e^+$ pairs (secondaries), neutrinos and $\gamma$-rays. Due to the small cross section for $pp$ collisions ($\sigma_{pp} \simeq 3 \times 10^{-26}$ cm$^2$), high CSM densities are required for a non-negligible contribution of secondary particles to the observed emission. Such conditions may be realized whenever a shock plunges through a dense stellar wind. As SNe occur in CSM with a wide range of densities, spreading over at least six orders of magnitude, they provide a promising testing ground for cosmic-ray (CR) acceleration theories through the detection of multi-messenger signatures produced by the secondary particles.
Although the smoking gun for CR acceleration in interaction-powered SNe would be the detection of high-energy neutrinos, a firm association of the IceCube events with one (or more) astrophysical candidate classes of sources is still lacking (e.g. Aartsen et al., 2015a,b). Yet, the radio synchrotron emission from secondary $e^-$ and the $\gamma$-ray emission from $\pi^0$ decays may be observable under certain conditions. Our preliminary semi-analytic estimates of the former are encouraging, as we have predicted observable features in the radio-mm spectra and light curves (Petropoulou et al., 2016).

Here, we present the first results of a theoretical investigation of the $\gamma$-ray emission in the energy band of Fermi-LAT. For this purpose, we have been developing an one-zone model for the time-dependent calculation of the multi-wavelength (MW) non-thermal emission in SNe with dense CSM, which makes testable predictions in the Fermi-LAT band. Ultimately, the model predictions can be used to probe CR acceleration in young SNe with dense CSM and, in particular, to indirectly estimate microphysical parameters, such as the (primary) electron-to-proton ratio $K_{ep}$ and the CR acceleration efficiency $\epsilon_p$.

2 Theoretical framework

The interaction of the freely-expanding SN ejecta with the CSM (modelled as an extended shell of matter) gives rise to two shock waves, i.e. a fast shock wave in the circumstellar material (forward shock) and a reverse shock in the outer parts of the SN ejecta. As long as the interaction between the SN ejecta and the CSM takes place within a region that is optically thick to Thomson scattering, the SN shock will be radiation-mediated and particle acceleration will be suppressed (e.g. Murase et al. 2011; Katz et al. 2011). For dense CSM environments the shock is expected to breakout in the progenitor wind (Weaver 1976); the previously radiation-mediated shock becomes collisionless and particle acceleration can, in principle, take place.

We assume that a fraction of the incoming particles (both electrons and protons) at the SN forward shock will be accelerated into a power-law distribution in energy (e.g. by the first order Fermi process (e.g. Axford et al., 1977; Bell, 1978)). In addition, the accelerated protons acquire a fraction $\epsilon_p$ of the incoming shock kinetic energy, while the shock-accelerated electron-to-proton ratio is $K_{ep} = 10^{-2} K_{ep,-2}$. The shock-accelerated protons are advected in the downstream region of the shock where they can interact with the thermal (non-relativistic) protons of the shocked CSM producing energetic pions. These, in return, decay into other secondary particles: $\pi^+ \to \mu^+ + \nu_\mu(\bar{\nu}_\mu)$, $\mu^+ \to e^+ + \nu_e(\bar{\nu}_e) + \nu_\mu(\bar{\nu}_\mu)$ and $\pi^0 \to 2\gamma$.

For a CSM mass density scaling as $\propto R^{-2}$ (e.g. Chevalier, 1982), the number density of the shocked CSM is written as $n(R) \approx 4n_{csm}(R) \approx 2 \times 10^{12} R_{14}^{-1.5} (R_{in}/R)^2 \text{cm}^{-3}$. Assuming that a fraction $\epsilon_B$ of the post-shock thermal energy density is magnetic, the strength of the magnetic field is estimated by $B(R) \approx 46 \epsilon_B^{1/2} (\beta_{-1,5}^{1/2})^{-1/2} R_{14}^{-1/2} (R_{in}/R)\alpha B$ G. Here, we introduced the notation $Q_x = Q/10^x$ in cgs units, $R_{in}$ is the effective inner radius of the CSM, i.e., the shock breakout radius, $\alpha_B = 1$ for a wind-like density profile and $\beta = v_{sh}/c$ where $v_{sh}$ is the forward shock velocity.

3 Numerical framework

We use the numerical code originally presented in Mastichiadis & Kirk (1995) which includes: synchrotron emission, inverse Compton scattering (ICS) on background photons and on synchrotron photons (i.e. synchrotron self-Compton), synchrotron self-absorption (SSA), photon-photon ($\gamma\gamma$) absorption and photohadronic ($p\gamma$) interactions. We expanded the original code by including two physical processes, namely $pp$ collisions and the adiabatic expansion of the source (for the relativistic
equivalent, see [Petropoulou & Mastichiadis, 2009]. The inclusion of secondary particle production by pp collisions was based on [Kelner et al., 2006].

4 Results

In Fig. 1 we present snapshots of the MW non-thermal emission of a fiducial SN Type IIn located at \( d_L = 5 \) Mpc (left panel). The radio (10\(^3\) GHz) and GeV \( \gamma \)-ray light curves are illustrated in the right panel. The parameters used for this indicative example are summarized below:

| Parameter                              | Symbol     | Default value |
|----------------------------------------|------------|---------------|
| Power-law index for the magnetic field profile | \( \alpha_B \) | 1             |
| Magnetic energy density fraction       | \( \epsilon_B \) | \( 10^{-4} \) |
| Accelerated proton energy fraction     | \( \epsilon_p \) | \( 3 \times 10^{-3} \) |
| Electron-to-proton ratio               | \( K_{e,p} \) | 0.01          |
| Proton injected luminosity (erg s\(^{-1}\)) | \( L_p \) | \( 10^{41} \) |
| Electron injected luminosity(erg s\(^{-1}\)) | \( L_e \) | \( 10^{59} \) |
| Power-law slope of the shock-accelerated particles | \( p \) | 2             |
| Maximum Lorentz factor                 | \( \gamma_{p,e,\text{max}} \) | \( 10^6 \) |
| Minimum Lorentz factor                 | \( \gamma_{p,e,\text{min}} \) | \( 10^{0.1} \) |
| Breakout radius (cm)                   | \( R_{\text{in}} \) | \( 10^{14} \) |
| Shock velocity at breakout radius      | \( v_s \) | \( 0.03c \) |
| Electron temperature of unshocked CSM (K) | \( T_e \) | \( 10^5 \) |

**Figure 1:** Left panel: Temporal evolution (for \( t \leq 10^{3.6}\) d \( \approx 11\) yr) of the MW non-thermal spectrum of a fiducial SN Type IIn at \( d_L = 5 \) Mpc. The radio emission is synchrotron self-absorbed at \( E \approx 10^{-5} \) eV, while the spectrum is dominated by the synchrotron emission of primary and secondary electrons up to \( E \approx 10 \) MeV. The \( \gamma \)-ray emission from \( \pi^0 \) decays extends from \( \approx 100 \) MeV up to \( E \approx 0.1 \) PeV for protons accelerated to \( \approx 1 \) PeV. The average MW spectrum predicted by the model for a time interval of 10 yr is overplotted with a blue line. Here, the radio emission does not include free-free absorption. The *Fermi*-LAT point-source sensitivity for a 10-yr exposure is depicted with red symbols ([link](http://www.slac.stanford.edu/exp/glast/groups/canda/lat_Performance.htm)). Right panel: Monochromatic light curves at 10\(^3\) GHz, 1 GeV, 10 GeV and 100 GeV. The radio light curve is calculated after taking into account the free-free absorption by thermal electrons of the unshocked CSM with \( T_e = 10^5 \) K. For display reasons, the GeV light curves are shifted upwards by a factor of 7 in logarithm. The early-time flattening of the \( \gamma \)-ray light curves is due to the \( \gamma\gamma \) absorption on the non-thermal synchrotron photons. The 10\(^3\) GHz emission peaks only after \( \approx 10 \) d due to the early-time free-free absorption. At later times the luminosity decays as a power-law, i.e., \( L_\nu \propto t^{-0.7} \) at 10\(^3\) GHz and \( L_\nu \propto t^{-1} \) at > 1 GeV.
5 Conclusions and outlook

We presented the temporal evolution of the non-thermal MW emission from interaction-powered SNe (e.g. Type II) while focusing on the γ-ray emission produced by pp collisions between the shock-accelerated protons and the non-relativistic protons of the CSM. We have shown that for sufficiently dense CSM ($n_{\text{csm}} > 10^{11}$ cm$^{-3}$) or for a nearby SN Type IIn ($d_L < 10$ Mpc), the γ-ray ($> 100$ MeV) emission would be detectable by Fermi-LAT. The non-detection of γ-rays from extragalactic interaction-powered SNe by the Fermi-LAT so far, can be thus used to constrain the CR acceleration efficiency. We have explicitly shown that the γ-ray emission ($\sim 100$ GeV) would be attenuated at early times (i.e. $< 10$ d) due to internal γγ absorption. The optical SN emission, which typically peaks several ($\gtrsim 10$ d) days after the shock break out, may also attenuate the $\sim 100$ GeV emission. We plan to include this in our numerical code by modelling the SN optical radiation as an external photon field of variable photon number density. Another significant process for producing γ-rays in such dense environments is the bremsstrahlung radiation of relativistic electrons. Although the results presented here do not include relativistic bremsstrahlung radiation, we plan to implement it in the code both as an energy loss process for electrons and a photon production process. We have also verified that the effect of pγ interactions upon the synchrotron photons is negligible. Yet, pγ interactions with the X-ray bremsstrahlung photons produced by the hot shocked plasma may be important for creating additional secondaries, especially at early times when the X-ray luminosity is high and the source is compact.
