Received: date / Accepted: date

Abstract We examine the squared error loss landscape of shallow linear neural networks. We show—with significantly milder assumptions than previous works—that the corresponding optimization problems have benign geometric properties: there are no spurious local minima and the Hessian at every saddle point has at least one negative eigenvalue. This means that at every saddle point there is a directional negative curvature which algorithms can utilize to further decrease the objective value. These geometric properties imply that many local search algorithms (such as the gradient descent which is widely utilized for training neural networks) can provably solve the training problem with global convergence.

Keywords deep learning · linear neural network · optimization geometry · strict saddle · spurious local minima

1 Introduction

A neural network consists of a sequence of operations (a.k.a. layers), each of which performs a linear transformation of its input, followed by a point-wise activation function, such as a sigmoid function or the rectified linear unit (ReLU) [37]. Deep artificial neural networks (i.e., deep learning) have recently led to state-of-the-art empirical performance in many areas including computer vision, machine learning, and signal processing [5,17,19,22,27,28,31].

One crucial property of neural networks is their ability to approximate nonlinear functions. It has been shown that even a shallow neural network (i.e., a network with only one hidden layer) with a point-wise activation function has the universal approximation ability [10,17]. In particular, a shallow network with a sufficient number of activations (a.k.a. neurons) can approximate continuous functions on compact subsets of \( \mathbb{R}^d_0 \) with any desired accuracy, where \( d_0 \) is the dimension of the input data.

However, the universal approximation theory does not guarantee the algorithmic learnability of those parameters which correspond to the linear transformation of the layers. Neural networks may be trained (or learned) in an unsupervised manner, a semi-supervised manner, or a supervised manner which is by far the most common scenario. With supervised learning, the neural networks are trained by minimizing a loss function in terms of the parameters to be optimized and the training examples that consist of both input objects and the corresponding outputs. A popular approach for optimizing or tuning the parameters is gradient descent with the backpropagation method efficiently computing the gradient [43].
Although gradient descent and its variants work surprisingly well for training neural networks in practice, it remains an active research area to fully understand the theoretical underpinnings of this phenomenon. In general, the training optimization problems are nonconvex and it has been shown that even training a simple neural network is NP-complete in general [4]. There is a large and rapidly increasing literature on the optimization theory of neural networks, surveying all of which is well outside our scope. Thus, we only briefly survey the works most relevant to ours.

In seeking to better understand the optimization problems in training neural networks, one line of research attempts to analyze their geometric landscape. The geometric landscape of an objective function relates to questions concerning the existence of spurious local minima and the existence of negative eigenvalues of the Hessian at saddle points. If the corresponding problem has no spurious local minima and all the saddle points are strict (i.e., the Hessian at any saddle point has a negative eigenvalue), then a number of local search algorithms [12,18,23,24] are guaranteed to find globally minimal solutions. Baldi and Hornik [2] showed that there are no spurious local minima in training shallow linear neural networks but did not address the geometric landscape around saddle points. Kawaguchi [20] further extended the analysis in [2] and showed that the loss function for training a general linear neural network has no spurious local minima and satisfies the strict saddle property (see Definition 4 in Section 2) for shallow neural networks under certain conditions. Kawaguchi also proved that for general deeper networks, there exist saddle points at which the Hessian is positive semidefinite (PSD), i.e., does not have any negative eigenvalues.

With respect to nonlinear neural networks, it was shown that there are no spurious local minima for a network with one ReLU node [11,42]. However, it has also been proven that there do exist spurious local minima in the population loss of shallow neural networks with even a small number (greater than one) of ReLU activation functions [36]. Fortunately, the number of spurious local minima can be significantly reduced with an over-parameterization scheme [36]. Soudry and Hoffer [39] proved that the number of sub-optimal local minima is negligible compared to the volume of global minima for multilayer neural networks when the number of training samples \( N \) goes to infinity and the number of parameters is close to \( N \). Haeffele and Vidal [15] provided sufficient conditions to guarantee that certain local minima (having an all-zero slice) are also global minima. The training loss of multilayer neural networks at differentiable local minima was examined in [38]. Yun et al. [44] very recently provided sufficient and necessary conditions to guarantee that certain critical points are also global minima.

A second line of research attempts to understand the reason that local search algorithms efficiently find a local minimum. Aside from standard Newton-like methods such as cubic regularization [32] and the trust region algorithm [6], recent work [12,18,23,24] has shown that first-order methods also efficiently avoid strict saddles. It has been shown in [23,24] that a set of first-order local search techniques (such as gradient descent) with random initialization almost surely avoid strict saddles. Noisy gradient descent [12] and a variant called perturbed gradient descent [18] have been proven to efficiently avoid strict saddles from any initialization. Other types of algorithms utilizing second-order (Hessian) information [1,7,9] can also efficiently find approximate local minima.

To guarantee that gradient descent type algorithms (which are widely adopted in training neural networks) converge to the global solution, the behavior of the saddle points of the objective functions in training neural networks is as important as the behavior of local minima. However, the former has rarely been investigated compared to the latter, even for shallow linear networks. It has been shown in [2,20,21,30] that the objective function in training shallow linear networks has no spurious local minima under certain conditions. The behavior of saddle points is considered in [20], where the strict saddle property is proved for the case where both the input objects \( X \in \mathbb{R}^{d_0 \times N} \) and the corresponding outputs \( Y \in \mathbb{R}^{d_2 \times N} \) of the training samples have full row rank, \( YX^T(XX^T)^{-1}XY^T \) has distinct eigenvalues, and \( d_2 \leq d_0 \). While the assumption on \( X \) can be easily satisfied, the assumption involving \( Y \) implicitly adds constraints on the true weights. Consider a simple case where \( Y = W_2^\star W_1^\top X \), with \( W_2^\star \) and \( W_1^\top \) the underlying weights to be learned. Then the full-rank assumption on \( YY^T = W_2^\star W_1^\top XX^T W_1^{\top \star} W_2^{\top \star} \) at least requires \( \min(d_0,d_1) \geq d_2 \) and \( \text{rank}(W_2 \hat{W}_1^\star) \geq d_2 \). Recently, the strict saddle property was also shown to hold without the above conditions on \( X, Y, d_0, \) and \( d_2 \), but only for degenerate critical points, specifically those points where \( \text{rank}(W_2 W_1) < \min\{d_2,d_1,d_0\} \) [33, Theorem 8].

In this paper we analyze the optimization geometry of the loss function in training shallow linear neural networks. In doing so, we first characterize the behavior of all critical points of the corresponding optimization
problems with an additional regularizer (see (2)), but without requiring the conditions used in [20] except the one on the input data $X$. In particular, we examine the loss function for training a shallow linear neural network with an additional regularizer and show that it has no spurious local minima and obeys the strict saddle property if the input $X$ has full row rank. This benign geometry ensures that a number of local search algorithms—including gradient descent—converge to a global minimum when training a shallow linear neural network with the proposed regularizer. We note that the additional regularizer (in (2)) is utilized to shrink the set of critical points and has no effect on the global minimum of the original problem. We also observe from experiments that this additional regularizer speeds up the convergence of iterative algorithms in certain cases. Building on our study of the regularized problem and on [33, Theorem 8], we then show that these benign geometric properties are preserved even without the additional regularizer under the same assumption on the input data. Table 1 summarizes our main result and those of related works on characterizing the geometric landscape of the loss function in training shallow linear neural networks.

Outside of the context of neural networks, such geometric analysis (characterizing the behavior of all critical points) has been recognized as a powerful tool for understanding nonconvex optimization problems in applications such as phase retrieval [35, 40], dictionary learning [41], tensor factorization [12], phase synchronization [29] and low-rank matrix optimization [3, 13, 14, 34, 35, 45, 46]. A similar regularizer (see (6)) to the one used in (2) is also utilized in [13, 25, 34, 45, 46] for analyzing the optimization geometry.

The outline of this paper is as follows. Section 2 contains the formal definitions for strict saddles and the strict saddle property. Section 3 presents our main result on the geometric properties for training shallow linear neural networks. The proof of our main result is given in Section 4.

### 2 Preliminaries

#### 2.1 Notation

We use the symbols $I$ and $0$ to respectively represent the identity matrix and zero matrix with appropriate sizes. We denote the set of $r \times r$ orthonormal matrices by $O_r := \{ R \in \mathbb{R}^{r \times r} : R^T R = I \}$. If a function $g(W_1, W_2)$ has two arguments, $W_1 \in \mathbb{R}^{d_1 \times d_0}$ and $W_2 \in \mathbb{R}^{d_2 \times d_1}$, then we occasionally use the notation $g(Z)$ where we stack these two matrices into a larger one via $Z = \begin{bmatrix} W_2 \\ W_1^T \end{bmatrix}$. For a scalar function $h(W)$ with a matrix variable $W \in \mathbb{R}^{d_2 \times d_0}$, its gradient is a $d_2 \times d_0$ matrix whose $(i, j)$-th entry is $\{ \nabla h(W) \}_{ij} = \frac{\partial h(W)}{\partial W_{ij}}$ for all $i \in [d_2], j \in [d_0]$. Here $[d_2] = \{ 1, 2, \ldots, d_2 \}$ for any $d_2 \in \mathbb{N}$ and $W_{ij}$ is the $(i, j)$-th entry of the matrix $W$. Throughout the paper, the Hessian of $h(W)$ is represented by a bilinear form defined via $[\nabla^2 h(W)](A, B) = \sum_{i,j,k,l} \frac{\partial^2 h(W)}{\partial W_{ij} \partial W_{kl}} A_{ij} B_{kl}$ for any $A, B \in \mathbb{R}^{d_2 \times d_0}$. Finally, we use $\lambda_{\min}(\cdot)$ to denote the smallest eigenvalue of a matrix.

### Table 1

Comparison of different results on characterizing the geometric landscape of the objective function in training a shallow linear network (see (1)). Here, ? means this point is not discussed and ✓ indicates the result covers degenerate critical points only.

| result | regularizer | condition | no spurious local minima | strict saddle property |
|--------|-------------|-----------|--------------------------|------------------------|
| [2, Fact 4] | no | $XX^T$ and $YY^T$ are of full row rank, $d_2 \leq d_0$, $YY^T(XX^T)^{-1}XY^T$ has $d_2$ distinct eigenvalues | ✓ | ? |
| [20, Theorem 2.3] | no | $XX^T$ and $YY^T$ are of full row rank, $d_2 \leq d_0$, $YY^T(XX^T)^{-1}XY^T$ has $d_2$ distinct eigenvalues | ✓ | ✓ |
| [30, Theorem 2.1] | no | $XX^T$ and $YY^T$ are of full row rank | ✓ | ? |
| [33, Theorem 1] | no | $d_1 \geq \min(d_0, d_2)$ | ✓ | ? |
| [33, Theorem 8] | no | $d_1 \leq \min(d_0, d_2)$ and conditions (4) and (5) | ✓ | ✓ |
| Theorem 2 | $\|W_2^T W_2 - W_1 X X^T W_1^T\|_F^2$ | $XX^T$ is of full row rank | ✓ | ✓ |
| Theorem 3 | no | $XX^T$ is of full row rank | ✓ | ✓ |
2.2 Strict saddle property

Suppose \( h : \mathbb{R}^n \to \mathbb{R} \) is a twice continuously differentiable objective function. The notions of critical points, strict saddles, and the strict saddle property are formally defined as follows.

**Definition 1 (Critical points)** A critical point of \( h \) is called a critical point if the gradient at \( x \) vanishes, i.e., \( \nabla h(x) = 0 \).

**Definition 2 (Strict saddles)** We say a critical point \( x \) is a strict saddle if the Hessian evaluated at this point has at least one strictly negative eigenvalue, i.e., \( \lambda_{\text{min}}(\nabla^2 h(x)) < 0 \).

In words, for a strict saddle, also called a ridable saddle [41], its Hessian has at least one negative eigenvalue which implies that there is a directional negative curvature that algorithms can utilize to further decrease the objective value. This property ensures that many local search algorithms can escape strict saddles by either directly exploiting the negative curvature [9] or adding noise which serves as a surrogate of the negative curvature [12, 18]. On the other hand, when a saddle point has a Hessian that is positive semidefinite (PSD), it is difficult for first- and second-order methods to avoid converging to such a point. In other words, local search algorithms require exploiting higher-order (at least third-order) information in order to escape from a critical point that is neither a local minimum nor a strict saddle. We note that any local maxima are, by definition, strict saddles.

The following strict saddle property defines a set of nonconvex functions that can be efficiently minimized by a number of iterative algorithms with guaranteed convergence.

**Definition 3 (Strict saddle property)** A twice differentiable function satisfies the strict saddle property if each critical point either corresponds to a local minimum or is a strict saddle.

Intuitively, the strict saddle property requires a function to have a negative curvature direction—which can be exploited by a number of iterative algorithms such as noisy gradient descent [12] and the trust region method [8] to further decrease the function value—at all critical points except for local minima.

**Theorem 1** [12, 24, 32, 41] For a twice continuously differentiable objective function satisfying the strict saddle property, a number of iterative optimization algorithms can find a local minimum. In particular, for such functions,

- gradient descent almost surely converges to a local minimum with a random initialization [12];
- noisy gradient descent [12] finds a local minimum with high probability and any initialization; and
- Newton-like methods such as cubic regularization [32] converge to a local minimum with any initialization.

Theorem 1 ensures that many local search algorithms can be utilized to find a local minimum for strict saddle functions (i.e., ones obeying the strict saddle property). This is the main reason that significant effort has been devoted to establishing the strict saddle property for different problems [20, 25, 34, 35, 40, 45].

In our analysis, we further characterize local minima as follows.

**Definition 4 (Spurious local minima)** We say a critical point \( x \) is a spurious local minimum if it is a local minimum but not a global minimum.

In other words, we separate the set of local minima into two categories: the global minima and the spurious local minima which are not global minima. Note that most local search algorithms are only guaranteed to find a local minimum, which is not necessarily a global one. Thus, to ensure the local search algorithms listed in Theorem 1 find a global minimum, in addition to the strict saddle property, the objective function is also required to have no spurious local minima.

In summary, the geometric landscape of an objective function relates to questions concerning the existence of spurious local minima and the strict saddle property. In particular, if the function has no spurious local minima and obeys the strict saddle property, then a number of iterative algorithms such as the ones listed in Theorem 1 converge to a global minimum. Our goal in the next section is to show that the objective function in training a shallow linear network with a regularizer satisfies these conditions.

### 3 Global Optimality in Shallow Linear Networks

In this paper, we consider the following optimization problem concerning the training of a shallow linear network:

\[
\min_{W_1 \in \mathbb{R}^{d_1 \times d_0}, W_2} f(W_1, W_2) = \frac{1}{2} \| W_2 W_1 X - Y \|_F^2, \tag{1}
\]

where \( X \in \mathbb{R}^{d_0 \times N} \) and \( Y \in \mathbb{R}^{d_2 \times N} \) are the input and output training examples, and \( W_1 \in \mathbb{R}^{d_1 \times d_0} \) and \( W_2 \in \mathbb{R}^{d_2 \times d_1} \) are the model parameters (or weights) corresponding to the first and second layers, respectively. Throughout, we call \( d_0, d_1, \) and \( d_2 \) the sizes of
the input layer, hidden layer, and output layer, respectively. The goal of training a neural network is to optimize the parameters $W_1$ and $W_2$ such that the output $W_2W_1X$ matches the desired output $Y$.

Instead of proposing new algorithms to minimize the objective function in (1), we are interested in characterizing its geometric landscape by understanding the behavior of all of its critical points.

3.1 Main results

We present our main theorems concerning the behavior of all of the critical points of problem (1). First, the following result shows that the objective function of (1) with an additional regularizer (see (2)) has no spurious local minima and obeys the strict saddle property without requiring any of the following conditions that appear in certain works discussed in Section 3.2: that $X$ is of full row rank, that $d_2 \leq d_0$, that $X^T(X^T)^{-1}XY^T$ has $d_2$ distinct eigenvalues, that $d_1 \leq \min(d_0, d_2)$, that (4) holds, or that (5) holds.

**Theorem 2** Assume that $XX^T$ is of full row rank. Then for any $\mu > 0$, the following objective function

$$g(W_1, W_2) = \frac{1}{2}||W_2W_1X - Y||_F^2 + \frac{\mu}{4}\rho(W_1, W_2)$$

(2)

with

$$\rho(W_1, W_2) := ||W_2^TW_2 - W_1XX^TW_1^T||_F^2$$

(3)

obeys the following properties:

(i) $g(W_1, W_2)$ has the same global minimum value as $f(W_1, W_2)$ in (1);

(ii) any critical point $(W_1, W_2)$ of $g$ is also a critical point of $f$;

(iii) $g(W_1, W_2)$ has no spurious local minima and the Hessian at any saddle point has a strictly negative eigenvalue.

The proof of Theorem 2 is given in Section 4.1. The main idea in proving Theorem 2 is to connect $g(W_1, W_2)$ in (2) with the following low rank factorization problem

$$\min_{\tilde{W}_1, \tilde{Y}} \frac{1}{2}||W_2\tilde{W}_1 - \tilde{Y}||_F^2 + \frac{\mu}{4}||W_2^TW_2 - \tilde{W}_1\tilde{W}_1^T||_F^2,$$

where $\tilde{W}_1$ and $\tilde{Y}$ are related to $W$ and $Y$; see (10) in Section 4.1 for the formal definitions.

Theorem 2(i) states that the regularizer $\rho(W_1, W_2)$ in (3) has no effect on the global minimum of the original problem, i.e., the one without this regularizer. Moreover, as established in Theorem 2(ii), any critical point of $g$ in (2) is also a critical point of $f$ in (1), but the converse is not true. With the regularizer $\rho(W_1, W_2)$, which mostly plays the role of shrinking the set of critical points, we prove that $g$ has no spurious local minima and obeys the strict saddle property.

As our results hold for any $\mu > 0$ and $g = f$ when $\mu = 0$, one may conjecture that these properties also hold for the original objective function $f$ under the same assumptions, i.e., assuming only that $XX^T$ has full row rank. This is indeed true and is formally established in the following result.

**Theorem 3** Assume that $X$ is of full row rank. Then, the objective function $f$ appearing in (1) has no spurious local minima and obeys the strict saddle property.

The proof of Theorem 3 is given in Section 4.2. Theorem 3 builds heavily on Theorem 2 and on [33, Theorem 8], which is also presented in Theorem 5. Specifically, as we have noted, [33, Theorem 8] characterizes the behavior of degenerate critical points. Using Theorem 2, we further prove that any non-degenerate critical point of $f$ is either a global minimum or a strict saddle.

3.2 Connection to previous work on shallow linear neural networks

As summarized in Table 1, the results in [2, 21, 30] on characterizing the geometric landscape of the loss function in training shallow linear neural networks only consider the behavior of local minima, but not saddle points. The strict saddle property is proved only in [20] and partly in [33]. We first review the result in [20] concerning the optimization geometry of problem (1).

**Theorem 4** [20, Theorem 2.3] Assume that $X$ and $Y$ are of full row rank with $d_2 \leq d_0$ and $YY^TX(X^TX)^{-1}XY^T$ has $d_2$ distinct eigenvalues. Then, the objective function $f$ appearing in (1) has no spurious local minima and obeys the strict saddle property.

Theorem 4 implies that the objective function in (1) has benign geometric properties if $d_2 \leq d_0$ and the training samples are such that $X$ and $Y$ are of full row rank and $YY^TX(X^TX)^{-1}XY^T$ has $d_2$ distinct eigenvalues. The recent work [30] generalizes the first point of Theorem 4 (i.e., no spurious local minima) by getting rid of the assumption that $YY^TX(X^TX)^{-1}XY^T$ has $d_2$ distinct eigenvalues. However, the geometry of the saddle points is not characterized in [30]. In [21], the authors also show that the condition on $YY^TX(X^TX)^{-1}XY^T$ is not necessary. In particular, when applied to (1), the result in [21] implies that the objective function in (1) has no spurious local minima when $d_1 \leq \min(d_0, d_2)$. 
This condition requires that the hidden layer is narrower than the input and output layers. Again, the optimization geometry around saddle points is not discussed in [21].

We now review the more recent result in [33, Theorem 8].

**Theorem 5** [33, Theorem 8] The objective function $f$ appearing in (1) has no spurious local minima. Moreover, any critical point $Z$ of $f$ that is degenerate (i.e., for which $\text{rank}(W_2W_1) < \min\{d_2, d_1, d_0\}$) is either a global minimum of $f$ or a strict saddle.

In cases where the global minimum of $f$ is non-degenerate—for example when $Y = W_2^T W_1 X$ for some $W_2$ and $W_1$ such that $W_2^T W_1$ is non-degenerate—Theorem 5 implies that all degenerate critical points are strict saddles. However, we note that the behavior of non-degenerate critical points in these cases is more important from the algorithmic point of view, since one can always check the rank of a convergent point and perturb it if it is degenerate, but this is not possible at non-degenerate convergent points. Our Theorem 3 generalizes Theorem 5 to ensure that every critical point that is not a global minimum is a strict saddle, regardless of its rank.

Next, as a direct consequence of [46, Theorem 3], the following result also establishes certain conditions under which the objective function in (1) with an additional regularizer (see (6)) has no spurious local minima and obeys the strict saddle property.

**Corollary 1** [46, Theorem 3] Suppose $d_1 \leq \min(d_0, d_2)$. Furthermore, for any $d_2 \times d_0$ matrix $A$ with rank($A$) $\leq 4d_1$, suppose the following holds

$$
\alpha \|A\|_F^2 \leq \text{trace}(AXX^T A^T) \leq \beta \|A\|_F^2
$$

for some positive $\alpha$ and $\beta$ such that $\frac{\alpha}{\beta} \leq 1.5$. Furthermore, suppose $\min_{W \in \mathbb{R}^{d_2 \times d_0}} \|W^t X - Y\|_F^2$ admits a solution $W^*$ which satisfies

$$
0 < \text{rank}(W^*) = r^* \leq d_1.
$$

Then for any $0 < \mu \leq \frac{\alpha}{16}$, the following objective function

$$
h(W_1, W_2) = \frac{1}{2} \|W_2W_1X - Y\|_F^2 + \frac{\mu}{4} \|W_2^2W_2 - W_1W_1^T\|_F^2,
$$

has no spurious local minima and the Hessian at any saddle point has a strictly negative eigenvalue with

$$
\lambda_{\min}(\nabla^2 h(W_1, W_2)) \leq \begin{cases} 
-0.08 \alpha \sigma_{d_1}(W^*), & d_1 = r^* \\
-0.05 \alpha \cdot \min\{\sigma_{d_1}^2(W_2W_1), \sigma_{r^*}(W^*)\}, & d_1 > r^* \\
-0.1 \alpha \sigma_{r^*}(W^*), & r_c = 0,
\end{cases}
$$

where $r_c \leq d_1$ is the rank of $W_1W_2$, $\lambda_{\min}(\cdot)$ represents the smallest eigenvalue, and $\sigma(\cdot)$ denotes the $\ell$-th largest singular value.

Corollary 1, following from [46, Theorem 3], utilizes a regularizer $\|W_2^2 W_2 - W_1W_1^T\|_F^2$ which balances the energy between $W_1$ and $W_2$ and has the effect of shrinking the set of critical points. This allows one to show that each critical point is either a global minimum or a strict saddle. Similar to Theorem 2(i), this regularizer also has no effect on the global minimum of the original problem (1).

As we explained before, Theorem 4 implicitly requires that $\min(d_0, d_1) \geq d_2$ and rank$(W_2W_1) \geq d_2$. On the other hand, Corollary 1 requires $d_1 \leq \min(d_0, d_2)$ and (4). When $d_1 \leq \min(d_0, d_2)$, the hidden layer is narrower than the input and output layers. Note that (4) has nothing to do with the underlying network parameters $W_1$ and $W_2$, but requires the training data matrix $X$ to act as an isometry operator for rank-$4d_1$ matrices.

To see this, we rewrite

$$
\text{trace}(AXX^T A^T) = \sum_{i=1}^{N} x_i^T A^T X_i = \sum_{i=1}^{N} \langle x_i, x_i^T, A^T A \rangle
$$

which is a sum of the rank-one measurements of $A^TA$.

Unlike Theorem 4, which requires that $YY^T$ is of full rank and $d_2 \leq d_0$, and unlike Corollary 1, which requires (4) and $d_1 \leq \min(d_0, d_2)$, Theorem 2 and Theorem 3 only necessitate that $XX^T$ is full rank and have no condition on the size of $d_0, d_1,$ and $d_2$. As we explained before, suppose $Y$ is generated as $Y = W_2^T W_1^T X$, where $W_2$ and $W_1$ are the underlying weights to be recovered. Then the full-rank assumption of $YY^T = W_2^2 W_2^T X X^T W_1 W_1^T$ at least requires $\min(d_0, d_1) \geq d_2$ and rank$(W_2^2 W_1^T) \geq d_2$. In other words, Theorem 4 necessitates that the hidden layer is wider than the output, while Theorem 2 and Theorem 3 work for networks where the hidden layer is narrower than the input and output layers. On the other hand, Theorem 2 and Theorem 3 allow for the hidden layer of the network to be either narrower or wider than the input and the output layers.

Finally, consider a three-layer network with $X = I$. In this case, (1) reduces to a matrix factorization problem where $f(W_1, W_2) = \|W_2W_1 - Y\|_F^2$ and the regularizer in (2) is the same as the one in (6). Theorem 4 requires that $Y$ is of full row rank and has $d_2$ distinct singular values. For the matrix factorization problem, we know from Corollary 1 that for any $Y$, $h$ has benign geometry (i.e., no spurious local minima and the strict saddle property) as long as $d_1 \leq \min(d_0, d_2)$. As
a direct consequence of Theorem 2 and Theorem 3, this benign geometry is also preserved even when \( d_1 > d_0 \) or \( d_1 > d_2 \) for matrix factorization via minimizing

\[
g(W_1, W_2) = \|W_2 W_1 - Y\|_F^2 + \frac{\mu}{4} \|W_2 W_1 W_1^T\|_F^2,
\]

where \( \mu \geq 0 \) (note that one can get rid of the regularizer by setting \( \mu = 0 \)).

## 4 Proof of Main Results

### 4.1 Proof of Theorem 2

In this section, we prove Theorem 2. We first show that the regularizer in (2) has no effect on the global minimum of the original problem. It is clear that \( g(W_1, W_2) \geq f(W_1, W_2) \) for any \( W_1, W_2 \), where we repeat that

\[
f(W_1, W_2) = \frac{1}{2} \|W_2 W_1 X - Y\|_F^2.
\]

Suppose the row rank of \( X \) is \( d_0 \leq d_0 \). Let

\[
X = U \Sigma V^T
\]

be a reduced SVD of \( X \), where \( \Sigma \) is a \( d_0 \times d_0 \) diagonal matrix with positive diagonals. Then,

\[
f(W_1, W_2) = \frac{1}{2} \|W_2 W_1 U \Sigma - Y V\|_F^2 + \|Y\|_F^2 - \|Y V\|_F^2 = f_1(W_1, W_2) + C,
\]

where

\[
f_1(W_1, W_2) = \frac{1}{2} \|W_2 W_1 U \Sigma - Y V\|_F^2 + \|Y\|_F^2 - \|Y V\|_F^2.
\]

Denote by \((W_1^*, W_2^*)\) a global minimum of \( f_1(W_1, W_2) \) :

\[
(W_1^*, W_2^*) = \arg \min_{W_1, W_2} f_1(W_1, W_2).
\]

Let \( W_2^* W_1^* \Sigma = P^j \Omega Q_1^T \) be a reduced SVD of \( W_2^* W_1^* \Sigma \), where \( \Omega \) is a diagonal matrix with positive diagonals. Let \( \tilde{W}_2 = P^j \Omega^{1/2} \) and \( \tilde{W}_1 = \Omega^{1/2} Q_1^T \Sigma^{-1} U^T \). It follows that

\[
\tilde{W}_2 W_1 \Sigma = P^1 \Omega Q_1^T = W_2^* W_1 \Sigma,
\]

which implies that \( f_1(W_1^*, W_2^*) = f_1(\tilde{W}_1, \tilde{W}_2) \) and

\[
f(W_1^*, W_2^*) = f_1(W_1^*, W_2^*) + C = f_1(\tilde{W}_1, \tilde{W}_2) + C = f(\tilde{W}_1, \tilde{W}_2)\]

since \( \|W_1^* \Sigma - \tilde{W}_1 \Sigma\|_F^2 = 0 \). This further indicates that \( g \) and \( f \) have the same global optimum (since \( g(W_1, W_2) \geq f(W_1, W_2) \) for any \((W_1, W_2)\)).

In the rest of the proof of Theorem 2 we characterize the behavior of all the critical points of the objective function \( g \) in (2). In particular, we show that any critical point of \( g \) is also a critical point of \( f \), and if it is not a global minimum of (2), then it is a strict saddle, i.e., its Hessian has at least one negative eigenvalue.

To that end, we first establish the following result that characterizes all the critical points of \( g \).

**Lemma 1** Let \( X = U \Sigma V^T \) be an SVD of \( X \) as in (8), where \( \Sigma \) is a diagonal matrix with positive diagonals \( \sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_{d_0} > 0 \). Let \( \hat{Y} := Y V = P \Omega \Sigma Q^T \) be a reduced SVD of \( \hat{Y} \), where \( \hat{r} \) is the rank of \( \hat{Y} \). Then any critical point \( Z = [W_2^T W_2^1] \) of (2) satisfies

\[
W_2^2 W_1 = W_1 X X^T W_1^T. \tag{9}
\]

Furthermore, any \( Z = [W_2^T W_2^1] \) is a critical point of \( g(Z) \) if and only if \( Z \in C_g \), where

\[
C_g = \{ Z = [W_2^T W_2^1] : \hat{Z} \in \{ \sqrt{\lambda_1} [p_1 q_1], \ldots, \sqrt{\lambda_r} [p_r q_r], 0 \}, \}
\]

\[
\hat{z}_i^T \hat{z}_j = 0, \forall i \neq j, R \in O(d_1),
\]

where \( \hat{z}_i \) denotes the \( i \)-th column of \( \hat{Z} \).

The proof of Lemma 1 is in Appendix A. From (9), \( g(Z) = f(Z) \) at any critical point \( Z \). We compute the gradient of the regularizer \( \rho(W_1, W_2) \) as

\[
\nabla \rho(W_1, W_2) := -\mu W_2 (W_2 U X X^T W_1^T) W_1 X X^T,
\]

\[
\nabla \rho(W_1, W_2) := -\mu W_2 (W_2 U X X^T W_1^T) W_1 X X^T.
\]

Plugging (9) into the above equations gives

\[
\nabla \rho(W_1, W_2) = \nabla \rho(W_1, W_2) = 0
\]

for any critical point \((W_1, W_2)\) of \( g \). This further implies that if \( Z \) is a critical point of \( g \), then it must also be a critical point of \( f \) since \( \nabla g(Z) = \nabla f(Z) + \nabla \rho(Z) \) and both \( \nabla g(Z) = \nabla \rho(Z) = 0 \), so that

\[
\nabla f(Z) = 0.
\]

This proves Theorem 2(ii).

To further classify the critical points into categories such as local minima and saddle points, for any \( Z \in C \), we compute the objective value at this point as

\[
g(Z) = \frac{1}{2} \|W_2 W_1 X - Y\|_F^2 = \frac{1}{2} \|\hat{W}_2 \hat{W}_1 \Sigma^{-1} U^T X - Y\|_F^2
\]

\[
= \frac{1}{2} \|\hat{W}_2 \hat{W}_1 - Y V\|_F^2 + \|Y\|_F^2 - \|Y V\|_F^2.
\]
where $U \Sigma V^T$ is a reduced SVD of $X$ as defined in (8), and $\tilde{W}_2$ and $\tilde{W}_1$ are defined in (10). Noting that $\|Y\|_F^2 - \|YV\|_F^2$ is a constant in terms of the variables $\tilde{W}_2$ and $\tilde{W}_1$, we conclude that $Z$ is a global minimum of $g(Z)$ if and only if $\tilde{Z}$ is a global minimum of
\[
\tilde{g}(\tilde{Z}) := \frac{1}{2}\|\tilde{W}_2\tilde{W}_1 - YV\|_F^2.
\] (12)

Lemma 2 With the same setup as in Lemma 1, let $C$ be defined in (10). Then all local minima of (2) belong to the following set (which contains all the global solutions of (2))
\[
\chi_g = \left\{ Z = \left[ \begin{array}{c} \tilde{W}_2 R \\ U \Sigma^{-1} \tilde{W}_1^T \end{array} \right] \in C : \|\tilde{W}_2\tilde{W}_1 - YV\|_F \right\}. \]
\[
= \min_{A \in \mathbb{R}^{d_2 \times d_1}, B \in \mathbb{R}^{d_1 \times d_0}} \|AB - YV\|_F \right\}. \] (13)

Any $Z \in \mathcal{C}_g \setminus \chi_g$ is a strict saddle of $g(Z)$ satisfying:

- if $r \leq d_1$, then
  \[
  \lambda_{\min}(\nabla^2 g(W)) \leq -\frac{\lambda_r}{1 + \sum_i \sigma_i^2}.
  \] (14)
- if $r > d_1$, then
  \[
  \lambda_{\min}(\nabla^2 g(W)) \leq -\frac{\lambda_{d_1} - \lambda_{r'}}{1 + \sum_i \sigma_i^2}.
  \] (15)

where $\lambda_{r'}$ is the largest singular value of $\tilde{Y}$ that is strictly smaller than $\lambda_{d_1}$.

The proof of Lemma 2 is given in Appendix B. Lemma 2 states that any critical point of $g$ is either a global minimum or a strict saddle. This proves Theorem 2(iii) and thus we complete the proof of Theorem 2.

4.2 Proof of Theorem 3

Building on Theorem 2 and Theorem 5, we now consider the landscape of $f$ in (1). Let $\mathcal{C}_f$ denote the set of critical points of $f$:
\[
\mathcal{C}_f = \{ Z : \nabla f(Z) = 0 \}.
\]

Our goal is to characterize the behavior of all critical points that are not global minima. In particular, we want to show that every critical point of $f$ is either a global minimum or a strict saddle.

Let $Z = \begin{bmatrix} W_2 \\ W_1 \end{bmatrix}$ be any critical point in $\mathcal{C}_f$. According to Theorem 5, when $W_2W_1$ is degenerate (i.e., rank($W_2W_1$) < min{d_2, d_1, d_0}), then $Z$ must be either a global minimum or a strict saddle. We now assume the other case that $W_2W_1$ is non-degenerate.

Let $W_2W_1U \Sigma = \Phi \Theta \Psi^T$ be a reduced SVD of $W_2W_1U \Sigma$, where $\Theta$ is a diagonal and square matrix with positive singular values, and $\Phi$ and $\Psi$ are orthonormal matrices of proper dimension. We now construct
\[
W_2 = W_2W_1U \Sigma \Theta^{-1/2} = \Phi \Theta^{1/2},
\]
\[
W_1 = \Theta^{-1/2} \Psi^T W_2 W_1 = \Theta^{1/2} \Psi^T \Sigma^{-1} U^T.
\] (16)

The above constructed pair $Z = \begin{bmatrix} W_2 \\ W_1 \end{bmatrix}$ satisfies
\[
\tilde{W}_2^T \tilde{W}_2 = W_1 X X^T W_1^T, \quad \tilde{W}_2 W_1 = W_2 W_1.
\] (17)

Note that here $\tilde{W}_2$ (resp. $\tilde{W}_1$) have different numbers of columns (resp. rows) than $W_2$ (resp. $W_1$). We denote by
\[
\tilde{f}(W_1, W_2) = \frac{1}{2}\|\tilde{W}_2\tilde{W}_1 U \Sigma - YV\|_F^2.
\]

Since $Z \in \mathcal{C}_f$, we have $\nabla_{W_1} f(W_1, W_2) = 0$ and $\nabla_{W_2} f(W_1, W_2) = 0$. It follows that
\[
\nabla_{W_2} \tilde{f}(W_1, W_2) = (W_2W_1U \Sigma - YV)(W_1U \Sigma)^T = \nabla_{W_2} f(W_1, W_2) W_2^T \Phi \Theta^{-1/2} = 0.
\]

And similarly, we have
\[
\nabla_{W_1} \tilde{f}(W_1, W_2) = \Theta^{-1/2} \Psi^T \Sigma^{-1} U^T W_1^T \nabla_{W_1} f(W_1, W_2) = 0,
\]
which together with the above inequation implies that $\tilde{Z}$ is also a critical point of $\tilde{f}$. Due to (17) which states that $\tilde{Z}$ also satisfies (9), it follows from the same arguments used in Lemma 1 and Lemma 2 that $\tilde{Z}$ is either a global minimum or a strict saddle of $\tilde{f}$. Moreover, since $\tilde{W}_2\tilde{W}_1$ has the same rank as $W_2W_1$ which is assumed to be non-degenerate, we have that $\tilde{Z}$ is a global minimum of $\tilde{f}$ if and only if
\[
\|\tilde{W}_2\tilde{W}_1 U \Sigma - YV\|_F^2 = \min_{A \in \mathbb{R}^{d_2 \times d_1}, B \in \mathbb{R}^{d_1 \times d_0}} \|AB - YV\|_F,
\]
where the minimum of the right hand side is also achieved by the global minimum of $f$ according to (13). Therefore, if $\tilde{Z}$ is a global minimum of $\tilde{f}$, then $Z$ is also a global minimum of $f$. 
Now we consider the other case when $Z$ is not a global minimum of $f$, i.e., it is a strict saddle. In this case, there exists $\Delta = \begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix}$ such that
\[
\{\nabla^2 f(Z)\} (\Delta, \Delta) < 0.
\]

Now construct
\[
\Delta_1 = W_1 U \Sigma \Psi \Theta^{-1/2} \Delta_1,
\]
\[
\Delta_2 = \Delta_2 \Theta^{-1/2} \phi^T W_2
\]

which satisfies
\[
W_2 \Delta_1 = W_2 \overline{W}_1, \quad \Delta W_2 \overline{W}_1 = \overline{W}_2 \Delta_1, \quad \Delta_2 \Delta_1 = \Delta_2 \overline{W}_1.
\]

By the Hessian quadratic form given in (31) (ignoring the $\mu$ terms), we have
\[
\{\nabla^2 f(Z)\} (\Delta, \Delta) = \{\nabla^2 f(Z)\} (\Delta, \Delta) < 0,
\]
which implies that $Z$ is a strict saddle of $f$. This completes the proof of Theorem 3.

5 Conclusion

We consider the optimization landscape of the objective function in training shallow linear networks. In particular, we proved that the corresponding optimization problems under a very mild condition have a simple landscape: there are no spurious local minima and any critical point is either a local (and thus also global) minimum or a strict saddle such that the Hessian evaluated at this point has a strictly negative eigenvalue. These properties guarantee that a number of iterative optimization algorithms (especially gradient descent, which is widely used in training neural networks) converge to a global minimum from either a random initialization or an arbitrary initialization depending on the specific algorithm used. It would be of interest to prove similar geometric properties for the training problem without the mild condition on the row rank of $X$.

A Proof of Lemma 1

We first prove the direction $\Rightarrow$. Any critical point $Z$ of $g(Z)$ satisfies $\nabla g(Z) = 0$, i.e.,
\[
\nabla g(W_1, W_2) = W_2^T (W_2 W_1 X - Y) X^T - \mu (W_2^T W_2 - W_1 XX^T W_2^T) W_1 X X^T = 0,
\]
and
\[
\nabla g(W_1, W_2) = (W_2 W_1 X - Y) X^T W_2^T + \mu W_2 (W_2^T W_2 - W_1 XX^T W_2^T) = 0.
\]

By (18), we obtain
\[
W_2^T (W_2 W_1 X - Y) X^T = \mu (W_2^T W_2 - W_1 XX^T W_2^T) W_1 X X^T.
\]
It follows from (25) that
\[ \tilde{Y}^T \phi = \| \phi \|_2^2 \psi, \]  
\[ \tilde{Y} \psi = \| \psi \|_2^2 \phi. \]  
Multiplying (27) by \( \tilde{Y} \) and plugging (28) into the resulting equation gives
\[ \tilde{Y} \tilde{Y}^T \phi = \| \phi \|_2^2 \phi, \]  
where we used (26). Similarly, we have
\[ \tilde{Y} \tilde{Y} \psi = \| \psi \|_2^2 \psi. \]  
Let \( \tilde{Y} = PAQ^T = \sum_{j=1}^r \lambda_j p_j q_j^T \) be the reduced SVD of \( \tilde{Y} \). It follows from (29) that \( \phi \) is either a zero vector (i.e., \( \phi = 0 \)), or a left singular vector of \( \tilde{Y} \) (i.e., \( \phi = \alpha p_j \) for some \( j \in [r] \)). Plugging \( \phi = \alpha p_j \) into (29) gives
\[ \lambda_j^2 = \alpha^4. \]  
Thus, \( \phi = \pm \sqrt{\lambda_j} p_j \). If \( \phi = 0 \), then due to (26), we have
\[ \psi = 0. \]  
If \( \phi = \pm \sqrt{\lambda_j} p_j \), then plugging into (27) gives
\[ \psi = \pm \sqrt{\lambda_j} q_j. \]  
Thus, we conclude that
\[ (\phi, \psi) \in \left\{ \pm \sqrt{\lambda_1}(p_1, q_1), \ldots, \pm \sqrt{\lambda_r}(p_r, q_r), (0, 0) \right\}, \]  
which together with (23) implies that any critical point \( Z \) belongs to (10) by absorbing the sign \( \pm \) into \( R \).

We now prove the other direction \( \Rightarrow \). For any \( Z \in C \), we compute the gradient of \( g \) at this point and directly verify it satisfies (18) and (19), i.e., \( Z \) is a critical point of \( g(Z) \). This completes the proof of Lemma 1.

B Proof of Lemma 2

Due to the fact that \( Z \) is a global minimum of \( g(Z) \) if and only if \( \tilde{Z} \) is a global minimum of \( \tilde{g}(\tilde{Z}) \), we know any \( Z \in X \) is a global minimum of \( g(Z) \). The rest is to show that any \( Z \in C \setminus X \) is a strict saddle. For this purpose, we first compute the Hessian quadrature form \( \nabla^2 g(Z)[\Delta, \Delta] \) for any \( \Delta = \begin{bmatrix} \Delta_1 \\ \Delta_2 \end{bmatrix} \) (with \( \Delta_1 \in \mathbb{R}^{d_1 \times d_3}, \Delta_2 \in \mathbb{R}^{d_2 \times d_4} \)) as
\[ \nabla^2 g(Z)[\Delta, \Delta] = \left( \begin{bmatrix} W_2 \Delta_1 + \Delta_2 W_1 \end{bmatrix} X \right) \tilde{R}^T \]  
\[ + \frac{1}{2} \left( \frac{\partial^2 w}{\partial x} \Delta_1 + (W_2 W_1 X - Y)X^T \right) \]  
\[ + \mu \left( \begin{bmatrix} W_2^T \Delta_1 + \Delta_2 W_1 \end{bmatrix} X_1 \right)^2 \]  
\[ + \frac{1}{2} \left( \begin{bmatrix} W_2^T \Delta_2 + \Delta_2 W_1 \end{bmatrix} X_2 \right)^2, \]  
\[ \mu \]  
where the second equality follows because any critical point \( Z \) satisfies (9). We continue the proof by considering two cases in which we provide explicit expressions for the set \( X \) that contains all the global minima and construct a negative direction for \( g \) at all the points \( C \setminus X \).

Case i: \( r \leq d_1 \). In this case, \( \min \tilde{g}(\tilde{Z}) = 0 \) and \( \tilde{g}(\tilde{Z}) \) achieves its global minimum 0 if and only if \( \tilde{W}_2 \tilde{W}_1 = YV \). Thus, we rewrite \( X \) as
\[ X = \left\{ Z \begin{bmatrix} \tilde{W}_2 \tilde{R} \\ U \Sigma^{-1} \tilde{W}_1^T \end{bmatrix} \in C : \tilde{W}_2 \tilde{W}_1 = YV \right\}, \]  
which further implies that
\[ C \setminus X = \left\{ Z \begin{bmatrix} \tilde{W}_2 \tilde{R} \\ U \Sigma^{-1} \tilde{W}_1^T \end{bmatrix} \in C \right\} \]  
\[ YV - \tilde{W}_2 \tilde{W}_1 = \sum_{i \in \Omega} \lambda_i p_i q_i^T, \Omega \subset [r]. \]  
Thus, for any \( Z \in C \setminus X \), the corresponding \( \tilde{W}_2 \tilde{W}_1 \tilde{W}_1 \) is a low-rank approximation to \( YV \).

Let \( k \in \Omega \). We have
\[ p_k^T \tilde{W}_2 = 0, \tilde{W}_1 q_k = 0. \]  
(32)

In words, \( p_k \) is orthogonal to \( W_2 \) and \( W_1 \), respectively. Let \( \alpha \in \mathbb{R}^{d_1} \) be the eigenvector associated with the smallest eigenvalue of \( \tilde{Z}^T \tilde{Z} \). Note that such \( \alpha \) simultaneously lives in the null spaces of \( W_2 \) and \( W_1 \) since \( Z \) is rank deficient, indicating
\[ 0 = \alpha^T \tilde{Z}^T \tilde{Z} \alpha = \alpha^T \tilde{W}_2^T \tilde{W}_2 \alpha + \alpha^T \tilde{W}_1 \tilde{W}_1 \alpha, \]  
which further implies
\[ \tilde{W}_2 \alpha = 0, \tilde{W}_1 \alpha = 0. \]  
(33)

With this property, we construct \( \Delta \) by setting \( \Delta_2 = p_k \alpha^T R \) and \( \Delta_1 = R^T \alpha q_k^T \Sigma^{-1} U^T \). Now we show that \( Z \) is a strict saddle by arguing that \( g(Z) \) has a strictly negative curvature along the constructed direction \( \Delta \), i.e., \( \nabla^2 g(Z)[\Delta, \Delta] < 0 \). For this purpose, we compute the three terms in (31) as follows:
\[ \| (W_2 \Delta_1 + \Delta_2 W_1) X \|_F^2 = 0 \]  
(34)

since \( W_2 \Delta_1 = W_2 R \alpha q_k^T \Sigma^{-1} U^T = \tilde{W}_2 \alpha q_k^T \Sigma^{-1} U^T = 0 \) and \( \Delta_2 W_1 = p_k \alpha^T RW_1 \) and \( p_k \alpha^T W_1 = 0 \) by utilizing (33);
\[ \| W_2^T \Delta_2 + \Delta_2^T W_2 - W_1 X X^T \Delta_1 - \Delta_1 X X^T W_1 \|_F^2 \]  
\[ = \| (W_2 \Delta_1 + \Delta_2 W_1) X \|_F^2 \]  
\[ + \| (\Delta_2 W_2 - \Delta_2 W_1 X Y)X^T \|_F^2 \]  
\[ + \| (W_2^T \Delta_2 + \Delta_2^T W_2 - W_1 X X^T \Delta_1 - \Delta_1 X X^T W_1 \|_F^2. \]  
(31)

since it follows from (32) that \( W_2^T \Delta_2 = R^T \tilde{W}_2 p_k \alpha^T R = 0 \) and
\[ \tilde{W}_1 X X^T \Delta_1^T = R^T \tilde{W}_1 \Sigma^{-1} U U^T \Sigma^2 U U^T \Sigma^{-1} q_k \alpha^T R \]  
\[ = R^T \tilde{W}_1 q_k \alpha^T R = 0; \]  
and
\[ (W_2 \Delta_1, (W_2 W_1 X - Y)X^T) \]  
\[ = \left( p_k q_k^T \Sigma^{-1} U X^T, (\tilde{W}_2 \tilde{W}_1 - Y V) \Sigma U^T \right) \]  
\[ = \left( p_k q_k^T, \tilde{W}_2 \tilde{W}_1 - (p_k q_k^T, Y V) \right) = -\lambda_k, \]  
where the last equality utilizes (32). Thus, we have
\[ \nabla^2 g(Z)[\Delta, \Delta] = -2 \lambda_k \leq -2 \lambda_r. \]
We finally obtain (14) by noting that
\[
\|\Delta_t\|_F^2 = \|\Delta_1\|_F^2 + \|\Delta_2\|_F^2
\]
\[
= \|p_\alpha R\|_F^2 + \|R^T \alpha q_1^T \Sigma^{-1} U^T\|_F^2
\]
\[
= 1 + \|\Sigma^{-1} q_1\|_F^2 \leq 1 + \|\Sigma^{-1}\|_F^2 \|q_1\|_F^2 = 1 + \|\Sigma^{-1}\|_F^2,
\]
where the inequality follows from the Cauchy-Schwarz inequality \(|a^T b| \leq \|a\| \|b\|\).

Case ii: \(r > d_1\). In this case, minimizing \(\tilde{g}(\tilde{Z})\) in (12) is equivalent to finding a low-rank approximation to \(YV\). Let \(I\) denote the indices of the singular vectors \(\{p_j\}\) and \(\{q_j\}\) that are included in \(\tilde{Z}\); that is
\[
\{\tilde{z}_i, i \in [d_1]\} = \left\{0, \sqrt{\lambda_i} p_j, q_j, j \in I \right\}.
\]

Then, for any \(\tilde{Z}\), we have
\[
\tilde{W}_2 \tilde{W}_1 - YV = \sum_{i \in I} \lambda_i p_i q_i^T.
\]

and
\[
\tilde{g}(\tilde{Z}) = \frac{1}{2} \|\tilde{W}_2 \tilde{W}_1 - YV\|_F^2 = \frac{1}{2} \sum_{i \in I} \lambda_i^2,
\]

which implies that \(\tilde{Z}\) is a global minimum of \(\tilde{g}(\tilde{Z})\) if
\[
\|\tilde{W}_2 \tilde{W}_1 - YV\|_F^2 = \sum_{i > d_1} \lambda_i^2.
\]

To simply the following analysis, we assume \(\lambda_{d_1} > \lambda_{d_1+1}\); but the argument is similar in the case of repeated eigenvalues at \(\lambda_{d_1}\) (i.e., \(\lambda_{d_1} = \lambda_{d_1+1} = \cdots\)). In this case, we know for any \(Z \in \mathbb{C} \setminus X\) that is not a global minimum, there exists \(\Omega \subset [r]\) which contains \(k \in \Omega, k \leq d_1\) such that
\[
YV - \tilde{W}_2 \tilde{W}_1 = \sum_{i \in \Omega} \lambda_i p_i q_i^T.
\]

Similar to Case i, we have
\[
p_i^T \tilde{W}_2 = 0, \tilde{W}_2 q_i = 0. \tag{35}
\]

Let \(\alpha \in \mathbb{R}^{d_1}\) be the eigenvector associated with the smallest eigenvalue of \(\tilde{Z}\). By the form of \(\tilde{Z}\) in (10), we have
\[
\|\tilde{W}_2 \alpha\|_2^2 = \|\tilde{W}_1 \alpha\|_2^2 \leq \lambda_{d_1+1}, \tag{36}
\]

where the inequality attains equality when \(d_1 + 1 \in \Omega\). As in Case i, we construct \(\Delta\) by setting \(\Delta_2 = p_\alpha \alpha^T R\) and \(\Delta_1 = R^T \alpha q_1^T \Sigma^{-1} U^T\). We now show that \(Z\) is a strict saddle by arguing that \(g(Z)\) has a strictly negative curvature along the constructed direction \(\Delta\) (i.e., \(\nabla^2 g(Z)(\Delta, \Delta) < 0\)) by computing the three terms in (31) as follows:
\[
\|\tilde{W}_2 \Delta_1 + \tilde{W}_2 \Delta_1 W_1 X_1\|_F^2 = \|	ilde{W}_2 \alpha q_1^T V^T + p_\alpha \alpha^T W_1 V^T\|_F^2
\]
\[
= \|\tilde{W}_2 \alpha\|_2^2 + \|\alpha^T W_1\|_2^2 + 2 \left(\tilde{W}_2 \alpha q_1^T, p_\alpha \alpha^T W_1\right)
\]
\[
\leq 2\lambda_{d_1+1},
\]
where the last line follows from (35) and (36);
\[
\|\tilde{W}_2 \Delta_1 + \tilde{W}_2 \Delta_1 W_1 X_1\|_F^2 = 0
\]
holds with a similar argument as in (34); and
\[
\langle \Delta_2 \Delta_1, (W_2 W_1 X - Y) X^T \rangle
\]
\[
= \langle p_\alpha q_1^T \Sigma^{-1} U^T, (W_2 W_1 - YV) \Sigma U^T \rangle
\]
\[
= \langle p_\alpha q_1^T \tilde{W}_2 W_1 - \langle p_\alpha q_1^T, YV\rangle
\]
\[
= -\lambda_k \leq -\lambda_{d_1},
\]
where the last equality used (35) and the fact that \(k \leq d_1\). Thus, we have
\[
\nabla^2 g(Z)(\Delta, \Delta) \leq -(\lambda_{d_1} - \lambda_{d_1+1}),
\]
completing the proof of Lemma 2.
