ABSTRACT

Primary cutaneous CD30-positive T-cell lymphoproliferative disorders are the second most common subgroup of cutaneous T-cell lymphomas. They include two clinically different entities with some overlapping features and borderline cases: lymphomatoid papulosis and primary cutaneous anaplastic large cell lymphoma. Molecular studies of primary cutaneous anaplastic large cell lymphoma reveal an increasing level of heterogeneity that is associated with histological and immunophenotypic features of the cases and their response to specific therapies. Here, we review the most significant genetic, epigenetic and molecular alterations described to date in primary cutaneous CD30-positive T-cell lymphoproliferative disorders, and their potential as therapeutic targets.

Introduction

CD30+ primary cutaneous T-cell lymphoproliferative disorders are the second most common subgroup of cutaneous T-cell lymphomas after mycosis fungoides (MF), accounting for approximately 30% of cases.¹ These cutaneous lymphomas have customarily been classified on the basis of their clinical presentation into lymphomatoid papulosis (LyP), primary cutaneous anaplastic large cell lymphoma (pcALCL) and borderline cases. In recent years, genomic analysis has become important for the diagnosis and clinical management of patients affected by systemic and cutaneous hematologic malignancies.² Systemic anaplastic large cell lymphoma (ALCL) is defined by mutually exclusive rearrangements of ALK, DUSP22/IRF4 and TP63, which have prognostic and survival implications and must be taken into account in the management of patients.² pcALCL have histopathological and immunophenotypic similarities with systemic ALCL, but have a more indolent behavior. Chromosomal translocations described in systemic ALCL can also be seen in pcALCL, although they have different clinical implications. Thus, there are some ALK+ pcALCL, and some cases of LyP and pcALCL share a DUSP22-IRF4 locus translocation. Bearing all this in mind, we have reviewed the molecular alterations in CD30+ primary cutaneous T-cell lymphoproliferative disorders, describing the various molecular alterations and considering their clinical and therapeutic implications.

Lymphomatoid papulosis

LyP is an enigmatic disease that follows the course of a chronic skin condition and has the histology of a lymphoma. It typically has a recurrent, self-healing course, with an excellent prognosis.³ Clinical features of all types of LyP are similar and consist of papular, papulonecrotic and/or nodular skin lesions at different stages of evolution. The number of lesions is, however, highly variable, ranging from only a few lesions to hundreds. Likewise, there is great variability in the duration of lesions, which may be present for a few weeks or persist for decades.
is seen more frequently in adult patients, but children can also be affected.4

Customarily, on the basis of its extremely variable histopathology, LyP has been divided into five types with similar prognosis, although distinguishing them is important for the differential diagnosis from more aggressive types of lymphoma.5 Although more descriptive terms have been proposed, in 2017 the World Health Organization (WHO) categorized LyP using consecutive alphabetical letters.6 Type A is the most frequent form of LyP, accounting for 80% of cases. Tumor cells are typically CD4+ and CD30+ and appear scattered or in small clusters, accompanied by numerous inflammatory cells, including neutrophils, eosinophils and small lymphocytes. The main differential diagnoses include reactive lesions, such as insect bites, and pityriasis lichenoides et varioliformis acuta (PLEVA).7 Type B is uncommon, accounting for 5% of cases, and has the same CD4+, CD8+ immunophenotype.7 It has a histology similar to that of plaque-stage MF with an epidermotropic infiltrate of small, atypical CD30+ cells, which is its main differential diagnosis; less frequently it must be distinguished from cutaneous epidermotropic gamma/delta lymphoma.8 Type C makes up around 10% of LyP cases and has a histology very similar to that of pcALCL, with a nodular cohesive infiltrate of large CD30+, CD4+, CD8+ pleomorphic and anaplastic tumor cells featuring mitotic figures and abundant cytoplasm.7 Apart from pcALCL, other entities, such as transformed MF, peripheral T-cell lymphoma not otherwise specified, and adult T-cell lymphoma/leukemia, may have a similar histology.7 Types D and E have only been described relatively recently, and are usually characterized by a cytotoxic phenotype, with CD8+ and CD30+ lymphocytes. Biopsies from patients with type D LyP show prominent epidermotropism of atypical small-to-medium-sized pleomorphic cells. There may be deep dermal and perivascular infiltrates. This variant accounts for about 5% of cases and needs to be differentiated from atypical lymphoid infiltrates, a peculiar CD8+ form of MF, more aggressive lymphomas such as primary cutaneous aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma, and from cutaneous gamma/delta lymphoma.8 Accounting for fewer than 5% of cases, type E LyP shows more extensive necrosis and ulceration due to angiocentric and angiodestructive infiltrates of mostly medium-sized, pleomorphic CD8+ and CD30+ lymphocytes with hemorrhage, vascular occlusion and thrombi, admixed with some eosinophils.9 Although clinically indolent, the histology can be confused with that of extranodal NK/T-cell lymphoma, nasal type, cutaneous gamma/delta lymphoma or ALCL (primary cutaneous or systemic form) with angiocentric and angiodestructive growth. It is important to highlight that histological differential diagnoses of LyP (such as aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma or MF) must be excluded by clinicopathological correlation based on characteristic clinical grounds with the typical “waxing and waning” presentation of LyP.

Recently, the detection of rearrangements of the DUSP22-IRF4 locus on chromosome 6p25.3 has enabled the identification of a new molecular-based type of LyP with a characteristic histological pattern.10

Lymphomatoid papulosis with 6p25.3 rearrangements

This molecular alteration at the DUSP22-IRF4 locus is less frequent in LyP than in pcALCL and accounts for fewer than 5% of cases of LyP. Typically, patients are older than those with other forms of LyP, and their lesions are characterized by a biphasic histological pattern showing, on the one hand, extensive epidermotropism with CD30+ small-to-medium-sized T-lymphocytes that simulate pagetoid reticulosis lesions and, on the other, a dermal neoplastic infiltrate composed of large T cells with strong CD30 positivity.11

T-cell receptor clonality

Detection of T-cell receptor clonality differs significantly between LyP types.12 This difference might be related to the number of tumor cells present in the infiltrate, which is lower in type A than in type C, hindering the detection technique in paraffin-embedded tissues. LyP presents atypical evolution for a peripheral T-cell lymphoma, exhibiting self-healing lesions and multiple outbreaks. T-cell receptor clonality studies have been performed in various LyP lesions to investigate the potential role of foreign antigens and the relationship between LyP and other cutaneous T-cell lymphomas in cases with overlapping histological findings. Chott et al. showed that multiple skin lesions and associated T-cell lymphomas (MF and ALCL) were clonally related in most LyP patients, which suggests that a non-random genetic event initiates the disease.13 Shared clonality has been confirmed for LyP and MF lesions occurring in the same patients by de la Garza Bravos et al.14 T-cell receptor-γ expression is considered a feature of primary cutaneous gamma-delta T-cell lymphoma, and is rare in other types of primary cutaneous lymphoma. However, there are cases of type D LyP with a cytotoxic phenotype and T-cell receptor-γ expression that, unlike in primary cutaneous gamma-delta T-cell lymphoma, is not associated with worse prognosis.15

Other findings in lymphomatoid papulosis

SATB1 (special AT-rich sequence-binding protein 1) is an important thymocyte nuclear protein, a chromatin organizer that is crucial to the development of T-lymphocytes.16,17 SATB1 plays a role in inducing resistance to the death of Sézary cells and has been implicated in the pathogenesis of the leukemic form of cutaneous T-cell lymphoma-Sézary syndrome.18 Sun et al. investigated its expression in a large cohort of patients with CD30+ lymphoproliferative disorders, and studied the potential for its use in classifying CD30+ lymphoproliferative disorders with differential clinicopathological behaviors and prognoses.19 They identified SATB1 expression in anaplastic T cells in 91.7% of LyP cases and in 81.4% of pcALCL cases. SATB1 cases showed T-helper 1 polarization with expression of T-helper 17 cytokines and repressed T-helper 1-related genes.19 They also described a better response to methotrexate and interferon treatment in cases with high levels of SATB1 expression. Furthermore, these cases showed more prominent epidermal hyperplasia and granulocytic infiltration.20 Sun et al. postulated that the variability of SATB1 expression in CD30+ lymphoproliferative disorders could be related to the extent of DNA methylation.20 Tumor necrosis factor receptor (TNFR)-associated factor 1 (TRAF1) is involved in intracellular signal transduction of a range of TNFR, including CD30 and those associated with nuclear factor-κB activation.21 Assal et al. studied the expression of TRAF1 using one antibody that recognized
a formalin-resistant epitope (Ber-TRAFA1). They found strong TRAF1 expression in the tumor cells in most LyP cases, in contrast to tumor cells of primary and secondary pcALCL, in which TRAF1 expression was much more restricted. Benner et al. also studied this marker in conjunction with MUM1, Bcl2 and CD15, but found it to be of no prognostic or diagnostic utility. We review the role of apoptosis in LyP pathogenesis in greater depth in the section on pcALCL, below.

Mahtas et al. studied gene deregulation and spatial genome reorganization near the ALCL translocation breakpoint in ALCL. They described the aberrant expression of Fra2 and of Id2 in LyP, the latter being consistent with the findings of Cotta et al. They found a lower level of expression in LyP compared with systemic ALCL and argued that gene dosage could be involved in the invasiveness and progression of LyP.

PS3 mutations have rarely been found in LyP. Kapur et al. reported two cases of LyP with PS3 mutations from an analysis of 11 exons of the PS3 gene. They found PS3 mutations to be infrequent in cutaneous CD30+ lymphoproliferative disorders, and the two patients with LyP who harbored the mutation did not show any changes in the clinical behavior of the disease.

Notch1 expression has been identified in LyP tumor cells, in which it is associated with the expression of the Notch1 ligand Jagged1, but not of the Delta1 ligand, which was expressed at low or negligible levels. The levels of expression of Notch1 and Jagged1 were higher in pcALCL samples, a finding that is discussed in greater detail in the section on pcALCL, below.

To date, no ALK fusions have been reported in LyP, in contrast to pcALCL, and no TP63 rearrangements have been found in these patients.

Primary cutaneous anaplastic large cell lymphoma

pcALCL is, by definition, a CD30+ large T-cell neoplasm composed of large cells with an anaplastic, pleomorphic or immunoblastic morphology. The CD30 antigen is expressed in more than 75% of tumor cells. pcALCL resembles other forms of ALCL but arises primarily in the skin. The clinical course of pcALCL differs from that of systemic forms of ALCL, both ALK+ and ALK-, which usually appear with absent or subtle epidermotropism (Figure 1). The levels of expression of Notch1 and Jagged1 were higher in pcALCL samples, a finding that is discussed in greater detail in the section on pcALCL, below.

To date, no ALK fusions have been reported in LyP, in contrast to pcALCL, and no TP63 rearrangements have been found in these patients. Other unusual histological presentations of pcALCL have been reported, including angiocentric or angiodestructive forms, sarcomatoid variants with prominent spindle-cell morphology, and small cell variants that are rarer than in systemic forms of ALK- ALCL and an intravascular ALCL that may involve the skin and must be distinguished from the more common intralymphatic spread of tumor cells in pcALCL, which seems to have no prognostic implications.

pcALCL cells usually carry an activated T-cell phenotype in which CD3 is expressed in more than 75% of tumor cells (the hallmark of the disease) (Figure 1), frequently accompanied by CD8, CD4 and CD45RO expression and varying degrees of loss of CD5 and CD2. The expression of other activation markers, such as CD71, HLA-DR and CD25 (IL-2R), has been noted in approximately half of the cases. Cytotoxic markers (TIA1, perforin and granzyme B) and cutaneous lymphocyte antigen (CLA, HECA-452) may also be found in around half of the patients.

In contrast to systemic ALK+ ALCL, in which approximately 43% of cases are EMA+, EMA is often negative or only focally positive in pcALCL. Interestingly, pcALCL shares with transformed MF and Sézary syndrome the expression of KIR5DL2
(CD158k) by neoplastic cells, a potential target reviewed in the next section.47

Altered expression of the T-cell receptor/CD3 complex, T-cell receptor-associated transcription factors and signal transduction molecules is a common feature of systemic and cutaneous CD30+ lymphoproliferations, a finding that may be of potential diagnostic utility.48

Monoclonal rearrangement of the TCR gene occurs in 65% to 90% of cases of pcALCL in contrast with a much lower frequency in LyP types A and B.12,49

Genetic variants of primary cutaneous anaplastic large cell lymphoma

pcALCL seems to carry the same molecular alterations as systemic ALCL, but with dramatic differences in frequencies. From the molecular point of view, most pcALCL cases would currently be classified as triple-negative (ALK-, DUSP22-, TP63-negative), since they do not carry any of these precise underlying molecular alterations. However, these lymphomas have an entirely different prognosis from their systemic counterparts, with some of them showing spontaneous regression and an absence of progression, with long-term survival in the vast majority of the cases (Figure 1). The molecular alterations present in pcALCL are, in descending order of frequency: (i) DUSP22 rearrangements (Figure 2);11,50-61 (ii) ALK translocations (Figure 3);62-65 (iii) TP63 rearrangements;77-79 and (iv) NPM1-TYK2 gene fusion.80-82 ALK translocations are much less frequent than in systemic lymphomas, having been described in isolated cases or very small series.83-86 TP63 rearrangements and NPM1-TYK2 gene fusion are exceptional and only isolated cases have been reported.27,67-69

ALK-negative primary cutaneous anaplastic large cell lymphoma with DUSP22 rearrangements

DUSP22 rearrangements in systemic ALK- ALCL have been associated with a better prognosis, similar to that of ALK- systemic ALCL, compared with TP63-translocated or triple-negative cases.90,91 About 20% of pcALCL cases harbor the DUSP22-IRF4 translocation, with no correlation with MUM1/IRF4 protein expression.11,12,25 First reported in LyP, a particular biphasic histological pattern has been linked to the presence of DUSP22 rearrangements in pcALCL (Figure 2). This pattern is characterized by:

Figure 1. “Classic”, ALK-, DUSP22-, TP63- (triple negative) primary cutaneous anaplastic large cell lymphoma. (A) Clinical picture showing two adjacent tumoral erythematous nodules located in the scapular region simulating dermatofibrosarcoma protubersans. (B,C) (x40), Hematoxylin & eosin stain showing the dermal infiltration consisting of a circumscribed infiltrate, composed of arranged large lymphoid cells with absent or subtle epidermotropism. (D,E) (x40), CD30 stain showing positivity in the membrane and Golgi of the tumoral large cells.

Figure 2. ALK-negative primary cutaneous anaplastic large cell lymphoma with DUSP22 rearrangements. (A) Clinical picture of a large ulcerated tumor in the left malar region of an elderly woman showing (B) the typical CD30 staining of a case of pcALCL with DUSP22 rearrangement (Ref. 58, courtesy of Onaindia et al.), evidencing extensive epidermotropism with CO30+ small-to-medium-sized T-lymphocytes that simulate pagetoid reticulosis lesions. (C) Hematoxylin & eosin-stained panoramic view of the case in (E) and (F) showing the tumor nodule with profuse dermal involvement. (D) Detail, stained with hematoxylin & eosin, of another case exemplifying the biphasic epidermal and dermal lymphocytic infiltrate. (E,F) (x40), CD3 stain highlights the intraepidermic neoplastic T cells in another case with DUSP22 rearrangement.
by the simultaneous presence of dermic CD30+ large cells and intraepidermal infiltrate by CD30+ small cells with a pagetoid reticulosis pattern.²⁵ The clinical behavior and prognosis of cases with DUSP22 rearrangements is similar to that of cases without such rearrangements.²⁶ Currently, clinical presentation and staging remain essential to differentiate cases of pALCL with DUSP22 rearrangement from LyP with this molecular alteration, because the two entities have similar histological features.²⁴ DUSP22 rearrangements have also been described in rare cases of CD30-rich tumoral MF.²⁸

Expression of the chemokine receptor gene CCR8 is associated with DUSP22 rearrangements in ALCL.²⁹ It has been proposed that the higher level of expression of this skin-homing chemokine receptor may explain the lower tendency of pALCL to disseminate to extracutaneous sites.²⁹

The pathways activated after DUSP22-IRF4 rearrangements in peripheral T-cell lymphomas have recently been investigated by Mélard et al.²⁹ They found a tumor suppressor function for DUSP22, with the restored expression of DUSP22 promoting apoptosis and impairing soft agar clonogenicity.²⁹ Negative regulation of the interleukin-6/leukemia inhibitory factor/signal transduction and activator of transcription (STAT)-3 pathway has been found in experimental studies.³⁰ Consistent with these findings, DUSP22 (also known as JKAP) knockout mice develop inflammation and autoimmunity.³¹

**ALK-positive primary cutaneous anaplastic large cell lymphoma**

Cutaneous involvement in cases of systemic ALK+ ALCL is generally indicative of a bad prognosis (relative risk: 2) and occurs in 26% of pediatric ALK+ ALCL cases.³² In contrast, ALK+ pALCL cases seem to have a more favorable outcome. Only a few cases of ALK+ pALCL have been reported, the largest series being that described by Oschlies et al.,³³ in which six pediatric patients with ALK+ pALCL had a favorable clinical course, comparable to that of patients with ALK- pALCL. Other ALK+ primary cutaneous cases occurred in adults and had peculiar features, such as cytoplasmic ALK expression and a lack of ALK translocation.³³ To date, no ALK fusion partners exclusive to the primary cutaneous cases have been reported. It is important to stage patients with ALK+ pALCL carefully because cutaneous lesions triggered by insect bites can be the first manifestation of systemic ALK+ ALCL.³³ The authors postulated that insect bite-associated antigens may attract T lymphocytes to the skin, some of which bear the ALK translocation t(2;5). The subsequent release of different cytokines at the site of the bite could act as a “second hit” and activate T cells, which may express the oncogenic NPM-ALK protein and initiate deregulated growth.³³

**Primary cutaneous anaplastic large cell lymphoma with TP63 rearrangements**

In 2012, Vasmatzis et al. described two of 19 pALCL that carried TP63 rearrangements,³³ both of which had an unusual, aggressive clinical behavior, analogous to that of systemic ALCL with TP63 rearrangements.³³ Subsequent work by the same group also identified a case of aggressive MF with a TP63 translocation.³⁴ In both series, TP63 translocations were associated with strong TP63 protein expression detectable by immunohistochemistry, but this was not a specific finding since the protein was also expressed in cases without a TP63 translocation. Schrader et al. reviewed a series of 17 cases of aggressive LyP and pALCL. They found no cases with a TP63 translocation, and confirmed the lack of specificity of the TP63 immunohistochemistry.³⁴

**NPM1-TYK2 gene fusion and oncogenic STAT3 activation**

Mutations on the JAK1/STAT3 pathway are common in systemic ALK+ ALCL.³³ However, these mutations have been found in only 5% of pALCL, which is further evidence of the distinct molecular pathogenesis of the two entities. Whole-transcriptome sequencing done in pALCL revealed the NPM1-TYK2 gene fusion, which encodes a protein containing an intact catalytic domain in TYK2 and an oligomerization domain of NPM. It was present in two (1 LyP, 1 pALCL) of the cases of primary cutaneous CD30+ lymphoproliferative disorders studied (n=47) and was not found in other mature T-cell neoplasms (n=151). Both cases showed nuclear STAT5 expression. This defective kinase activates the STAT signaling pathway (STAT1/3/5), implying that TYK2 could be a therapeutic target in this subset of patients.³⁵

**Epigenetic abnormalities in primary cutaneous anaplastic large cell lymphoma**

Epigenetic abnormalities, including histone tail post-translational modifications and DNA methylation, are a
hallmark of cancer and a potential target for therapy. DNA methylation profiling studies have not been done specifically in cutaneous ALCL; data derived from the analysis of systemic ALCL show an ALK-independent methylation signature, characteristic of and different from that of other peripheral T-cell lymphomas, establishing a relation with the promoter DNA methylation of early T-cell stages.

The enhancer of the zeste homolog 2 (EZH2) constitutes the core catalytic subunit of polycomb repressive complex2 (PRC2) and has a “canonical” function as a PRC2-dependent lysine 27 of the histone H3 (H3K27) methylator, which can also methylate a number of non-histone proteins, thereby promoting transcriptional activation, and making it a potential therapeutic target. Yi et al. found EZH2 overexpression in pcALCL and large cell transformed cutaneous T-cell lymphomas, in which it regulates apoptosis, cell-cycling in the neoplastic cells, and the interaction between the tumor and its microenvironment.

Non-coding RNA play an important epigenetic regulatory role that has implications for cell development and cancer, above all in the pathogenesis of T-cell lymphomas. MicroRNA (miRNA, miR) are small, non-coding RNA molecules that regulate gene expression at the post-transcriptional level by targeting the 3’-untranslated regions of messenger RNA to promote their degradation or decrease their translation. Several studies have identified different miRNA signatures for CD30+ pcALCL. Bennet et al. showed upregulation of an oncogenic miRNA signature in pcALCL comprising miR-155, miR-27b, miR-30c and miR-29. Sandoval’s study confirmed the upregulation of miR155 and identified upregulation of miR-21, miR-142-3p/5p, let-7i, miR-424, miR-431, miR-542-5p, and miR-484, with downregulation of some tumor-suppressor miRNA such as miR-342-p, miR-27b, miR-125b, miR-29b-1, miR155 and identified upregulation of miR-21, miR-142-3p/5p, let-7i, miR-424, miR-431, miR-542-5p, and miR-484, with downregulation of some tumor-suppressor miRNA such as miR-342-p, miR-27b, miR-125b. This miRNA profile reported for pcALCL differs considerably from those reported in systemic ALCL, which suggests a different underlying pathogenic mechanism or reflects differences in the microenvironment.

In this setting, epigenetic therapy (histone deacetylase inhibitors, such as romidepsin or belinostat, and methylation inhibitors) has shown some benefit in the treatment of ALCL and cutaneous T-cell lymphomas. In the future, more precise identification of miRNA profiling in pcALCL could allow us to develop specific diagnostic and progression markers and may lead to the use of more specific targeted therapies.

NOTCH signaling in primary cutaneous anaplastic large cell lymphoma

The deregulation of Notch signaling in hematopoietic cells has been linked to the development of several hematologic malignancies, including acute lymphoblastic T-cell leukemia, B-cell chronic lymphocytic leukemia, multiple myeloma, acute myeloid leukemia, Hodgkin lymphoma and systemic ALCL. Increased expression of Notch signaling molecules has been described in primary cutaneous CD30+ lymphoproliferative disorders, as previously mentioned. The same group found that pcALCL cells increased their expression of the intracellular domains of Notch receptors Notch1, Notch2, Notch3 and Notch4, as well as of the Notch ligand Delta and the product HE5. In addition, it was demonstrated that the inhibition of the Notch pathway through inhibition of gamma-secretase with gamma-secretase inhibitors induces apoptosis and decreases cell viability in pcALCL cell lines, findings that identify the Notch pathway as a potential therapeutic target in pcALCL.

**CDKN2A-CDKN2B losses in primary cutaneous anaplastic large cell lymphoma**

The **CDKN2A-CDKN2B** locus on the 9p21 chromosomal band encodes the proteins p14ARF, p16INK4A and p15INK4B. p14ARF-mdm2-p53 and p16INK4A/p15INK4B-Rb1 pathways are important for controlling the cell cycle, especially progression between G1 and S phases. Combined **CDKN2A-CDKN2B** deletion has been linked to aggressive behavior in cutaneous T-cell lymphomas, but more rarely in pcALCL, as confirmed by two research groups.

**Other cytogenetic abnormalities in primary cutaneous anaplastic large cell lymphoma**

Additional chromosomal alterations, such as gains of 7q31 and losses on 6q16-6q21, 6q27 and 13q34 regions, are recurrently present in pcALCL. Genomic imbalances have been found in chromosomal regions coding for FGFR1 (8p11), NRAS (1p13.2), MYCN (2p24.1), RAF1 (5p25) and others.

**Targeted therapies for primary cutaneous CD30-positive lymphoproliferative disorders**

Currently, complete surgical excision and local radiotherapy are the recommended first-line therapies for solitary or grouped localized pcALCL lesions. However, the most appropriate treatment in the relapsed/refractory setting has not been clearly identified. Multiaagent chemotherapy is customarily indicated for extracutaneous tumor spread beyond locoregional lymph nodes. In recent years, brentuximab vedotin, an anti-CD30 antibody-drug conjugate has been proposed as one of the best options for achieving complete remission with low toxicity in these patients. ALCANZA, an international, open-label, randomized, phase 3, multicenter clinical trial, has shown significant improvement in objective responses lasting at least 4 months with brentuximab vedotin compared with the physician’s choice of methotrexate or bexarotene in CD30+ cutaneous T-cell lymphomas, especially MF and pcALCL (having excluded Sézary syndrome and LyP from the study, since these are entities in which brentuximab vedotin is successful). The mean duration of response to this drug in pcALCL is 7.6 months. Peripheral neuropathy and fatigue are the most commonly reported adverse events (in 57.2% and 35.6% of cases, respectively). Recently the US Food and Drug Administration and the European Medicines Agency approved the use of brentuximab vedotin in cutaneous T-cell lymphomas. Besides the use of anti-CD30 molecules in the treatment of primary cutaneous CD30+ lymphoproliferative disorders, molecular data generated in the study of pcALCL offer multiple opportunities for targeted therapies (Figure 4).

The recognition of convergent mutations and kinase fusions leading to STAT3 activation in a subgroup of pcALCL could allow the use of JAK1/2/3 inhibitors in the...
treatment of this subgroup. In addition, patients with the rare subtype of ALK+ pcALCL could benefit from therapy with the ALK kinase inhibitor crizotinib, and other new-generation inhibitors such as alectinib or ceritinib. KIR3DL2 (CD158K) is a killer cell immunoglobulin-like receptor normally expressed by minor subsets of circulating CD8+ lymphocytes and natural killer cells. In contrast, tumor cells of pcALCL and CD30+ lymphoproliferative disorders, which are derived from cell lines Mac2a and Mac2b, express KIR3DL2 strongly. In Sézary syndrome, the expression of KIR3DL2 in malignant blood cells has been proposed as a marker of blood tumor burden. The novel agent IPH4102 is a monoclonal antibody directed against the cellular receptor KIR3DL2 that has proven effective in vitro cell lines of advanced pcALCL.

Finally, therapies acting at the epigenetic level, based on the mutations and epigenetic alterations described above, could be useful in pcALCL. More specifically, romidepsin and vorinostat, inhibitors of histone deacetylase, derived from the bacterium Chromobacterium violaceum are effective at inducing apoptosis with an antitumor effect in cutaneous T-cell lymphomas, alone and in combination. Recently, researchers from the Yale School of Medicine, using cell lines derived from patients with advanced MF and Sézary syndrome (MyLa, Sez4, HH, Hut78), observed in vitro that bromodomain and extraterminal (BET) protein inhibitors are synergistically potentiated by BCL2 inhibitors (e.g., venetoclax) and histone deacetylase inhibitors (e.g., vorinostat and romidepsin) in cutaneous T-cell lymphomas with MYC oncogene amplification. Patients with cutaneous CD30+ lymphoproliferative disorders with MYC-induced Id2 overexpression could also be candidates for this therapy. Recently, it was proposed that miR-155 inhibition could be used in combination with apoptotic treatments...
and checkpoint inhibitors in MF patients. MiR-155 is also upregulated in pcALCL, providing an additional therapeutic opportunity for these tumors.
