Fine-tuning CNN Image Retrieval with No Human Annotation

Filip Radenović Giorgos Tolias Ondřej Chum

1 Introduction

In instance image retrieval an image of a particular object, depicted in a query, is sought in a large unordered collection of images. Convolutional neural networks (CNNs) have been lately shown to provide an attractive solution to this problem. Besides having a small memory footprint, the CNN based approaches also achieve high accuracy. Neural networks have attracted a lot of attention after the success of Krizhevsky et al. [1] in the image classification task. Their success is mainly due to the use of very large annotated datasets, e.g. ImageNet [2]. The acquisition of the training data is a costly process of manual annotation, often prone to errors. Networks trained for image classification have shown strong adaptation abilities [3]. Specifically, using activations of CNNs trained for classification as the off-the-shelf image descriptors [4], [5] and adapting them for a number of tasks [6], [7], [8] have shown acceptable results. In particular, for image retrieval, a number of approaches directly use the network activations as image features and successfully perform image search [8], [9], [10], [11], [12].

Fine-tuning of the network, i.e. initialization by a pre-trained classification network and re-train for another specific task, is an alternative to a direct application of a pre-trained network. Fine-tuning significantly improves the adaptation ability [13], [14], however, further annotation of training data is required. The first fine-tuning approach for image retrieval is proposed by Babenko et al. [15], in which a significant amount of manual effort is invested to collect images and label them as specific building classes. They have shown to improve retrieval accuracy, however, their formulation is much closer to classification than to the desired properties of instance retrieval. In another approach, Arandjelovic et al. [16] perform fine-tuning guided by geo-tagged image databases and, similar to our work, they directly optimize the similarity measure to be used in the final task by selecting matching and non-matching pairs to perform the training.

In contrast to previous methods of training-data acquisition for image search, we dispense with the need of manually annotated data or any assumptions on the training dataset. We propose to achieve this by exploiting the geometry and the camera positions from 3D models reconstructed automatically by a structure-from-motion (SfM) pipeline. The state-of-the-art retrieval-SfM pipeline [17] takes an unordered image collection as an input and attempts to build all possible 3D models. To make the process efficient, fast image clustering is employed. A number of image clustering methods based on local features have been introduced [18], [19], [20]. Due to the spatial verification, the clusters discovered by these methods are reliable. In fact, the methods provide not only clusters, but also a matching graph or subgraph on the cluster images. The SfM filters out virtually all mismatched images, and provides image-to-model matches and camera positions for all matched images in the cluster. The whole process, from unordered collection of images to detailed 3D reconstructions, is fully automatic. Finally, the 3D models guide the selection of matching and non-matching pairs. We propose to exploit the training data acquired by the same procedure also in the descriptor post-processing stage to learn a discriminative whitening.

Additional contribution of this work lies in the introduction of a novel pooling layer after the convolutional layers. Previously, a number of approaches have been used. These range from fully connected layers [8], [15], to different global pooling layers, e.g. max pooling [9], average pooling [10], hybrid pooling [21] and weighted average pooling [11], or regional pooling [12]. We propose a pooling layer based on generalized-mean that has learnable parameters, either one global or one per output dimension. Both max and average pooling are its special cases. Our experiments show that it offers significant performance boost over standard non-trainable pooling layers. Our architecture is shown in Figure 1.
To summarize, we address unsupervised fine-tuning of CNNs for image retrieval. In particular, we make the following contributions: (1) We exploit SfM information and enforce not only hard non-matching (negative) but also hard matching (positive) examples for CNN training. This is shown to enhance the derived image representation. We show that compared to previous supervised approaches, the variability in the training data from 3D reconstructions delivers superior performance in the image retrieval task. (2) We show that the whitening traditionally performed on short representations [22] is, in some cases, unstable. We propose to learn the whitening through the same training data. Its effect is complementary to fine-tuning and it further boosts performance. Also, performing such a whitening as a post-processing step is better and much faster to train compared to end-to-end learning of it. (3) We propose a trainable pooling layer that generalizes existing popular pooling schemes for CNNs. It significantly improves the retrieval performance while preserving the same descriptor dimensionality. (4) We have two technical contributions: a novel aggregation method for multi-scale representation that uses the same aggregation parameter as learned in our pooling layer; and, a novel $\alpha$-weighted query expansion that is more robust compared to the standard average query expansion technique widely used for compact image representations. (5) Finally, we set a new state-of-the-art for Oxford Buildings, Paris, and Holidays datasets by retraining the commonly used CNN architectures, such as AlexNet [1], VGG [23], and ResNet [24].

This manuscript is an extension of our previous work [25]. We additionally propose a novel pooling layer (Section 3.2), a novel multi-scale image representation (Section 5.2), and a novel query expansion method (Section 5.3). Each one of the newly proposed methods boosts image retrieval performance, and is accompanied by experiments that give useful insights. In addition, we provide an extended related work discussion including the different pooling procedures used in prior CNN work and descriptor whitening. Finally, we compare our approach to the concurrent work of Gordo et al. [26], [27] that bears similarities to ours. They significantly improve the retrieval performance through end-to-end learning which incorporates building specific region proposals. In contrast to their work, we focus on the importance of hard training data examples, and employ a much simpler but equally powerful pooling layer.

The rest of the paper is organized as follow. Related work is discussed in Section 2, our network architecture and learning procedure is presented in Section 3, and our proposed automatic acquisition of the training data is described in Section 4. Finally, in Section 5 we perform an extensive quantitative and qualitative evaluation of all proposed novelties with different CNN architectures, and compare to the state of the art.

2 Related work

CNN-based representation is an appealing solution for image retrieval and in particular for compact image representations. Previous compact descriptors are typically constructed by aggregation of local features, where representatives are Fisher vectors [28], VLAD [29] and alternatives [30], [31], [32]. Impressively, in this work we show that CNNs dominate the image search task by outperforming state-of-the-art methods that have reached a higher level of maturity by incorporating large visual codebooks [33], [34], spatial verification [35], [36] and query expansion [37], [38].

In this work, instance retrieval is cast as a metric learning problem, i.e., an image embedding is learned so that the Euclidean distance captures the similarity well. Typical architectures for metric learning, such as two-branch siamese [39], [40], [41] or triplet networks [42], [43], [44] employ matching and non-matching pairs to perform the training and better suit to this task. Here, the problem of annotations is even more pronounced, i.e., for classification one needs only object category label, while for particular objects the labels have to be per image pair. Two images from the same object category could potentially be completely different, e.g., different viewpoints of the building or different buildings. We solve this problem in a fully automatic manner, without any human intervention, starting from a large unordered image collection.

In the following we discuss the related work for our main contributions, i.e., the training data collection, the pooling approach to construct a global image descriptor and the descriptor whitening.
2.1 Training data

A variety of previous methods apply CNN activations on the task of image retrieval [8], [9], [10], [11], [12], [45]. The achieved accuracy on retrieval is evidence for the generalization properties of CNNs. The employed networks are trained for image classification using ImageNet dataset [2], optimizing classification error. Babenko et al. [15] go one step further and re-train such networks with a dataset that is closer to the target task. They perform training with object classes that correspond to particular landmarks/buildings. Performance is improved on standard retrieval benchmarks. Despite the achievement, still, the final metric and the utilized layers are different to the ones actually optimized during learning.

Constructing such training datasets requires manual effort. In a recent work, geo-tagged datasets with timestamps offer the ground for weakly supervised fine-tuning of a triplet network [16]. Two images taken far from each other can be easily considered as non-matching, while matching examples are picked by the most similar nearby images. In the latter case, similarity is defined by the current representation of the CNN. This is the first approach that performs end-to-end fine-tuning for image retrieval and in particular for the task of geo-localization. The employed training images are now much closer to the final task. We differentiate by discovering matching and non-matching image pairs in an unsupervised way. Moreover, we derive matching examples based on 3D reconstruction which allows for harder examples.

Even though hard negative mining is a standard process [6], [16], this is not the case with hard positive examples. Mining of hard positive examples have been exploited in the work Simo-Serra et al. [46], a patch level examples were extracted though the guidance from a 3D reconstruction. Hard positive pairs have to be sampled carefully. Extremely hard positive examples (such as minimal overlap between images or extreme scale change) do not allow to generalize and lead to over-fitting.

A concurrent work to ours also uses local features and geometric verification to select positive examples [26]. In contrast to our fully unsupervised way, they start from a landmarks dataset that involved manual cleaning and the spatial verification uses the landmarks labels to avoid exhaustive evaluation.

2.2 Pooling method

Early approaches applying CNNs for image retrieval experiment by setting the fully connected layer activations to be the global image descriptors [8], [15]. The work by Razavian et al. [9] moves the focus to the activations of convolutional layers followed by a global pooling operation. A compact image representation is constructed in this fashion with dimensionality equivalent to the number of feature maps of the corresponding convolutional layer. In particular, they propose to use max pooling, which is later approximated with integral max pooling [12].

Sum pooling is initially proposed by Babenko and Lempitsky [10] which is shown to perform well especially due to the subsequent descriptor whitening. One step further is the weighted sum pooling of Kalantidis et al. [11] which can also be seen as a way to perform transfer learning. Popular encodings such as BoW, VLAD, and Fisher vectors are adapted in the context of CNN activations in the work of Mohedano et al. [47], Arandjelovic et al. [16], and Ong et al. [48], respectively. Sum pooling is employed once an appropriate embedding is performed beforehand.

A hybrid scheme is the R-MAC method [12] performing max pooling over regions and finally sum pooling the regional descriptors. Mixed pooling is proposed globally for retrieval [21] and in the standard local pooling for object recognition [49]. It is a linear combination of max and sum pooling.

2.3 Descriptor whitening

Whitening the data representation is known to be very essential for image retrieval since the work of Jégou and Chum [22]. Their interpretation lies on jointly down-weighting co-occurrences and, thus, handling the problem of over-counting. This benefit is further pronounced in the case of CNN based descriptors [5], [10], [12]. It is commonly learned from a generative model in an unsupervised way by PCA on an independent dataset.

We propose to learn the whitening transform in a discriminative manner, using the same acquisition procedure of the training data from 3D models. A similar approach has been used to whiten local-feature descriptors by Mikolajczyk and Matas [50].

Gordo et al. [26] rather learn the whitening in the CNN and in an end-to-end manner. In our experiments we found this choice to be at most as good as the descriptor post-processing and less efficient due to slower convergence of the learning.

3 Network architecture and learning

In this section we describe the network architecture and present the proposed generalized pooling layer. Then, we explain the process of fine-tuning using the contrastive loss and a two branch network. Finally, we describe how, after fine-tuning, we use the same training data to learn projections that appear to be an effective post-processing step. Our proposed architecture is depicted in Figure 1.

3.1 Fully convolutional network

Our methodology applies to any fully convolutional CNN [51]. In practice, popular CNNs for generic object recognition are adopted, such as AlexNet [1], VGG [23], or ResNet [24], while their fully connected layers are discarded. This provides a good initialization to perform the fine-tuning.

Now, given an input image, the output is a 3D tensor $X$ of $W \times H \times K$ dimensions, where $K$ is the number of feature maps in the last layer. Let $X_k$ be the set of $W \times H$ activations for feature map $k \in \{1 \ldots K\}$. The network output consists of $K$ such activation sets or 2D feature maps. We additionally assume that the very last layer is a Rectified Linear Unit (ReLU) such that $X$ is non-negative.
3.2 Generalized-mean pooling and image descriptor

We now add a pooling layer that takes \( \mathcal{X} \) as an input and produces a vector \( f \) as an output of the pooling process. This vector in the case of the conventional global max pooling (MAC vector \([9, 12]\)) is given by

\[
f^{(m)} = [f^{(m)}_1 \ldots f^{(m)}_K]^\top, \quad f^{(m)}_k = \max_{x \in \mathcal{X}_k} x,
\]

while for average pooling (SPoC vector \([10]\)) by

\[
f^{(a)} = [f^{(a)}_1 \ldots f^{(a)}_K]^\top, \quad f^{(a)}_k = \frac{1}{|\mathcal{X}_k|} \sum_{x \in \mathcal{X}_k} x. \tag{2}
\]

Instead, we exploit the generalized mean \([52]\) and propose to use generalized-mean (GeM) pooling whose result is given by

\[
f^{(g)} = [f^{(g)}_1 \ldots f^{(g)}_K]^\top, \quad f^{(g)}_k = \left( \frac{1}{|\mathcal{X}_k|} \sum_{x \in \mathcal{X}_k} x^{p_k} \right)^{\frac{1}{p_k}}. \tag{3}
\]

Pooling methods (1) and (2) are special cases of GeM pooling given in (3), i.e., max pooling when \( p_k \to \infty \) and average pooling for \( p_k = 1 \). The feature vector finally consists of a single value per feature map, i.e., the generalized-mean activation, and its dimensionality is equal to \( K \). For many popular networks this is equal to 256, 512 or 2048, making it a compact image representation.

The pooling parameter \( p_k \) can be manually set or learned since this operation is differentiable and can be part of the back-propagation. The corresponding derivatives (while skipping the superscript \((g)\) for brevity) are given by

\[
\frac{\partial f_k}{\partial x_j} = \frac{1}{|\mathcal{X}_k|} f^{1-p_k}_k x_j x^{p_k-1}_j, \tag{4}
\]

\[
\frac{\partial f_k}{\partial p_k} = f_k \left( \log \frac{|\mathcal{X}_k|}{\sum_{x \in \mathcal{X}_k} x^{p_k}} + p_k \sum_{x \in \mathcal{X}_k} x^{p_k} \log x \right). \tag{5}
\]

There is a different pooling parameter per feature map in (3), but it is also possible to use a shared one. In this case \( p_k = p, \forall k \in [1, K] \) and we simply denote it by \( p \) and not \( p_k \). We examine such options in the experimental section and compare to hand tuned and fixed parameter values.

Max pooling, in the case of MAC, retains one activation per 2D feature map. In this way, each descriptor component corresponds to an image patch equal to the receptive field. Then, pairwise image similarity is evaluated via descriptor inner product. Therefore, MAC similarity implicitly forms patch correspondences. The strength of each correspondence is given by the product of the associated descriptor components. In Figure 2 we show the image patches in correspondence that contribute most to the similarity. Such implicit correspondences are improved after fine-tuning. Moreover, the CNN fires less to ImageNet classes, e.g. cars and bicycles.

Fig. 2. Visualization of patches corresponding to the MAC vector components that have the highest contribution to the pairwise image similarity. Examples shown use CNN before (top) and after (bottom) the fine-tuning of VGG. The same color corresponds to the same vector component (feature map) per image pair. The patch size is equal to the receptive field of the last pooling layer.
Fig. 3. Visualization of CNN responses $X_k$ raised to the power $p$. We project $X_k^p$ on the original image for several feature maps. We show the case of the fine-tuned VGG with GeM layer of single pooling parameter $p$ for all feature maps. We show 9 feature maps in total. The value of $p$ has converged to 2.92. The selected feature maps are the ones that correspond to the GeM vector components that have the highest contribution (strength) to the pairwise image similarity.

In Figure 4 we visualize how the activations are affected by the generalized mean. We show how larger $p$ results in more localized feature maps. Finally, in Figure 3 we present a matching example after fine-tuning VGG followed by a global GeM pooling layer (GeM layer in short). The feature maps are improved and fire more on the common object while they tend to be better localized.

The last network layer comprises an $\ell_2$-normalization layer. Vector $f$ is $\ell_2$-normalized so that similarity between two images is finally evaluated with inner product. In the rest of the paper, GeM vector corresponds to the $\ell_2$-normalized vector $\tilde{f}$ and constitutes the image descriptor.

3.3 Siamese learning and loss function

We adopt a siamese architecture and train a two branch network. Each branch is a clone of the other, meaning that they share the same parameters. The training input consists of image pairs $(i, j)$ and labels $Y(i, j) \in \{0, 1\}$ declaring whether a pair is non-matching (label 0) or matching (label 1). We employ the contrastive loss [39] that acts on matching and non-matching pairs and is defined as

$$L(i, j) = \begin{cases} \frac{1}{2}||\tilde{f}(i) - \tilde{f}(j)||^2, & \text{if } Y(i, j) = 1 \\ \frac{1}{2} \left( \max\{0, \tau - ||\tilde{f}(i) - \tilde{f}(j)||\} \right)^2, & \text{if } Y(i, j) = 0 \end{cases}$$

where $\tilde{f}(i)$ is the $\ell_2$-normalized GeM vector of image $i$, and $\tau$ is a margin parameter defining when non-matching pairs have large enough distance in order not to be taken into account in the loss. We train the network using a large number of training pairs created automatically (see Section 4).

In contrast to other methods [16], [42], [43], [44], we find that the contrastive loss generalizes better and converges at higher performance than the triplet loss.
3.4 Whitening and dimensionality reduction

In this section, the post-processing of fine-tuned GeM vectors is considered. Previous methods [10], [12] use PCA of an independent set for whitening and dimensionality reduction, i.e. the covariance matrix of all descriptors is analyzed. We propose to take advantage of the labeled data provided by the 3D models and use linear discriminant projections originally proposed by Mikolajczyk and Matas [50]. The projection is decomposed into two parts, whitening and rotation. The whitening part is the inverse of the square-root of the intraclass (matching pairs) covariance matrix $C_S^{-\frac{1}{2}}$, where

$$
C_S = \sum_{Y(i,j)=1} (\bar{f}(i) - \bar{f}(j)) (\bar{f}(i) - \bar{f}(j))^\top. \tag{7}
$$

The rotation part is the PCA of the interclass (non-matching pairs) covariance matrix in the whitened space eig($C_S^{-\frac{1}{2}} C_D C_S^{-\frac{1}{2}}$), where

$$
C_D = \sum_{Y(i,j)=0} (\bar{f}(i) - \bar{f}(j)) (\bar{f}(i) - \bar{f}(j))^\top. \tag{8}
$$

The projection $P = C_S^{-\frac{1}{2}} \text{eig}(C_S^{-\frac{1}{2}} C_D C_S^{-\frac{1}{2}})$ is then applied as $P^\top (\bar{f}(i) - \mu)$, where $\mu$ is the mean GeM vector to perform centering. To reduce the descriptor dimensionality to $D$ dimensions, only eigenvectors corresponding to $D$ largest eigenvalues are used. Projected vectors are subsequently $\ell_2$-normalized.

Our approach uses all available training pairs efficiently in the optimization of the whitening. It is not optimized in an end-to-end manner and it is performed without using batches of training data. We first optimize the GeM descriptor and then optimize the whitening.

The described approach acts as a post-processing step, once the fine-tuning of the CNN is finished. We additionally compare with the end-to-end learning of whitening. Whitening consists of vector shifting and projection which is straightforwardly modeled by a fully connected layer. The results are in favor of our approach and are discussed in the experimental section.

4 Training dataset

In this section we briefly summarize the tightly-coupled Bag-of-Words (BoW) image retrieval and Structure-from-Motion (SfM) 3D reconstruction system [17], [53] that is employed to automatically select our training data. Then, we describe how we exploit the 3D information to select harder matching pairs and hard non-matching pairs with larger variability.

4.1 BoW and 3D reconstruction

The retrieval engine used in the work of Schonberger et al. [17] builds upon BoW with fast spatial verification [33]. It uses Hessian affine local features [54], RootSIFT descriptors [55], and a fine vocabulary of 16M visual words [56]. Then, query images are chosen via min-hash and spatial verification, as in [18]. Image retrieval based on BoW is used to collect images of the objects/landmarks. These images serve as the initial matching graph for the succeeding SfM reconstruction, which is performed using the state-of-the-art SfM pipeline [57], [58], [59]. Different mining techniques, e.g. zoom in, zoom out [60], [61], sideways crawl [17], help to build larger and more complete model.

In this work, we exploit the outcome of such a system. Given a large unannotated image collection, images are clustered and a 3D model is constructed per cluster. We use the terms 3D model, model and cluster interchangeably. For each image, the estimated camera position is known, as well as the local features registered on the 3D model. We drop redundant (overlapping) 3D models, that might have been constructed from different seeds. Models reconstructing the same landmark but from different and disjoint viewpoints are considered as non-overlapping.

4.2 Selection of training image pairs

A 3D model is described as a bipartite visibility graph $G = (I \cup P, E)$ [62], where images $I$ and points $P$ are the vertices of the graph. The edges of this graph are defined by visibility relations between cameras and points, i.e. if a point $p \in P$ is visible in an image $i \in I$, then there exists an edge $(i, p) \in E$. The set of points observed by an image $i$ is given by

$$
P(i) = \{p \in P : (i, p) \in E\}. \tag{9}
$$

We create a dataset of tuples $(q, m(q), N(q))$, where $q$ represents a query image, $m(q)$ is a positive image that matches the query, and $N(q)$ is a set of negative images that do not match the query. These tuples are used to form training image pairs, where each tuple corresponds to $|N(q)| + 1$ pairs. For a query image $q$, a pool $M(q)$ of candidate positive images is constructed based on the camera positions in the cluster of $q$. It consists of the $k$ images with closest camera centers to the query. Due to the wide range of camera orientations, these do not necessarily depict the same object. We therefore compare three different ways to select the positive image. The positive examples are fixed during the whole training process for all three strategies.

Positive images: CNN descriptor distance. The image that has the lowest descriptor distance to the query is chosen as positive, formally

$$
m_1(q) = \arg\min_{i \in M(q)} ||f(q) - f(i)||. \tag{10}
$$

This strategy is similar to the one followed by Arandjelovic et al. [16]. They adopt this choice since only GPS coordinates are available and not camera orientations. As a consequence, the chosen matching images already have small descriptor distance and, therefore, small loss too. The network is thus not forced to drastically change/learn by the matching examples, which is the drawback of this approach.

Positive images: maximum inliers. In this approach, the 3D information is exploited to choose the positive image, independently of the CNN descriptor. In particular, the image that has the highest number of co-observed 3D points with the query is chosen. That is,

$$
m_2(q) = \arg\max_{i \in M(q)} |P(q) \cap P(i)|. \tag{11}
$$
This measure corresponds to the number of spatially verified features between two images, a measure commonly used for ranking in BoW-based retrieval. As this choice is independent of the CNN representation, it delivers more challenging positive examples.

**Positive images: relaxed inliers.** Even though both previous methods choose positive images depicting the same object as the query, the variance of viewpoints is limited. Instead of using a pool of images with similar camera position, the positive example is selected at random from a set of images that co-observe enough points with the query, but do not exhibit too extreme scale change. The positive example in this case is

\[
m_3(q) = \text{rnd} \left\{ i \in \mathcal{M}(q) : \frac{|\mathcal{P}(i) \cap \mathcal{P}(q)|}{|\mathcal{P}(q)|} \geq t_i, \text{scale}(i, q) \leq t_s \right\},
\]

where \(\text{scale}(i, q)\) is the scale change between the two images. This method results in selecting harder matching examples which are still guaranteed to depict the same object. Method \(m_3\) chooses different image than \(m_1\) on 86.5% of the queries. In Figure 6 we present examples of query images and the corresponding positives selected with the three different methods. The relaxed method increases the variability of viewpoints.

**Negative images.** Negative examples are selected from clusters different than the cluster of the query image, as the clusters are non-overlapping. We choose hard negatives \([6], [46]\), that is, non-matching images with the most similar descriptor. Two different strategies are proposed. In the first, \(\mathcal{N}_1(q)\), k-nearest neighbors from all non-matching images are selected. In the other, \(\mathcal{N}_2(q)\), the same criterion is used, but at most one image per cluster is allowed. While \(\mathcal{N}_1(q)\) often leads to multiple, and very similar, instances of the same object, \(\mathcal{N}_2(q)\) provides higher variability of the negative examples, see Figure 5. While positives examples are fixed during the whole training process, hard negatives depend on the current CNN parameters and are re-mined multiple times per epoch.
5 Experiments

In this section we discuss implementation details of our training, evaluate different components of our method, and compare to the state of the art.

5.1 Training setup and implementation details

Structure-from-Motion (SfM). Our training samples are derived from the dataset used in the work of Schonberger et al. [17], which consists of 7.4 million images downloaded from Flickr using keywords of popular landmarks, cities and countries across the world. The clustering procedure [18] gives around 20k images to serve as query seeds. The extensive retrieval-SfM reconstruction [33] of the whole dataset results in 1,474 reconstructed 3D models. Removing overlapping models leaves us with 713 3D models containing more than 163k unique images from the initial dataset. The initial dataset contains, on purpose, all images of Oxford5k and Paris6k datasets. In this way, we are able to exclude 98 clusters that contain any image (or their near duplicates) from these test datasets.

Training pairs. The size of the 3D models varies from 25 to 11k images. We randomly select 551 models (around 133k images) for training and 162 (around 30k images) for validation. The number of training queries per 3D model is 10% of its size and limited to be less or equal to 30. Around 6,000 and 1,700 images are selected for training and validation queries per epoch, respectively.

Each training and validation tuple contains 1 query, 1 positive and 5 negative images. The pool of candidate positives consists of \( k = 100 \) images with the closest camera centers to the query. In particular, for method \( m_3 \), the inliers overlap threshold is \( t_i = 0.2 \), and the scale change threshold \( t_s = 1.5 \). Hard negatives are re-mined 3 times per epoch, i.e. roughly every 2,000 training queries. Given the chosen queries and the chosen positives, we further add 20 images per model to serve as candidate negatives during re-mining. This constitutes a training set of around 22k images per epoch when all the training 3D models are used. The query-tuple selection process is repeated every epoch. This slightly improves the results.

Learning configuration. We use MatConvNet [63] for the fine-tuning of networks. To perform the fine-tuning as described in Section 3, we initialize by the convolutional layers of AlexNet [1], VGG16 [23], or ResNet101 [24]. AlexNet is trained using stochastic gradient descent (SGD), while training of VGG and ResNet is more stable with Adam [64]. We use initial learning rate equal to \( \ell_0 = 10^{-3} \) for SGD, initial stepsize equal to \( \ell_0 = 10^{-6} \) for Adam, an exponential decay \( \ell_0 \exp(-0.1i) \) over epoch \( i \), momentum 0.9, weight decay \( 5 \times 10^{-4} \), margin \( \tau \) for contrastive loss 0.7 for AlexNet, 0.75 for VGG, and 0.85 for ResNet, justified by the increase in the dimensionality of the embedding, and batch size of 5 training tuples. All training images are resized to a maximum size of 362 × 362, while keeping the original aspect ratio. Training is done for at most 30 epochs and the best network is selected based on performance, measured via mean Average Precision (mAP) [33], on validation tuples. Fine-tuning of VGG for one epoch takes around 2 hours on a single TITAN X (Maxwell) GPU with 12 GB of memory.

We overcome GPU memory limitations by associating each query to a tuple, i.e., query plus 6 images (5 positive and 1 negative). Moreover, the whole tuple is processed in the same batch. Therefore, we feed 7 images to the network that represent 6 pairs. In a naive approach, when the query image is different for each pair, 6 pairs require 12 images.

5.2 Test datasets and evaluation protocol

Test datasets. We evaluate our approach on Oxford buildings [33], Paris [65] and Holidays² [66] datasets. The first two are closer to our training data, while the last differentiates by containing similar scenes and not only man made objects or buildings. These are also combined with 100k distractors from Oxford100k to allow for evaluation at larger scale. The performance is measured via mAP. We follow the standard evaluation protocol for Oxford and Paris and crop the query images with the provided bounding box. The cropped image is fed as input to the CNN.

Single-scale evaluation. The dimensionality of the images fed into the CNN is limited to 1024 × 1024 pixels. In our experiments, no vector post-processing is applied if not otherwise stated.

Multi-scale evaluation. During test time we adopt a multi-scale procedure similarly to the work of Gordo et al. [27] who show that multi-scale feature extraction results in improved retrieval. We resize the input image to different sizes, then feed multiple input images to the network, and finally combine the global descriptors from multiple scales into a single descriptor. Instead of average pooling the descriptors [27] we combine them with the generalized mean. We set the pooling parameter equal to the value learned in the global pooling layer of the network. In this case, the whitening is learned on the final multi-scale image descriptors. In our experiments, a single-scale evaluation is followed if not otherwise stated.

5.3 Results on image retrieval

Learning. We evaluate the off-the-shelf CNN and our fine-tuned ones after different number of training epochs. The different methods for positive and negative selection are evaluated independently in order to decompose the benefit of each one. Finally, we also perform a comparison with the triplet loss [16], trained on the same training data as the contrastive loss; a triplet forms two pairs. Results are presented in Figure 7. The results show that positive examples with larger view point variability and negative examples with higher content variability acquire a consistent increase in the performance. The triplet loss ³ appears to be inferior in our context; we observe oscillation of the error in the validation set from early epochs, which implies over-fitting. In the rest of the paper, we adopt the \( m_3, N_2 \) approach.

2. We use the up-right version of Holidays dataset where images are manually rotated so that depicted objects are up-right. This makes us directly comparable to [27]. A different version of up-right Holidays is used in our earlier work [25], where EXIF metadata is used to rotate the images.

3. The margin parameter for the triplet loss is set equal to 0.1 [16].
Dataset variability. We perform fine-tuning by using a subset of the available 3D models. Results are presented in Figure 8 with 10, 100 and 551 (all available) clusters, while keeping the amount of training data, i.e. number of training queries, fixed. In the case of 10 and 100 models we use the largest ones. It is better to train with all 3D models due to the higher variability in the training set. Remarking, significant increase in performance is achieved even with 10 or 100 models. However, the network is able to over-fit in the case of few clusters. In the rest of our experiments we use all 551 3D models for training.

Pooling methods. We evaluate the effect of different pooling layers during CNN fine-tuning. We present the results in Table 1. GeM layer consistently outperforms the conventional max and average pooling. This holds for each of the following cases, (i) a single shared pooling parameter $p$ is used, (ii) each feature map has different $p_k$ and (iii) the pooling parameter(s) is (are) either fixed or learned. Learning a shared parameter turns out to be better than learning multiple ones, as the latter makes the cost function more complex. Additionally, the initial values seem to matter to some extent, with a preference for intermediate values. Finally, a shared fixed parameter and a shared learned parameter perform similarly, with the latter being slightly better. This is the case which we adopt for the rest of our experiments, i.e. a single shared parameter $p$ is learned.

Learned projections. The PCA-whitening [22] (PCA$_w$) is shown to be essential in some cases of CNN-based descriptors [10], [12], [15]. On the other hand, it is shown that on some datasets, the performance after PCA$_w$ substantially drops compared to the raw descriptors (max pooling on Oxford5k [10]). We perform comparison of this traditional way of whitening and our learned discriminative whitening ($L_w$), described in Section 3.4. Table 2 shows results without post-processing, with PCA$_w$ and with $L_w$. Our experiments confirm, that PCA$_w$ often reduces the performance. In contrast to that, the proposed $L_w$ achieves the best performance in most cases and is never the worst performing method. Compared with the no post-processing baseline, $L_w$ reduces the performance twice for AlexNet, but the drop is negligible compared to the drop observed for PCA$_w$. For VGG, the proposed $L_w$, always outperforms the no post-processing baseline.

We conduct an additional experiment by appending a whitening layer at the end of the network during fine-tuning. In this way, whitening is learned in an end-to-end manner, along with the convolutional filters, and with the same training data in batch-mode. Dropout [67] is additionally used for this layer which we find to be essential. We observe that convergence of the network comes much slower in this case, i.e. after 60 epochs. Moreover, the final achieved performance is not higher than our $L_w$. In particular, end-to-end whitening on AlexNet MAC achieves 49.6 and 52.1 mAP on Oxford105k and Paris106k, respectively, while our $L_w$ on the same network achieves 52.8 and 54.7 mAP on Oxford105k and Paris106k, respectively. Therefore, we adopt $L_w$ as it is much faster to train and more effective.

Dimensionality reduction. We compare dimensionality reduction performed with PCA$_w$ [22] and with our $L_w$. The performance for varying descriptor dimensionality is plotted in Figure 9. The plots suggest that $L_w$ works better in most dimensionalities.
Multi-scale representation. We evaluate multi-scale representation constructed at test time without any additional learning. We compare the previously used averaging of descriptors at multiple image scales [27] with our generalized-mean of the same descriptors. Results are presented in Table 3, where there is a significant benefit when using the multi-scale GeM. It also offers some improvement over the average pooling. In the rest of our experiments we adopt multi-scale representation, pooled by generalized mean, for scales $1, \frac{1}{\sqrt{2}},$ and $\frac{1}{2}$. Results using the supervised dimensionality reduction by $L_w$ on the multi-scale GeM representation are shown in Table 4.

Query expansion. It has recently become a standard policy to combine simple average query expansion (AQE) with CNN global image descriptors [10], [11], [12], [27]. It is applied on the top-ranked nQE images. Herein, we argue that tuning nQE to work well across different datasets is not easy. We rather perform weighted averaging, where the weight of the $i$-th ranked image is given by $(f(q)^\top f(i))^\alpha$. We refer to this approach as $\alpha$-weighted query expansion ($\alpha$QE). The proposed $\alpha$QE reduces to AQE for $\alpha = 0$. As shown in Figure 10 this is a more stable choice across datasets. We finally set $\alpha = 3$ and nQE = 50.

---

### Table 1

Performance (mAP) comparison after CNN fine-tuning for different pooling layers. GeM is evaluated with a single shared pooling parameter or multiple pooling parameters (one for each feature map), which are either fixed or learned. A single value or a range is reported in the case of a single or multiple parameters, respectively. Results reported with AlexNet and with the use of $L_w$. The best performance highlighted in **bold**.

| Pooling | Initial p | Learned p | GeM | GeM PCA | GeM L | MAC | MAC PCA | MAC L |
|---------|-----------|-----------|-----|---------|-------|------|---------|-------|
| MAC     | inf       | –         | 62.2 | 52.8    | 68.9  | 54.7 | 78.4    | 66.0  |

### Table 2

Performance (mAP) comparison of CNN vector post-processing: no post-processing, PCA-whitening [22] (PCA$_w$) and our learned whitening ($L_w$).

No dimensionality reduction is performed. Fine-tuned AlexNet (Alex) produces a 256D vector and fine-tuned VGG a 512D vector. The best performance highlighted in **bold**, the worst in *blue*. The proposed method consistently performs either the best (22 out of 24 cases) or on par with the best method. On the contrary, PCA$_w$ [22] often hurts the performance significantly. Best viewed in color.

| 8   |     | 25.3     | 16.3       | 44.3    | 27.8      | 37.8     | 11.4    |

**Over-fitting and generalization.** In all experiments, all clusters including any image (not only query landmarks) from Oxford5k or Paris6k datasets are removed. We now repeat the training using all 3D models, including those of Oxford and Paris landmarks. In this way, we evaluate whether the network tends to over-fit to the training data or to generalize. The same amount of training queries is used for a fair comparison. We observe negligible difference in the performance of the network on Oxford and Paris evaluation results, i.e. the difference in mAP was on average +0.3 over all testing datasets. We conclude that the network generalizes well and is relatively insensitive to over-fitting.

**Comparison with the state of the art.** We extensively compare our results with the state-of-the-art performance on compact image representations and on approaches that do query expansion. The results for the fine-tuned GeM based networks are summarized together with previously published results in Table 5. The proposed methods outperform the state of the art on all datasets when the VGG network architecture and initialization are used. Our method is outperformed by the work of Gordo et al. on Paris with the ResNet architecture, while we have the state-of-the-art score on Oxford and we are on par on Holidays. Note, however, that we did not perform any manual labeling or cleaning of our training data, while in their work landmark labels are involved. We additionally combine GeM with query expansion and further boost the performance.

## 6 Conclusions

We addressed fine-tuning of CNN for image retrieval. The training data are selected from an automated 3D reconstruction system applied on a large unordered photo collection. The proposed method does not require any manual annotation and yet achieves top performance on standard benchmarks. The achieved results are reaching the level of the best systems based on local features with spatial matching and query expansion, while being faster and requiring less memory. The proposed pooling layer that generalizes previously adopted mechanisms is shown to improve the retrieval accuracy while it is also effective for constructing a joint multi-scale representation. Training data, trained models, and code are publicly available.

## Table 5

Performance (mAP) comparison with the state-of-the-art image retrieval using VGG and ResNet (Res) deep networks, and using local features. F-tuned: Use of the fine-tuned network (yes), or the off-the-shelf network (no), not applicable for the methods using local features (n/a). Dim: Dimensionality of the final compact image representation, not applicable (n/a) for the BoW based methods due to their sparse representation. Our methods are marked with ** and they are always accompanied by the multi-scale representation and our learned whitening $L_w$.

1: Our evaluation of MAC and SPoC with PCA and with the off-the-shelf network.

$\dagger$: Evaluation of R-MAC by [27] with the off-the-shelf network.
