(Dated: September 9, 2009)

Abstract

We calculate the entropic part of partition function of a bubble embedded in a double stranded DNA (dsDNA) by considering the total weights of possible configurations of a system of two single stranded DNA (ssDNA) of given length which start from a point along the contour of dsDNA and reunite at a position vector \( r \) measured from the first point and the distribution function of the position vector \( r \) which separates the two zipper forks of the bubble in dsDNA. For the distribution function of position vector \( r \) we use the distribution of the end-to-end vector \( r \) of strands of given length of dsDNA found from the wormlike chain model. We show that when the chains forming the bubble are assumed to be Gaussian the so called loop closure exponent \( c \) is 3 and when we made correction by including self avoidance in each chain the value of \( c \) becomes 3.2.

PACS numbers: 87.14.gk,87.15.-v,87.15.ad
DNA is a set of two entangled polymers connected by hydrogen bonds between complementary bases and base-stacking between nearest neighbour pairs of base pairs and wound around each other to make a helix [1]. Though a very long DNA behaves like a flexible polymer in a solution, at smaller length scales (which may be of the order of hundreds of base-pairs,) it exhibits considerable stiffness. The stiffness of a polymer chain is measured by the persistent length $l_p$, the length scale at which the tangent vectors to the polymer curves are decorrelated [2]. On scale smaller than $l_p$, bending energy dominates and the chain is relatively stiff with little or no bending. The $l_p$ for the double-stranded DNA (dsDNA) is experimentally known to be about 500 Å which is equivalent to 145 bases long along its contour [3]. In comparison, the persistent length for single stranded DNA (ssDNA) depends sensitively on the ionic strength of the solvent and can be as short as 10 Å [4].

In physiological solvent conditions the average value of the interactions for a base-pair that stabilize the dsDNA structure is of the order of few $k_B T$ (thermal energy) [5] and thermal fluctuations can lead to local and transitory unzipping of the double-strands [6, 7]. The cooperative opening of a sequence of consecutive base-pairs leads to formation of local denaturation zones (bubbles). A DNA bubble consists of flexible single-stranded DNA and its size fluctuates by zipping and unzipping of base-pairs at the two zipper forks (points $P_1$ and $P_2$ in Fig. 1(b)) where the bubble connects the intact double-strands. As the persistent length $l_s$ of the ssDNA is several times smaller than that of dsDNA the two chains fluctuate relatively freely and make entropic contributions to free energy of the bubble. The existence of bubbles in dsDNA represents the classic competition between energy and entropy; the intact dsDNA regions are dominated by the interaction energy due to hydrogen bonding of pairs and base stacking, bubbles by the entropy gain on disruption of base-pairs. The average size of a bubble depends on the sequence of base-pairs, temperature and ionic strength and varies from few broken base-pairs at room temperature to few hundreds open base pairs close to melting temperature $T_m$ [8,9]. Below $T_m$, once formed a bubble is intermittent feature and eventually zip close again. This DNA breathing can be probed on the single molecule level in real time by fluorescence method [7]. Above $T_m$ individual bubbles continuously increase in size and merge with vicinal bubbles until complete denaturation [10].

In the study of thermal denaturation of dsDNA [10,11,12] as well as in the study of static and dynamic properties of an intermittent bubble [13,14] one needs to know its free energy. The partition function of a bubble of length $l_b$ has been approximated by the number of
configurations of walks of $2l_b$ length returning for the first time to the origin \cite{15} which in the limit $l_b \to \infty$ assumes the following form \cite{16}

$$Z(l_b) \sim \sigma \mu^{2l_b} \left(\frac{2l_b}{c}\right)^c$$

where $\mu$ is a non-universal geometric factor while $c$, so called loop closure exponent, is a universal quantity. We refer the model leading to (1) as closed walks model. The factor $\sigma$ is used as an adjustable parameter to fit the denaturation curves of DNA and its value has been found to depend on the value of exponent $c$ \cite{12}. For example for $c=1.75$ the value of $\sigma$ that fits the experimental data is equal to $1.26 \times 10^{-5}$ whereas for $c=2.15$, its value is found to be ten times larger ($i.e., \sigma = 1.26 \times 10^{-4}$). Though $\sigma$ is called cooperativity parameter, its use is essentially to correct the configurations of the bubble which have been overestimated by the closed walks model.

For closed random walks embedded in three dimensional space (3-d) the exponent $c$ has been found to be 1.5. The inclusion of the excluded volume interactions within the bubble gives $c=1.76$ \cite{15}. When the excluded volume interactions between a bubble and the rest of the chain is taken, then $c \simeq 2.11$ \cite{17,18}. The nature of the melting transition depends on the value of $c$ \cite{10}. For $c \leq 1$ there is no transition, for $1 < c \leq 2$, the transition is continuous while for $c > 2$, the transition is first order.

The closed walks model which lead to Eq.(1) with values of $c$ given above for the partition function of a bubble, however, ignores the fact that the bubble is embedded in a dsDNA which imposes constraints on the distribution function of vector $\mathbf{r}$ connecting the two ends (zipper forks) of the bubble. In this Letter we show that when this constraint is taken into account the value of $c$ becomes greater than 2 even when the bubble is assumed to be formed by two non-interacting Gaussian chains.

In Fig.1(a) we show a segment of dsDNA in which points $P_1$ and $P_2$ are separated by distance $l_b = nb_0$ along the contour of the chain. Here $n$ is the number of base-pairs between $P_1$ and $P_2$ and $b_0 = 3.4\text{Å}$, the average distance between successive base-pairs in the Watson-Crick model of dsDNA \cite{1}. In space the points $P_1$ and $P_2$ are separated by vector $\mathbf{r}$. In Fig.1(b) we show a bubble which is formed by unzipping of all $n$ base-pairs between $P_1$ and $P_2$. The points $P_1$ and $P_2$ represent the two zipper-forks of the bubble. Each of the two chains $C_1$ and $C_2$ of the bubble is of length $l_0 = na_0$ where $a_0 \simeq 6\text{Å}$. To calculate
the entropic part of partition function of the bubble of length \( l_b \) formed by unzipping of \( n \) base-pairs of dsDNA we use the relation

\[
Z_n(l_b) = \int dr Z_n(r, l_0) \rho(r, l_b)
\]  

(2)

where \( Z_n(r, l_0) \) are the total weights of the possible configurations of a system of two ssDNA each of length \( l_0 \) which start at origin and reunite through hydrogen bonds and stacking interactions at a point defined by position vector \( r \) and \( \rho(r, l_b) \) is the normalized probability density of position vector \( r \) separating the two zipper forks of the bubble in dsDNA. As we show below the factor \( \rho(r, l_b) \) which has been ignored in the closed walks model plays crucial role in determining the total number of configurations of a bubble.

If we assume each chain forming the bubble to be Gaussian, its distribution for the end-to-end vector for \( l_0 >> l_s \) can be written as

\[
P_n(r, l_0) = \left( \frac{4\pi}{3} l_0 l_s \right)^{-3/2} \exp \left( -\frac{3r^2}{4l_0 l_s} \right)
\]  

(3)

where \( 2l_s \) is taken to be equal to Kuhn statistical segment length. All distances here and below are expressed in unit of \( b_0 \) and therefore made dimensionless. The total weights of the possible configurations of two random walks starting from point \( P_1 \) (origin) and reuniting at a distance \( r \) at point \( P_2 \) are therefore

\[
Z_n(r, l_0) = \left( \frac{4\pi}{3} l_0 l_s \right)^{-3} \exp \left( -\frac{3r^2}{2l_0 l_s} \right)
\]  

(4)

When one substitutes Eq.(4) in Eq.(2) and chooses \( \rho(r, l_b) = 1 \) one gets \( Z_n(l_b) \propto 1/l_b^c \) with \( c = 1.5 \) in agreement with the result reported in literature for closed random walks. Note that choosing \( \rho(r, l_b) = 1 \) amounts to assuming that the vector \( r \) separating the zipper forks of the bubble of length \( l_b \) in a dsDNA can have values between zero and infinity with equal probability which is obviously incorrect as it ignores the fact that the bubble is embedded in a dsDNA and its ends separation is constrained by the dsDNA strands. As shown in Fig.1(b) the zipper forks \( P_1 \) of the bubble on its left and the fork \( P_2 \) on its right are connected to long strands of dsDNA. The fluctuational motion of these forks in space (not along the dsDNA chain which changes the value of \( l_b \)) will therefore be controlled by these strands. Here we are considering dsDNA of contour length \( L \rightarrow \infty \), \( l_b/L \rightarrow 0 \) and the bubble located away from the two ends of dsDNA. For a dsDNA which contour length is of the order of \( l_p \) or less the bubble formation may change the conformational behaviour of the chain [26,27], but for
L→ ∞ such change is expected to be negligible as any change in their position amounts to moving or rotating the dsDNA segments attached to these points on either or both sides which may cost huge energy. It therefore seems reasonable to assume that the distribution of distance \( r \) separating points \( P_1 \) and \( P_2 \) in Fig.1(a) remains unchanged after the formation of the bubble and \( \rho(r, l_b) \) can be approximated by the probability density of finding points \( P_1 \) and \( P_2 \) at separation \( r = r(s) - r(s)' \) where \( l_b = s - s' \) is the distance between \( P_1 \) and \( P_2 \) along the contour of dsDNA.

In order to understand the effect of possible approximation to \( \rho(r, l_b) \) it may be useful to consider some limiting cases: In the case of dsDNA being a rigid rod of infinite length, \( \rho(r, l_b) \) can be given as \( \rho(r, l_b) = \delta(r - l_b)/4\pi l_b^2 \) as positions of \( P_1 \) and \( P_2 \) remain unchanged due to formation of the bubble. For this case the partition function \( Z_n(l_b) \) reduces to

\[
Z_n(l_b) = \frac{K_1(\mu_G)}{l_b^3}
\]

where

\[
K_1 = \left( \frac{3}{4\pi a_0} \right)^3 \quad \text{and} \quad \mu_G = e^{-\frac{3}{2a_0}}
\]

In another limit of dsDNA being a freely joined phantom chain, \( \rho(r, l_b) \) can be found from the end-to-end distribution function of a Gaussian chain of length \( l_b >> l_p \). Thus

\[
\rho(r, l_b) = \left( \frac{4\pi l_b l_p}{3} \right)^{-3/2} \exp \left( -\frac{3r^2}{4l_b l_p} \right)
\]

where Kuhn statistical segment length is equal to \( 2l_p \). Substituting this in Eq.(2) we get

\[
Z_n(l_b) = \frac{K_2}{l_b^3}, \quad K_2 = \left( \frac{3}{4\pi} \right)^3 \left( \frac{1}{2a_0 l_p + a_0 l_s^2} \right)^{3/2}
\]

In both limits we find \( c=3 \).

A dsDNA being a semi-flexible polymer, its conformational properties can be found from a wormlike chain model in which the polymer is represented by a differential space curve \( \mathbf{r}(s) \) of length \( L \) parametrized to arc length \( \beta \). The model is specified by the Hamiltonian,

\[
\beta H = \frac{1}{2} l_p \int_0^L ds \left( \frac{d\mathbf{\hat{u}}(s)}{ds} \right)^2
\]

where \( \mathbf{\hat{u}}(s) = \frac{d\mathbf{r}(s)}{ds} \) is the unit tangent vector to the curve \( \mathbf{r}(s) \), \( s \) measures the position along the contour, \( \beta = (k_B T)^{-1} \) and \( k_B T l_p = \kappa \) specify the stiffness of the chain. The
inextensibility of the chain is expressed by the local constraint \(|\hat{\mathbf{t}}(s)|=1\). The distribution function \(\rho_s(\mathbf{r}, l_b)\) of end-to-end vector \(\mathbf{r}\) of a segment of contour length \(l_b\) can be found from the average of \(\xi(1,n)\delta(\mathbf{r} - \int_0^{l_b} \hat{\mathbf{t}}(s)ds)\) over all chain conformations. Here \(\xi(1,n)\) represents the boundary condition that ensures smooth variation of tangent vectors at the two ends of the segment in dsDNA. In an ensemble of segment of length \(l_b\) in a dsDNA which in solvents forms a fractal structure, we may relax the boundary condition and approximate \(\rho_s(\mathbf{r}, l_b)\) by the end-to-end distribution function of a chain of length \(l_b\) with a free end.

The distribution function \(\rho_s(\mathbf{r}, l_b)\) has been found by Monte Carlo simulation [21,22] and analytically using approximate schemes [23,24,25]. For \(l_b/l_p \leq 1\), \(\rho_s(\mathbf{r}, l_b)\) exhibits sharp peak at \(r \sim l_b\) whereas for \(l_b/l_p > 1\) the peak broadens and shifts to smaller values of \(r/l_b\). For \(l_b/l_p \geq 1\) a simple analytical expression has been found [23], which can be written as

\[
\rho_s(r, l_b) = N_c \left(1 - \frac{r^2}{l_b^2}\right)^{-9/2} \exp \left(-\frac{3l_b}{4l_p} \frac{1}{(1 - r^2/l_b^2)}\right)
\]

where \(N_c\) is the normalization constant and its value is found by the requirement

\[
4\pi \int_0^\infty \rho(r, l_b) r^2 dr = 1
\]

Eq.(9) reproduces quite accurately the simulation results for \(l_b/l_p > 1\) [21].

If we use \(\rho_s(r, l_b)\) given by Eq.(9) for \(\rho(r, l_b)\) and substitute into Eq.(2) we get for \(l_b/l_p \geq 1\)

\[
Z_n(l_b) = \frac{K_2(l_b)}{l_b^3}
\]

where

\[
K_3(l_b) \simeq \frac{1}{\gamma^{3/2}} \frac{4 + 12(\gamma \alpha)^{-1} + 15(\gamma \alpha)^{-2}}{4 + 12\alpha^{-1} + 15\alpha^{-2}} \left(\frac{3}{4\pi a_0 l_s}\right)^3
\]

\[
\alpha = \frac{3}{4} l_b/l_p \quad \text{and} \quad \gamma = 1 + \frac{2l_p}{a_0 l_s}
\]

The value of \(K(l_b)\) depends on the value of \(l_b/l_p\). For \(l_b/l_p \gg 1\), \(K_3(l_b)\) reduces to

\[
\left(\frac{3}{4\pi a_0 l_s}\right)^3 \left(\frac{1}{\gamma}\right)^{3/2}
\]

which agrees with the value given in (7). We note that while the exponent \(c\) remains 3 the prefactor \(K\) depends on the form chosen for \(\rho(r, l_b)\).

The inclusion of excluded volume interactions will decrease the number of configurations found from the Gaussian chains forming the bubble. To see this we consider the effect
of self-avoiding interactions within chains $C_1$ and $C_2$. The number of self-avoiding walks (SAWs) which start at origin and arrive at a point defined by the position vector $r$ is given as

$$P_n(r, l_0) \sim \mu l_0^{(\gamma-1-3\nu)}g(r/l_0^\nu)$$

(14)

where $\mu$ is the connectivity constant, $g(x)$ is a scaling function, $\gamma$ is the entropic and $\nu$ is the metric exponent. Though the function $g(x)$ is not exactly known for SAWs, it has been approximated as $g(x) \sim x^\phi e^{-\lambda x^\delta}$ where $\lambda > 0$, $\delta = \frac{1}{1-\nu}$ and $\phi$ can be expressed in terms of known exponents [15,28].

For the random walks $\phi = 0$ and $\nu = 1/2$. As the bubble is formed by two self-avoiding walks each of length $l_0$ with common end points, the total weights of all configurations of the bubble of which the two end points are separated by distance $r$ are

$$Z_n(r, l_0) \sim \mu^{2l_0}l_0^{2(r-1-3\nu)}H(r/l_0^\nu)$$

(15)

where

$$H(r/l_0^\nu) \sim \left(\frac{r}{l_0^\nu}\right)^{2\phi} exp \left[-2\lambda(r/l_0^\nu)^{1/\nu}\right]$$

The integral in Eq.(2) is no longer Gaussian, but can be evaluated using the steepest descent method. Here we, however, take simple view and consider the limiting case of the bubble being embedded in an infinitely long rod shaped dsDNA. As for this case $\rho(r, l_b) = \delta(r-l_b)/4\pi l_b^2$, the integral is easily evaluated giving $c = 2-2\nu+6\nu$. Using approximate SAW exponents, $\gamma = 1.158$, $\nu = 0.588$ [16] we find $c = 3.2$. The analysis given here ignores the excluded volume interactions between the two chains and between chains and the segments of dsDNA which inclusion will further increase the value of $c$. A more systematic treatment of the effect of excluded volume interactions on $c$ will be given in a future publication.

In conclusion, we suggest that the partition function of the bubble embedded in a dsDNA should be calculated using expression given by Eq.(2). There are two terms in this expression. First, the total weights of possible configurations of a system of two ssDNA of given lengths which start from a point along the contour of dsDNA and reunit at another point on dsDNA at a distance $r$. The points of origin and reuniting of two ssDNA are the points where bubble connects with the intact dsDNA strands and are called zipper forks. Second, the probability density of finding the zipper forks of a bubble of given length at distance $r$ apart. In the closed walks models which have been used to estimate the partition function of the bubble the second term has been neglected. We calculate the total weights of possible configurations
of two chains forming the bubble by treating them to be noninteracting Gaussian chains. We also consider the case when they are represented by the self-avoiding walks model. For the probability density of finding the zipper forks at distance $r$ apart in long dsDNA we suggest that it can be approximated by the distribution function of end-to-end vector $r$ calculated for dsDNA using the wormlike chain model. For the Gaussian chain model the exponent $c$ is found to be 3 and when self-avoidence in each chain were considered its value increased to 3.2. Inclusion of the excluded volume interaction between chains and between segments of dsDNA will further increase the value of $c$.
