Error-Correction of Multidimensional Bursts

Tuvi Etzion, Fellow, IEEE and Eitan Yaakobi, Student Member, IEEE

Abstract—In this paper we present several methods and constructions to generate codes for correction of a multidimensional cluster-error. The goal is to correct a cluster-error whose shape can be a box-error, a Lee sphere error, or an error with an arbitrary shape. Our codes have very low redundancy, close to optimal, and large range of parameters of arrays and clusters. Our main results are summarized as follows:

1) A construction of two-dimensional codes capable to correct a rectangular-error with considerably more flexible parameters from previously known constructions. Another advantage of this construction over previously known constructions is that it is easily generalized for D dimensions.

2) A novel method based on D colorings of the D-dimensional space for constructing D-dimensional codes correcting D-dimensional cluster-error of various shapes. This method is applied efficiently to correct a D-dimensional cluster error with parameters not covered efficiently by the previous constructions.

3) A transformation of the D-dimensional space into another D-dimensional space in a way that a D-dimensional Lee sphere is transformed into a shape located in a D-dimensional box of a relatively small size. This transformation enables us to use the previous constructions to correct a D-dimensional error whose shape is a D-dimensional Lee sphere.

4) Applying the coloring method to correct more efficiently a two-dimensional error whose shape is a Lee sphere. The D-dimensional case is also discussed.

5) A construction of one-dimensional codes capable to correct a burst-error of length b in which the number of erroneous positions is relatively small compared to b. This construction is generalized for D-dimensional codes.

6) Applying the construction for correction of a Lee sphere error and the construction for correction of a cluster-error with small number of erroneous positions, to correct a D-dimensional arbitrary cluster-error.

Index Terms—burst-error, burst-locator code, cluster-correcting code, coloring, Lee sphere, multidimensional code.

I. INTRODUCTION

In current memory devices for advanced storage systems the information is stored in two or more dimensions. In such systems errors usually take the form of multidimensional bursts. Usually, a cluster of errors either will be affected by the position in which the error event occurred or will be of an arbitrary shape. But, since an arbitrary cluster-error is hard to correct efficiently it is common to assume some type of cluster-error (as any arbitrary cluster is located inside a cluster with a certain shape, e.g., any two-dimensional cluster is located inside a rectangle). These types of errors can be of specific shapes like rectangles or Lee spheres. We will consider these types of errors as well as arbitrary cluster-errors. The main measure to compute the efficiency of a cluster-error correcting code is its redundancy. If we want to design a code which corrects one multidimensional cluster-error with volume B (of an arbitrary or a specific shape) then the redundancy of the code r satisfies r ≥ 2B. This bound, known as the Reiger bound [14], is attained for binary two-dimensional codes, which correct a rectangular error, constructed recently by Boyarinov [7]. If the volume of the array is N then the redundancy of the code must also satisfy r ≥ \log_2 N + B − 1 (usually r − [\log_2 N] ≥ B). The difference r − [\log_2 N] will be called the excess redundancy of the code [1], [4] (even so our definition is slightly different). Abdel-Ghaffar [1] constructed a binary two-dimensional code which corrects a burst with a rectangle shape for which r = [\log_2 N] + B. The code has a few disadvantages: very limited size, complicated construction, and there is no obvious generalization for higher dimensions.

Our goal is to design codes which are capable to correct a cluster-error whose shape is a box, a Lee sphere, or an arbitrary shape. The method should be able to work on two-dimensional codes and multidimensional codes, and the parameters of the size of the codewords and the size of the cluster are as flexible as possible. There will be a price for our flexibility and our ability to generalize a two-dimensional construction into multidimensional construction. This price will be in the excess redundancy. While the two-dimensional codes which correct a rectangle-error of Abdel-Ghaffar [1] have optimal excess redundancy, the excess redundancy of our codes is only close to optimality. Moreover, the novel methods enable us to correct a cluster whose shape is a Lee sphere and an arbitrary cluster, with excess redundancy close to optimal or very low, depending on the exact parameters. Previous to our methods the way to correct such a cluster-error was to use a code which corrects a box-error in which the cluster-error is located, a method for which the excess redundancy is far from optimality.

The rest of the paper is organized as follows. In Section II we briefly survey some of the known constructions which are essential to understand our results. In Section III we present a construction for codes which correct a multidimensional box-error. The construction is a generalization and a modification of the construction of Breitbach, Bossert, Zybalov, and Sidorenko [8] for correction of bursts of size \(b_1 \times b_2\). Better codes are constructed when the volume of the D-dimensional box-error is an odd integer. These constructions and the constructions which follow use auxiliary codes, called...
component codes, one code for each dimension. In Section \[**IX**\] we present a novel method for correction of a \(D\)-dimensional cluster. The construction uses \(D\) colorings of the \(D\)-dimensional space. The construction of Section \[**III**\] is a special case of this construction. The new construction enables us to handle different burst patterns. In Section \[**IV**\] we use this method to handle \(D\)-dimensional box-error, where the volume of the box is an even integer. In Section \[**V**\] we discuss how to correct a \(D\)-dimensional cluster-error whose shape is a Lee sphere. Two types of constructions are used. The first one uses a transformation of the \(D\)-dimensional space into another \(D\)-dimensional space in a way that each Lee sphere is transformed into a shape located inside a reasonably small \(D\)-dimensional box, so that we can use the constructions of the previous sections. The transformation is especially efficient for two-dimensions. The second construction uses colorings as in Section \[**IV**\]. For two-dimensional array the colorings that we use result in codes with excess redundancy close to optimality (where our measure for optimality is the lower bound on the excess redundancy), which improves on the construction obtained by the two-dimensional transformation. The generalization for multidimensional Lee sphere errors usually does not make the same improvement. This is also discussed in Section \[**IV**\]. In Section \[**VI**\] we show how we handle bursts of size \(b\), where the number of erroneous positions is limited. First, we present a construction for one-dimensional codes and afterwards we generalize it into \(D\)-dimensional codes. In Section \[**VII**\] we combine the constructions of codes which are capable to correct Lee sphere error and the construction capable to correct a burst with a limited number of erroneous positions for a construction of codes capable to correct arbitrary bursts. In Section \[**VIII**\] we describe codes with the same or slightly better parameters than the parameters of the codes from the previous sections by using parity-check matrices. Finally, a conclusion and a list of problems for further research are given in Section \[**IX**\].

II. KNOWN CONSTRUCTIONS

Five constructions are important to understand our constructions and their comparison with previous results.

- Abdel-Ghaffar, McEliece, Odlyzko, and van Tilborg [3] construction of optimum binary cyclic burst-correcting codes.
- Abdel-Ghaffar [2] construction of optimum cyclic burst-correcting codes over GF\((q)\).
- Abdel-Ghaffar construction [2] of two-dimensional codes which correct rectangular-error of size \(b_1 \times b_2\) with excess redundancy \(b_1 b_2\).
- Breitbach, Bosserz, Zybalov, and Sidorenko construction [8] of two-dimensional codes for correction of a \((b_1 \times b_2)\)-rectangular-error by using vertical and horizontal component codes.
- Abdel-Ghaffar, McEliece, and van Tilborg construction [4] of two-dimensional burst identification codes, which are used to identify the shape of an error and together with burst location codes are used for correction of a two-dimensional cluster.

Most of two-dimensional codes known in the literature are designed to correct a single cluster-error of size \(b_1 \times b_2\) [1], [4], [7], [8], [11] (only in some recent papers [6], [9], [17] it is assumed that the cluster-error can have an arbitrary shape). Two of these methods are important in our discussion. Abdel-Ghaffar [1] gave a construction of such \(n_1 \times n_2\) code with excess redundancy \(b_1 b_2\). One disadvantage of his method is that \(n_2\) must be considerably larger than \(n_1\) (with a possible exception when \(b_2 \leq 2\), subject to a list of restrictive conditions), and the existence of the code depends on series of restricted conditions. The main goal of his construction was to show that for any given integers \(b_1\) and \(b_2\) there exists a cyclic \((b_1 \times b_2)\)-cluster-correcting code of some size \(n_1 \times n_2\) having optimal excess redundancy. Therefore, the size of the array was not a factor in his construction. His construction is a generalization of the optimum cyclic one-dimensional codes which correct a single cyclic burst of length \(b\) [2], [3]. Over GF\((q)\) such code has length \(n\), redundancy \(r\), and it can correct a single cyclic burst of length \(b \geq 1\), where \(n = \frac{q^r-b+1-1}{q-1}\). The existence of such codes was obtained by the following necessary and sufficient conditions.

**Theorem 1:** If a polynomial \(g(x)\) generates an optimum \(b\)-burst-correcting code over GF\((q)\), then it can be factored as \(g(x) = e(x)p(x)\), where \(e(x)\) and \(p(x)\) satisfy the conditions:

1) \(e(x)\) is a square-free polynomial of degree \(b - 1\) which is not divisible by \(x\) such that \(h_x\) and \(m_x\) are relatively primes to \(q - 1\), where \(h_x\) and \(m_x\) are the period of \(e(x)\) and the degree of the splitting field of \(e(x)\), respectively.

2) \(p(x)\) is an irreducible polynomial of degree \(m \geq b + 1\) and period \(\frac{q^m-1}{q-1}\) such that \(m\) and \(q - 1\) are relatively primes and \(m \equiv 0 \pmod{m_x}\).

A monic polynomial over GF\((q)\) which satisfies condition 1) of Theorem 1 will be called a \(b\)-polynomial.

**Theorem 2:** Let \(e(x)\) be a \(b\)-polynomial over GF\((q)\). Then, for all sufficiently large \(m\) relatively prime to \(q - 1\) such that \(m \equiv 0 \pmod{m_x}\), where \(m_x\) is the degree of the splitting field of \(e(x)\), there exists an irreducible polynomial \(p(x)\) of degree \(m\) such that \(e(x)p(x)\) generates an optimum \(b\)-burst correcting code of length \(\frac{q^m-1}{q-1}\).

**Remark:** If the polynomial \(p(x)\) in Theorems 1 and 2 is binary then \(p(x)\) in the Theorems is a primitive polynomial.

The second method is due to Breitbach, Bosserz, Zybalov, and Sidorenko [8], who gave three constructions of binary two-dimensional codes of size \(n_1 \times n_2\) which correct a rectangular-error of size \(b_1 \times b_2\). Their goal in presenting these constructions was not to obtain low excess redundancy, which is one of the goals in our constructions, but to present new constructions of codes with relatively large array size and redundancy close to the Reiger’s bound. We will use ideas from one of the constructions which will be called Construction BBZS.

A codeword \(\{c_{ij}\}\) of the construction has size \(n_1 \times n_2 = 2b_2 \times 2b_1\) with \(4b_1 b_2\) redundancy bits located in positions \(\{(i, j) : 0 \leq i \leq 2b_1 - 1, n_2 - b_2 - b_j \leq j \leq n_2 - 1\}\) \(\cup \{(i, j) : n_1 - b_1 - i \leq j \leq b_2 - b_1\}\) (see Fig. 1). These bits are set initially to be zeroes. Two temporary component codes are being used, a vertical code and an horizontal code (see Fig. 1). We will describe the construction of the vertical
code. We note an earlier construction [16] which use similar component codes.

For each row \( i = 2b_1, \ldots, n_1 - 1 \), \( b_2 \) parity check bits are generated. \( p_{i\ell} \), \( \ell = 0, 1, \ldots, b_2 - 1 \) is computed as

\[
p_{i\ell} = \sum_{j=\ell+b_2, i+b_2, \ldots, j<n_2} c_{ij}.
\]

The parity bits \( p_{i\ell} \), \( \ell = 0, 1, \ldots, b_2 - 1 \) generate afterward a symbol \( p_i = (p_{i0}, p_{i1}, \ldots, p_{ib_2-1}) \) from the extension field \( \text{GF}(2^{b_2}) \). The symbols \( p_i \), \( i = 2b_1, \ldots, n_1 - 1 \) are considered as the information symbols of a Reed-Solomon (RS) code of length \( n_1 \), dimension \( n_1 - 2b_1 \), and minimum distance \( d = 2b_1 + 1 \). By the encoding procedure of the RS code we obtain \( 2b_1 \) redundancy symbols \( p_i \), \( i = 0, \ldots, 2b_1 - 1 \), and the \( 2b_1 b_2 \) upper right corner redundancy bits of the array are computed in a way that (1) will hold for \( i = 0, 1, \ldots, 2b_1 - 1 \) and \( \ell = 0, 1, \ldots, b_2 - 1 \). The encoding procedure of the horizontal code is done in the same manner, where all the \( 4b_1 b_2 \) redundancy bits of the array are assumed to be zeroes (it is possible to encode also with their new computed values, but we want to follow the construction exactly as in [8]).

In the decoding procedure each row generates \( b_2 \) parity bits according to (1) such that a word of length \( n_1 \) over \( \text{GF}(2^{b_2}) \) is received (the redundancy bits of the horizontal code are assumed to be zeroes). Assuming that the error occurred in the array can be confined inside a rectangle of size \( b_1 \times b_2 \). The generated word, of the vertical code, has at most \( b_1 \) erroneous symbols, which can be corrected by the decoding procedure of the RS code. The same process is implemented for the horizontal code. The positions of the erroneous elements in the vertical codeword induce the rows in which errors occurred in the array. The positions of the erroneous elements in the horizontal codeword induce the columns in which errors occurred in the array. Hence, we locate the positions of the \( b_1 \times b_2 \) cluster-error in the array. The shape of the cluster, up to \( b_2 \) horizontal cyclic shifts, is found by the vertical code. The shape of the cluster up to \( b_1 \) vertical cyclic shifts, is found by the horizontal code. As we know the location of the cluster, we can use one of the component codes to identify the exact shape of the error and to correct it.

**Remark:** Note that the vertical code cannot find errors inside the lower left corner redundancy bits. The horizontal code cannot find errors inside the upper right corner redundancy bits. But, these facts does not affect the decoding procedure, i.e., the vertical code is able to know the erroneous rows even if some the erroneous bits are the lower left redundancy bits.

There is no obvious generalization to the construction of Abdel-Ghaffar [1] for multidimensional codes, while immediate generalizations of Construction BBZS cannot support good redundancy or excess redundancy. One simple way to generalize this construction is to use the optimum burst-correcting codes of [2], [3] instead of the RS codes. The vertical component code over \( \text{GF}(2^{b_2}) \) has length \( 2^{b_2-1}r_1-1 \) redundancy \( r_1 \), and it can correct a burst of length \( b_1 \). The horizontal component code over \( \text{GF}(2^{b_1}) \) has length \( 2^{b_1-1}r_2-1 \) redundancy \( r_2 \), and it can correct a burst of length \( b_2 \). Instead of \( 4b_1 b_2 \) redundancy bits we will use \( r_1 b_2 \) redundancy bits for the vertical code and \( b_1 r_2 \) redundancy bits for the horizontal code. The excess redundancy of this construction is \( 2b_1 b_2 - 1 \) and the excess redundancy of its generalization for \( D \) dimensions is \( DB - 1 \), where \( B \) is the volume of the \( D \)-dimensional box error.

Further improvements of this construction are presented in the next section. Henceforth we assume that if a \( D \)-dimensional code is discussed then \( D \) is a constant. Furthermore, we assume \( b_i > 1 \) for \( 1 \leq i \leq D \); this assumption can be made since if for some \( j \), \( b_j = 1 \) then the cluster can be corrected as a \((D-1)\)-dimensional cluster in a \( D \)-dimensional array.

### III. Construction for Multidimensional Arrays

In this section we present our first idea for construction of multidimensional codes capable to correct a box-error of size \( b_1 \times b_2 \times \cdots \times b_D \). First, we will present the two-dimensional version of the construction. We combine Construction BBZS with the constructions of Abdel-Ghaffar et al. [3] and Abdel-Ghaffar [2] to obtain codes with variety of parameters. The redundancy of the construction is kept relatively small as our horizontal code will find only the location of the error and not its shape. This idea is the first key of all our constructions. The second idea to reduce the redundancy is to use a binary horizontal code instead of a code over \( \text{GF}(2^{b_1}) \). Finally, the structure of the construction makes it possible to generalize it to any dimension. The generalization is relatively quite simple, with low redundancy, and can be applied on a large range of parameters. One disadvantage is that the construction is defined for a box-error whose volume is an odd integer. To apply the construction on a box-error whose volume is an even integer, we have to increase the box-error artificially such that its volume will be an odd integer and the real box error will be located inside the artificial box error. This will cost us extra unnecessary redundancy. In the next section we will solve this problem by giving a novel construction for correction of a box-error whose volume is an even integer.
A. Two-dimensional codes

The vertical component code of Construction BBZS finds the rows in which the burst occurred and the shape of the cluster up to a cyclic permutation of the columns. Hence, the work done by the horizontal code to find the shape of the cluster is redundant. Therefore, we want to find an horizontal component code that will determine only the first column of the cluster. More explicitly, a burst \( e = (e_0, e_1, \ldots, e_{b_2-1}) \), where \( e_i \in \text{GF}(2^{b_2}) \), for \( 0 \leq i \leq b_2 - 1 \) found by the vertical code, can start at any column \( 0 \leq i \leq n_2 - b_2 \) (See Fig. 2). However, if the first column of the cluster is \( i \), then the cluster occurred is \( e' = (e_{i_0}, e_{i_0+1}, \ldots, e_{i_0+b_2-1}) \) where \( i_0 \equiv i \pmod{b_2} \), and indices are taken modulo \( b_2 \).

Our new construction, in which the horizontal code only locates the first column of the cluster, is based on two lemmas. The first one is proved here only for the binary case.

**Lemma 1:** If \( e_2(x) = 1 + x + x^2 + \cdots + x^{b_2-1} \) and \( b \) is an odd integer then \( e_2(x) \) is a \( b \)-polynomial over \( \text{GF}(2) \).

**Proof:** Clearly, \( e_2(x) \) is not divisible by \( x \). The derivative of \( x^{b_2-1} \) over \( \text{GF}(2) \) is \( x^{b_2-1} \), and since \( \text{g.c.d.}(x^{b_2-1}, x^{b_2-1}) = 1 \), it follows that \( x^{b_2-1} \) is a square-free polynomial and hence \( e_2(x) \) is also square-free. Therefore, by Theorem 1 \( e_2(x) \) is a \( b \)-polynomial over \( \text{GF}(2) \).

There is an alternative more general version of Lemma 1.

**Lemma 2:** Let \( e_2(x) \) be the polynomial \( e_2(x) = 1 + x + x^2 + \cdots + x^{b_2-1} \) over \( \text{GF}(2^{b_2}) \), where \( b_1 \) and \( b_2 \) are positive integers. Assume that the following conditions hold:
1. \( \gcd(b_2, 2) = 1 \),
2. \( \gcd(b_2, 2^{b_1} - 1) = 1 \),
3. \( \gcd(p(b_2), 2^{b_1} - 1) = 1 \).

Then, \( e_2(x) \) is a \( b_2 \)-polynomial over \( \text{GF}(2^{b_1}) \).

We omit the proof of the lemma (see [18]) as the construction which uses the lemma, and is described in this subsection, has inferior redundancy than the one described in the next subsection and uses Lemma 1. We will compare these redundancies in the sequel. The code over \( \text{GF}(2^{b_1}) \) is described since it is a bridging step to understand the one over \( \text{GF}(2) \).

By Theorem 2 for the \( b_2 \)-polynomial \( e_2(x) = 1 + x + x^2 + \cdots + x^{b_2-1} \), over \( \text{GF}(2^{b_1}) \), there exists an irreducible polynomial \( p_2(x) \) of degree \( n_2 = r_2 - b_2 + 1 \) such that \( e_2(x)p_2(x) \) generates an optimum \( b_2 \)-burst-correcting code \( C^* \) of length \( n_2 = (2^{b_1})^{n_2} - 1 \) and redundancy \( r_2 \). Let
\[
C^* = \{ f(x) \in \text{GF}(2^{b_1})[x] : e_2(x)p_2(x)|f(x), \deg f(x) < n_2 \},
\]
and let
\[
C_2 = \{ f(x) \in \text{GF}(2^{b_1})[x] : p_2(x)|f(x), \deg f(x) < n_2 \}.
\]
The code \( C_2 \) is also of length \( n_2 \) and has \( n_2 \) redundancy symbols over \( \text{GF}(2^{b_1}) \). We will show now that \( C_2 \) can serve as the horizontal component code, i.e., given that the cluster occurred up to a cyclic permutation is \( e = (e_0, e_1, \ldots, e_{b_2-1}) \), where \( e_i \in \text{GF}(2^{b_2}) \), for \( 0 \leq i \leq b_2 - 1 \), it will be possible to determine the first column \( i \), \( 0 \leq i \leq n_2 - b_2 \), of the cluster with \( C_2 \).

**Lemma 3:** Let \( e = (e_0, e_1, \ldots, e_{b_2-1}) \) be a given cluster, up to a cyclic permutation, which occurred in a transmitted codeword and found by the vertical component code. Then, the horizontal component code \( C_2 \) can determine the first column of the given burst.

**Proof:** We have to prove that if the burst \( e \), or a cyclic shift of \( e \), occurred in two different codewords \( f_1(x), f_2(x) \) then two different words will be generated. Since \( C_2 \) is a linear code it is sufficient to prove that there is no codeword which is equal to the difference of two clusters which are cyclic shifts of the cluster \( e \). Assume the first column of the cluster \( e \) is \( i \), i.e., the cluster is \( e' = (e_{i_0}, e_{i_0+1}, \ldots, e_{i_0+b_2-1}) \) where \( i_0 \equiv i \pmod{b_2} \) and indices are taken modulo \( b_2 \). The polynomial
representing this cluster is

\[ h_i(x) = x^{\ell_i}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1} x^{b_2-1} + e_0 x^{b_2} + e_1 x^{b_2+1} + \cdots + e_{i-1} x^{b_2+i-1}), \]

where \( \ell_i = \left\lfloor \frac{i}{b_2} \right\rfloor \). We can write \( h_i(x) \) as

\[ h_i(x) = x^{\ell_i}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1} x^{b_2-1} + e_0 x^{b_2-1} + e_1 x^{b_2+1} + \cdots + e_{i-1} x^{b_2+i-1}) = x^{\ell_i}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1} + (x^{b_2-1})(e_0 + e_1 x + \cdots + e_{i-1} x^{i-1})) = x^{\ell_i}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1}) + x^{\ell_i}b_2(x^{b_2-1}) (e_0 + e_1 x + \cdots + e_{i-1} x^{i-1}) = h_i(x) - h_j(x) \]

Assume the contrary, that the difference between two clusters which are cyclic shifts of the cluster \( e \) is a codeword. Assume that these two clusters start at columns \( i \) and \( j \). Hence, the polynomial \( h_i(x) - h_j(x) \) is the codeword

\[ h_i(x) - h_j(x) = x^{\ell_i}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1} x^{b_2-1}) + x^{\ell_j}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1} x^{b_2-1}) + (x^{b_2-1})(e_0 + e_1 x + \cdots + e_{i-1} x^{i-1}) = x^{\ell_i}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1}) + x^{\ell_j}b_2(e_0 + e_1 x + \cdots + e_{2b_2-1}) + (x^{b_2-1})(e_0 + e_1 x + \cdots + e_{i-1} x^{i-1}). \]

This last presentation of \( h_i(x) - h_j(x) \) implies that it is divisible by \( x^{b_2-1} \) and hence also by \( e_2(x) = \frac{x^{b_2-1}}{2b_2-1} \). Since \( h_i(x) - h_j(x) \) is a codeword in \( C_2 \) it follows that \( p_2(x)|h_i(x) - h_j(x) \). Since also \( e_2(x)h_i(x) - h_j(x), p_2(x) \) is an irreducible polynomial, and its degree is greater than \( b_2 \) it follows that \( e_2(x)p_2(x)h_i(x) - h_j(x) \). Therefore, \( h_i(x) - h_j(x) \) is also a codeword of \( C^* \), a contradiction since \( C^* \) can correct any burst of length \( b_2 \).

A code \( C \) that can find the first column of a burst \( e = (e_0, e_1, \ldots, e_{b_2-1}) \) given up to a cyclic shift will be called a \( b \)-burst-locator code. Thus, by Lemma 3 \( C_2 \) is a \( b_2 \)-burst-locator code. Based on the constructions of [3], [8] and Lemma 3 we can construct an \( n_1 \times n_2 \)-dimensional \((b_1 \times b_2)\)-cluster-correcting code with small excess redundancy.

Let \( C_1 \) be an optimum \( b_1 \)-burst-correcting code, over \( GF(2^{b_1}) \), of length \( n_1 = \left( \frac{2^{b_2} - 1}{b_2 - 1} \right) \) and redundancy \( r_1 \). Let \( C_2 \) be a \( b_2 \)-burst-correcting code, over \( GF(2^{b_2}) \), of length \( n_2 = \left( \frac{2^{b_2} - 1}{b_2 - 1} \right) \) and redundancy \( m_2 = r_2 - b_2 + 1 \). We can give a construction where each codeword of size \( n_1 \times n_2 \) has \( r_1 b_2 + m_2 b_1 + 1 \) = \( \lceil \log_2(n_1 n_2) \rceil + b_1 b_2 + b_1 \) redundancy bits. The redundancy bits are partitioned into three subsets:

- \( r_1 b_2 \) redundancy bits are located in the upper right corner of the array and are computed from the complete vertical codeword as done in Construction BBZS.
- \( m_2 b_1 \) redundancy bits which are computed from the complete horizontal codeword as done in Construction BBZS. These redundancy bits are spread in the array in a way that they will fulfill the following requirement. If a redundancy bit is erroneous it will be possible to determine its row (note, that if the vertical code finds only one row where errors occurred, there are \( b_1 \) different sets of \( b_1 \) rows in which the burst occurred). Hence, in \( 2b_1 - 1 \) consecutive rows there can be at most one redundancy bit. This requirement implies also that in any \((b_1 \times b_2)\)-cluster we have at most one redundancy bit.
- One redundancy bit which is a parity of all redundancy bits of the second subset. Its role is to determine whether this bit or a redundancy bit from the second subset is erroneous.

The encoding is done similarly to Construction BBZS with two exceptions. When we compute the elements of the horizontal component code the \( r_1 b_2 \) redundancy bits of the first subset are not assumed to be zeroes as in Construction BBZS, but have the values which were computed by the previous steps of the encoding procedure. The second exception is the extra computation of the redundancy bit of the third subset, which will be recovered by this code also in our construction. The redundancy bits in the right upper corner are recovered by the vertical component code. They will be recovered by this code also in our construction. The redundancy bits in the left lower corner, of Construction BBZS, are recovered by the horizontal component code in Construction BBZS. Since, in our construction we don’t use a burst-correcting code as an horizontal component code we cannot use this code to recover the related redundancy bits of the second subset. Each \( b_1 \times b_2 \) sub-codeword can contain at most one redundancy bit from the second or third subset. By summing all these redundancy bits we will know if one of them is erroneous. Also, these redundancy bits are spaced in a way that if we know in which rows errors occurred then we will know which one of these bits is in error. Once we will find this erroneous bit we will know the shape of the burst and the horizontal burst-locator code will find the column in which the cluster started. If only a redundancy bit from the second or third subset is in error then the vertical code will not find erroneous bits. In this case the sum of these bits is odd. If a bit from the second subset is in error then the horizontal burst-locator code will correct this error since this code is generated by a primitive polynomial and hence it can also correct a single error. Otherwise, the horizontal code will not find an error, which implies that the redundancy bit of the third subset is erroneous.
B. Binary burst-locator code

The redundancy of the construction is improved if we use as the horizontal burst-locator code a binary \((b_1b_2)\)-burst-locator code \(\mathcal{C}\) of length \(2^m - 1\), where \(m = r - b_1b_2 + 1\), \(b_1b_2\) odd and \(c_2(x) = 1 + x + \cdots + x^{b_1b_2-1}\). This is done simply by taking the \(b_1\) parity symbols which are computed for each column as \(b_1\) consecutive symbols in \(C_2\) instead of an element in GF\((2^{b_1})\).

Each codeword \(\{c_{ij}\}\) of size \(n_1 \times n_2\) has \(r_1b_2 + m + 1\) redundancy bits in the following positions:

- \(\{(i, j) : 0 \leq i \leq r_1 - 1, n_2 - b_2 - 2 \leq j \leq n_2 - 1\}\). These redundancy bits are computed from the vertical component code.
- \(\{(i(2b_1 - 1) + j(2b_1 - 1)b_1), j) : 0 \leq i \leq b_1 - 1, 0 \leq j, (j + 1)b_1 + i + 1 \leq m\}\). These redundancy bits are computed from the horizontal component code.
- \(\{(b_n_1 - 1, n_2 - 1)\}\). This redundancy bit is an even parity bits for the redundancy bits of the second subset.

Encoding:

All the redundancy bits in a codeword are set initially to be zeroes. The vertical component code and the first set of redundancy bits are computed as in Construction BBZS, i.e., for each row \(i = r_1, \ldots, n_1 - 1\), \(b_2\) parity check bits are generated. \(p_{i\ell}, \ell = 0, 1, \ldots, b_2 - 1\) is computed as

\[
p_{i\ell} = \sum_{j=\ell+b_2, \ell+b_2+1}^{\ell+b_2+b_2 \cdots < n_2} c_{ij},
\]

The parity bits \(p_{i\ell}, \ell = 0, 1, \ldots, b_2 - 1\) generate afterward a symbol \(p_{i}(p_{i0}, p_{i1}, \ldots, p_{ib_2-1})\) from the extension field GF\((2^{b_2})\). The symbols \(p_{i}, i = r_1, \ldots, n_1 - 1\) are considered as the information symbols of the code \(C_1\). By the encoding procedure for \(C_1\) we obtain \(r_1\) redundancy symbols \(p_{i}, i = 0, \ldots, r_1 - 1\), and the \(r_1b_2\) upper right corner redundancy bits of the array are computed in a way that \(2^2\) holds for \(i = 0, 1, \ldots, r_1 - 1\) and \(\ell = 0, 1, \ldots, b_2 - 1\). We now turn to the encoding procedure of the horizontal component code. During this process the \(r_1b_2\) redundancy bits of the first subset will have the values which were just computed (as said before this is different from Construction BBZS, in which they were assumed to be zeroes). The second subset of redundancy bits spans over \(\lceil \frac{m}{b_1} \rceil\) consecutive columns. In each column, with a possible exception of the last one, there are \(b_1r_1\) redundancy bits in \(b_1\) positions (rows) which cover all the \(b_1\) distinct residues modulo \(b_1\). We compute \(n_2 - m\) information symbols of the horizontal component codeword as in Construction BBZS. The remaining \(m\) symbols are the redundancy symbols of the horizontal \((b_1b_2)\)-burst-locator code and they are computed from the \(n_2 - m\) information symbols. The only redundancy bit of the third subset is the binary sum of the computed redundancy bits from the second subset.

Decoding:

The decoding is done similarly to the one of Construction BBZS. First, each row generates \(b_2\) parity bits by using \(2^2\) (this includes also the first \(r_1\) rows, but the \(m + 1\) redundancy bits of the second and the third subsets are assumed to be zeroes). These \(b_2\) bits are considered as a symbol in GF\((2^{b_2})\) and hence a word of length \(n_1\) over GF\((2^{b_2})\) is generated. Now, we use the decoding procedure of the vertical \(b_1\)-burst-correcting code to correct a burst of length \(b_1\). If such a burst occurred it “almost” determines the rows in which errors occurred and also the shape of the cluster up to horizontal cyclic permutation. We say “almost” since the vertical code does not find erroneous redundancy bits from the second and the third subsets. These bits are spaced in a way that at most one such bit is in error. We sum these \(m + 1\) bits and if the result is not zero then one of these bits is erroneous. If this is the case then from rows of the cluster-error, discovered by the vertical code, we will know the exact row of this bit. If the vertical code didn’t find any burst and a redundancy bit from either the second subset or the third subset is erroneous then we have exactly a single error in the array. Now, since the \((b_1b_2)\)-burst-locator code is also a single-error-correcting code (binary Hamming code) this single error can be corrected. If there are more errors in the cluster then we continue by either correcting the redundancy bit of the last two subsets (and the corresponding bit in the horizontal codeword) or adding this erroneous redundancy bit to the shape of the burst. In either cases the horizontal \((b_1b_2)\)-burst-locator code will discover the first column in which the cluster occurred, and hence the pattern discovered by the vertical component code enables us to correct the errors.

**Remark 1:** The parity bits of the second set can be chosen in other ways as long as they form a set of redundancy symbols for the burst-locator code, e.g., they don’t have to be in consecutive columns. Such choices can result in other array sizes.

**Remark 2:** A natural question is to ask why not to use also a binary vertical component code? The answer is that we can. The main advantage will be that we will have more flexibility in the parameters of our two-dimensional array. The disadvantage is that the excess redundancy will be increased by \(\lceil \log b_2 \rceil\).

The consequence of this construction is the following theorem (the computational part of the proof will be given in the next subsection).

**Theorem 3:** The given construction produces a \((b_1 \times b_2)\)-cluster-correcting code of size \(n_1 \times n_2 = (2^{b_2})^r - 2^{b_1} - 1\) with redundancy \(r_1b_2 + r - b_1b_2 + 2 \leq \lceil \log b_2(n_1n_2) \rceil + b_1 + 1\) \(b_2\). The construction can be applied whenever \(b_1b_2\) is odd integer, and there exists

- An optimum \(b_1\)-burst-correcting code, over GF\((2^{b_2})\), with redundancy \(r_1\) and length \(2^{b_2} - b_1b_2 + 1\).
- A binary \((b_1b_2)\)-burst-locator code with redundancy \(r\) and length \(2^{b_1b_2} - b_1b_2 + 1\).

C. Multidimensional arrays

As said earlier, one of the advantages of our construction is that it can be generalized in relatively simple way to \(D\) dimensions, while the excess redundancy remains relatively small. Assume we want to construct a \(D\)-dimensional code of size \(n_1 \times n_2 \times \cdots \times n_D\) which corrects a box-error of size \(b_1 \times b_2 \times \cdots \times b_D\). Let \(B = \prod_{i=1}^{D} b_i\), where \(B\) is an odd integer. For the first dimension we use a component code of
length \( n_1 \) over \( \text{GF}(2^{n_1}) \) which corrects a burst error of size \( b_1 \).

In each of the other \( D - 1 \) dimensions we use a burst-locator code which locates the position of the burst and its cyclic permutation in the corresponding direction. In dimension \( i, 2 \leq i \leq D \), we use a \( b_i \)-burst-locator code of length \( n_i \) over \( \text{GF}(2^{n_i}) \). The code of the first dimension finds the position of the error in the first dimension and the shape of the error, with a possible cyclic shift in each of the other \( D - 1 \) dimensions. The code in dimension \( i, 2 \leq i \leq D \), finds the location of the position where the cluster starts in dimension \( i \). After each code discovers the position where the cluster starts in its dimension (note, that this can be done in parallel), we have the corresponding cyclic shift in each dimension of the box-error found by the first code. Hence, we can now form the actual burst which occurred and correct it. As before, we can use in dimension \( i, 2 \leq i \leq D \), a binary \( B \)-burst-locator code.

For the first dimension we can choose consecutive redundancy bits as the redundancy bits of the first subset. For each other dimension we will have to choose positions for the redundancy bits, which will fulfill the requirements for the redundancy bits of the second subset (only one redundancy bit will be needed as a parity bit for all the redundancy bits of this form for the burst-locator codes of all dimensions).

**Theorem 4:** Assume \( b_1, b_2, \ldots, b_D \) are odd integers, \( B = \prod_{i=1}^{D} b_i \) and the following codes exist:

- An optimum \( b_1 \)-burst-correcting code, over \( \text{GF}(2^{n_1}) \), with redundancy \( r_1 \) and length \( \left( \frac{2^{n_1} - 1}{2^{n_1} - b_1} + 1 \right) \).
- For each \( i, 2 \leq i \leq D \), a binary \( B \)-burst-locator code with redundancy \( r_i \) and length \( 2^{n_i} - 1 = 2^{r_i} + B + 1 - 1 \).

Then, there exists a \( (b_1 \times b_2 \times \cdots \times b_D) \)-burst correcting code of size \( n_1 \times n_2 \times \cdots \times n_D = \left( \frac{2^{n_1} - 1}{2^{n_1} - b_1} + 1 \right) \times \left( \frac{2^{n_2} - 1}{2^{n_2} - b_2} + 1 \right) \times \cdots \times \left( \frac{2^{n_D} - 1}{2^{n_D} - b_D} + 1 \right) \) and redundancy \( r = r_1 b_1 + \sum_{j=2}^{D} m_j + 1 \leq \left\lceil \log_2(n_1 \cdots n_D) \right\rceil + B + \left\lceil \log_2(b_1 B^{D-2}) \right\rceil + 1 \).

**Proof:** The existence of the code is implied by the proceeding description and we only have to compute its redundancy. For each \( j, 2 \leq j \leq D \), \( n_j = \left( \frac{2^{m_j} - 1}{2^{m_j} - b_j} \right) \geq \left( \frac{2^{2^{m_j}}}{2^{2^{m_j}}} \right) = 2^{2^{m_j} - 2} \). Then, taking into account that for each \( j, 2 \leq j \leq D \), \( m_j > B \), and w.l.o.g. we can assume that for each \( i, 1 \leq i \leq D \), \( b_i > 1 \), we have that for each \( j, 2 \leq j \leq D \), \( 2^{m_j} B_j > 2(D - 1)B \). It follows that \( \log_2(n_1 n_2 \cdots n_D) \geq n_1 + \log_2(B) + \sum_{j=2}^{D} m_j - 1 \). Hence we have that the redundancy of the code is \( r = r_1 b_1 + \sum_{j=2}^{D} m_j + 1 \leq \left\lceil \log_2(n_1 \cdots n_D) \right\rceil + B + \left\lceil \log_2(b_1 B^{D-2}) \right\rceil + 1 \).

When \( B \) is even we have to modify our method in order to obtain similar results. The modifications include binary component codes in all dimensions. Each one of the \( D - 1 \) burst-locator codes locates the position of a cyclic burst of size \( B + 1 \). This modification is described in the next section.

**IV. Colorings for Error-Correction**

The constructions presented in Section III are best applied when the volume of the box error is an odd integer. The reason is that Lemma I is true only when \( b \) is an odd integer. Hence, if the volume of the box-error is an even integer then the construction of Section III has to be used in a slightly different way. We have to apply the construction for correcting a box-error which has odd volume and contains the "real" box-error. The price will be an increase in the excess redundancy. In this section we offer a novel method which will be useful to correct a box-error with even volume and also for correcting other types of cluster-errors. The excess redundancy will be similar to the one of the constructions in Section III.

A. The coloring method

The constructions with binary component codes use \( D \) components codes from which the first one is a burst-correcting code and the other \( D - 1 \) codes are burst-locator codes. Position \( k \) in component code \( s \) is the binary summation of certain positions in the array, which were defined with correspondence to some modulo value related to \( s, k \), and the \( D \) indices which define the position in the array. We generalize this idea to handle more complicated cluster-errors to a method which will be called the coloring method. A codeword is a \( D \)-dimensional array \( A \) (not necessarily a \( D \)-dimensional box). We want to correct any cluster-error with a given shape whose volume is \( B \).

Again, we use \( D \) binary component codes to correct the cluster-error. The first code is a \((B + \delta_1)\)-burst-correcting code, \( \delta_1 \geq 0 \). The \( s \)-th component code, \( 2 \leq s \leq D \), is a \((B + \delta_s)\)-burst-locator code, \( \delta_s \geq \delta_1 \). We further use \( D \) different colorings of the \( D \)-dimensional array. To each position of \( A \) we assign a color for each one of the \( D \) colorings. Each coloring will be associated with a different binary component code. For a given coloring and the corresponding component code, position \( k \) in the component code is the binary sum of all bits which are colored with color \( k \). As we want to correct a cluster-error of a certain shape in the array we want that the colorings will satisfy a few properties:

- **(p.1)** For the \( s \)-th coloring, for each \( s, 1 \leq s \leq D \), the colors inside a burst of the given shape are distinct integers and the difference between the largest integer and the smallest one is at most \( B + \delta_s - 1 \).
- **(p.2)** Given \( D \) colorings, a color \( \nu_s \) for the \( s \)-th coloring, \( 1 \leq s \leq D \). There is at most one position in the array which is colored with the colors \( \nu_1, \nu_2, \ldots, \nu_D \).
- **(p.3)** Any two positions which are colored with the same color by the first coloring, have colors which differ by a multiple of \( B + \delta_s \) by the \( s \)-th coloring, for each \( s, 2 \leq s \leq D \).

Finally, we have to choose redundancy bits in the array, in a similar way to the method used in Section III.

**Theorem 5:** Assume that there exists a \((B + \delta_1)\)-burst-correcting code of length \( n_1 \) and for each \( s, 2 \leq s \leq D \), there exists a \((B + \delta_s)\)-burst-locator code of length \( n_s \). Assume further that there exist \( D \) colorings which satisfy properties (p.1), (p.2), and (p.3), such that the \( s \)-th coloring assigns colors...
between 1 to \( n_s \) to the \( D \)-dimensional array. Then the coloring method implies the existence of a \( B \)-cluster-correcting code for a \( D \)-dimensional array \( A \) and a cluster with a given shape and volume \( B \).

**Proof:** The proof is straightforward from the description. We just note, that by property (p.2) there is no ambiguity in the erroneous positions. By property (p.1), for each \( s, 1 \leq s \leq D \), the erroneous positions affect at most \( B + \delta_s \) consecutive positions in the codeword of the \( s \)-th component code. Finally, since two positions in the array which are assigned the same color, have been assigned by the \( s \)-th coloring colors which differ by a multiple of \( B + \delta_s \) (see property (p.3)), it follows that the possible bursts in the \( s \)-th \((B + \delta_s)\)-burst-locator code are cyclic shifts of a burst with length \( B + \delta_s \).

It will be more convenient if each coloring is a linear function of the coordinate indices, i.e., given a position \((i_1, i_2, \ldots, i_D)\) its color for the \( s \)-th coloring will be defined by

\[
\alpha_s^g i_j
\]

where \( \alpha_s^g \) is a constant integer which depends on the coloring \( s \) and the shape of the \( D \)-dimensional cluster. Such a coloring will be called a linear coloring. With a linear coloring we associate a coloring matrix \( A_D \), where \((A_D)_{s,j} = \alpha_s^g \). It is easy to verify that property (p.2), is fulfilled for a linear coloring if and only if the coloring matrix is an invertible matrix.

One can verify that the coloring method is a generalization of the method described in Section [I]. To observe this we should assign a color to position \((i_1, i_2, \ldots, i_D)\) by the \( s \)-th coloring, \( 1 \leq s \leq D \), in a slightly different way than the assignment in the next subsection. If position \( k \) in component code \( s \) is the binary sum of a certain set \( S \) of positions in the array, then all positions of \( S \) are colored with color \( k \) by the \( s \)-th coloring. We leave the exact definitions of the colorings as an exercise for the reader.

**B. Multidimensional box-errors**

To demonstrate how the coloring method works we will first show how it is used to correct multidimensional box-errors, where the volume of the box error is an even integer.

Assume we want to construct an \( n_1 \times n_2 \times \cdots \times n_D \) \( D \)-dimensional \((b_1 \times b_2 \times \cdots \times b_D)\)-cluster-correcting code, where \( B = \prod_{i=1}^D b_i \) is an even integer. We will use \( D \) binary component codes. One component code will be able to correct a burst of length \( B \) and \( D-1 \) component codes will be able to locate the position of a burst, whose length is \( B + 1 \), given by a cyclic shift. Let

\[
B_j = b_j B_{j-1}, \text{ where } 1 \leq j \leq D, \text{ and } B_0 = 1.
\]

For each entry \((i_1, i_2, \ldots, i_D)\) in the array we assign \( D \) colors. The \( s \)-th color, \( 1 \leq s \leq D \) is defined by

\[
a_{s,i_1i_2\cdots i_D} = \sum_{j=1}^{s-1} -B_{j-1} B_{s-1}^{-1} i_j + \sum_{j=s}^{D} B_{j-1} B_{s-1}^{-1} i_j.
\]

Each coloring corresponds to one component code. Codeword of component code \( s, C_s, 1 \leq s \leq D \) is defined according to coloring \( s \). Position \( k \) in the codeword is the sum modulo 2 of the values in positions colored with color \( k \) by the \( s \)-th coloring. We will prove that these \( D \) codes satisfy properties (p.1) through (p.3).

**Lemma 4:** If the \( D \)-dimensional code has a box error of size \( b_1 \times b_2 \times \cdots \times b_D \) then each one of the \( D \) component codewords has a burst whose length is at most \( B \).

**Proof:** A cluster occurred in the array is located inside a multidimensional box of the form \((i_1^* + 1, i_2^* + 1, \ldots, i_D^* + 1) : 0 \leq i_j \leq b_j - 1, 1 \leq j \leq D\), for a fixed position \((i_1^*, i_2^*, \ldots, i_D^*)\). The smallest color, \( \ell_{C_s} \), of an erroneous position in \( C_s, 1 \leq s \leq D \) is

\[
\ell_{C_s} = \sum_{j=1}^{s-1} -B_{j-1} B_{s-1}^{-1} (i_j^* + b_j - 1) + \sum_{j=s}^{D} B_{j-1} B_{s-1}^{-1} i_j^*;
\]

which is the color of position \((i_1^* + 1, i_2^* + 1, \ldots, i_s^* + b_s - 1, i_{s+1}^*, \ldots, i_D^* + b_D - 1)\). Now, we compute the difference \( h_{C_s} - \ell_{C_s} \).

\[
h_{C_s} - \ell_{C_s} = \sum_{j=1}^{s-1} B_{j-1} B_{s-1}^{-1} (b_j - 1) + \sum_{j=s}^{D} B_{j-1} B_{s-1}^{-1} (b_j - 1)
\]

\[
= \frac{B_D}{B_{s-1}} \left( \sum_{j=1}^{s-1} B_{j-1} (b_j - 1) \right) + \frac{1}{B_{s-1}} \left( \sum_{j=s}^{D} B_{j-1} (b_j - 1) \right)
\]

\[
= \frac{B_D}{B_{s-1}} (B_{s-1} - B_0) + \frac{1}{B_{s-1}} (B_D - B_{s-1})
\]

\[
= B_D - \frac{B_D}{B_{s-1}} + \frac{B_D}{B_{s-1}} - 1 = B - 1
\]

Therefore, the length of a burst in each component code is at most \( B \).

**Lemma 5:** For each one of the \( D \) colorings, the \( B \) colors in each \( D \)-dimensional box of size \( b_1 \times b_2 \times \cdots \times b_D \) in the array are all distinct.

**Proof:** Assume the contrary, that there exist two different positions \((i_1, \ldots, i_D), (t_1, \ldots, t_D)\) located inside a box of size \( b_1 \times b_2 \times \cdots \times b_D \) in the array whose \( s \)-th color is identical. Therefore, by definition,

\[
\sum_{j=1}^{s-1} -B_{j-1} B_{s-1}^{-1} i_j + \sum_{j=s}^{D} B_{j-1} B_{s-1}^{-1} i_j = \sum_{j=1}^{s-1} -B_{j-1} B_{s-1}^{-1} t_j + \sum_{j=s}^{D} B_{j-1} B_{s-1}^{-1} t_j
\]
which implies

\[ t_s - i_s = \sum_{j=1}^{s-1} -B_j^{-1} \frac{B_D}{B_{s-1}} (i_j - t_j) + \sum_{j=s+1}^{D} B_j^{-1} (i_j - t_j) \]

\[ = b_s \left( \sum_{j=1}^{s-1} -B_j^{-1} \frac{B_D}{B_s} (i_j - t_j) + \sum_{j=s+1}^{D} B_j^{-1} (i_j - t_j) \right) \tag{4} \]

Since these two positions are located inside a box of size \( b_1 \times \cdots \times b_D \) it follows that \( 0 \leq |t_s - i_s| \leq b_s - 1 \) and hence \( t_s - i_s = 0 \). We continue with (4) and by induction we prove similarly that \( t_k - i_k = 0 \) for each \( k, s+1 \leq k \leq D \). Therefore by (3) we have

\[ \sum_{j=1}^{s-1} -B_j^{-1} \frac{B_D}{B_{s-1}} (i_j - t_j) = 0 \]

which implies

\[ \sum_{j=1}^{s-1} -B_j^{-1} (i_j - t_j) = 0. \]

Now, we will show by induction that for each \( j, 1 \leq j \leq s-1, t_j - i_j = 0 \). For \( j = 1 \), we have

\[ t_1 - i_1 = \sum_{j=2}^{s-1} B_j^{-1} (i_j - t_j) = b_1 \left( \sum_{j=2}^{s-1} \frac{B_j^{-1}}{b_1} (i_j - t_j) \right) \]

and since \( 0 \leq |t_1 - i_1| \leq b_1 - 1 \) we have \( t_1 - i_1 = 0 \). We continue in similar way and obtain for each \( j, 1 \leq j \leq s-1, t_j - i_j = 0 \). Therefore, for each \( 1 \leq s \leq D \), we have \( t_s = i_s \). Thus, for each one of the \( D \) colorings, the \( B \) colors in each \( D \)-dimensional box of size \( b_1 \times b_2 \times \cdots \times b_D \) in the array are all distinct.

**Lemma 6**: Any two positions which are colored with the same color by the first coloring, have colors which differ by a multiple of \( B + 1 \) by the \( s \)-th coloring, for each \( s, 2 \leq s \leq D \).

**Proof**: Assuming the \( k \)-th position in the codeword of \( C_1 \) is erroneous. This error results from an array error in position \( (i_1, i_2, \ldots, i_D) \) such that \( a_{i_1, i_2, \ldots, i_D} = \sum_{j=1}^{D} B_j i_j = k \), and hence \( i_1 = k - \sum_{j=2}^{D} B_j i_j \). The possible error locations in

\[ C_s, 2 \leq s \leq D \] are of the form

\[ a^*_{i_1, i_2, \ldots, i_D} = \sum_{j=1}^{s-1} -B_j^{-1} \frac{B_D}{B_{s-1}} i_j + \sum_{j=s}^{D} B_j^{-1} i_j = \]

\[ -\frac{B_D}{B_{s-1}} (k - \sum_{j=2}^{D} B_j i_j) + \sum_{j=2}^{s-1} B_j^{-1} i_j + \sum_{j=s}^{D} B_j^{-1} i_j = \]

\[ -\frac{B_D}{B_{s-1}} k + \sum_{j=2}^{D} B_j^{-1} \frac{B_D}{B_{s-1}} i_j - \sum_{j=2}^{s-1} B_j^{-1} i_j + \sum_{j=s}^{D} B_j^{-1} i_j = \]

\[ -\frac{B_D}{B_{s-1}} k + (B + 1) \sum_{j=s}^{D} B_j^{-1} i_j. \]

\( \frac{B_D}{B_{s-1}} k \) is a constant and therefore, two positions which have the same color by the first coloring, have colors which differ in a multiple of \( B + 1 \) by the \( s \)-th coloring, \( 2 \leq s \leq D \).

**Lemma 7**: Given a position \( c_s \) in the \( s \)-th component code, \( 1 \leq s \leq D \), the set of equations

\[ c_s = a^*_{i_1, i_2, \ldots, i_D}, 1 \leq s \leq D \] has exactly one solution for \( (i_1, \ldots, i_D) \).

**Proof**: We will prove that the coloring matrix is invertible by proving that its determinant is not equal to zero. The \( (s, j) \) entry of the coloring matrix \( A_D \) is given by

\[ (A_D)_{s,j} = \begin{cases} -\frac{B_j^{-1} B_D}{B_{s-1}} & \text{for } j < s \\ \frac{B_j^{-1}}{B_{s-1}} & \text{for } j \geq s \end{cases}. \]

We will prove by induction on \( D \), \( D \geq 2 \), that \( |A_D| = (1 + B')^{D-1} \), where \( B \) is the volume of the box-error.

For the basis of the induction, \( A_2 = \begin{pmatrix} 1 & b_1 \\ -b_2 & 1 \end{pmatrix} \) and hence \( |A_2| = 1 + b_1 b_2 = 1 + b_1 b_2 \), where the two-dimensional cluster has size \( b_1 \times b_2 \).

For the induction hypothesis we assume that the determinant of every coloring matrix of size \( (D - 1) \times (D - 1) \) is given by \( |A_{D-1}| = (1 + B')^{D-2} \), where \( B' \) is the volume of the corresponding \( (D - 1) \)-dimensional box-error.

For the induction step let \( A_D \) be a coloring matrix of size \( D \times D \). The determinant of \( A_D \) is given by

\[ |A_D| = \sum_{j=1}^{D} (-1)^{j+1} B_j^{-1} |A_D|_{[1,j]}, \]

where \( A_D|_{[1,j]} \) is the matrix obtained from \( A_D \) by deleting row 1 and column \( j \). For \( 2 \leq s \leq D - 1 \) the \( s \)-th row of \( A_D|_{[1,s]} \) is given by:

\[ \frac{1}{B_{s-1}} (-B_D B_0, -B_D B_1, \ldots, -B_D B_{s-2}, B_s, \ldots, B_{D-1}), \]
and the \((s + 1)\)-th row is given by:

\[
\frac{1}{B_s}(-B_D b_0, -B_D b_1, \ldots, -B_D b_{s-2}, b_s, \ldots, B_D -1).
\]

These two rows are linearly dependent and therefore, 
\(|A_D|_{1:s} = 0\) for \(2 \leq s \leq D - 1\) and we have

\[
|A_D| = B_0|A_D|_{1:s} + |A_D|_{D - 1} = B_0|A_D|_{1:s} + (-1)^{D - 1}B_{D - 1}|A_D|_{1:s}.
\]

(6)

The matrix \((A_D)_{1:s}\) is also a coloring matrix with respect to coloring related to the box-error to the last row of \((A_D)_{1:D}\) by \(-b_D\) and shifting this row cyclically to be the first row. Clearly, \(|(A_D)_{1:D}| = |(A_D)_{1:D}|(1 + B)D - 2\) and from \(6\) we have \(|(A_D)_{1:D}| = (1 + B)D - 2 + (-1)^{D - 1}B_{D - 1}|(A_D)_{1:s}|\).

To summarize, by Lemmas \(4\) and \(5\) the \(D\)-dimensional Lee sphere with radius \(R\) for each \(i\) is of the form \(c_i\) and \(c_i\) is an erroneous position.

Another important observation is that any arbitrary cluster-error of size \(b\) is located inside a Lee sphere with radius \(\lfloor \frac{b}{2} \rfloor\). We wish to supply a method to correct all errors which might occur in such a given Lee sphere. The size of such sphere is \(\sum_{\ell = 0}^{\lfloor \frac{b}{2} \rfloor} 2^D\binom{D}{\ell}\) and each position can be erroneous. We can think about three different methods to perform the task.

- We can use any method which is able to correct all errors occurred in a \((2R + 1) \times \cdots \times (2R + 1)\) \(D\)-dimensional cube since a Lee sphere with radius \(R\) is located inside such a cube. The main disadvantage of this method is that the code can correct much more errors than the ones needed in its goal. For example, the size of the \(D\)-dimensional cube is \((2R + 1)^D\), while the size of the \(D\)-dimensional Lee sphere with radius \(R\) is \((2R + 1)^D\) when \(R\) is fixed and \(R \rightarrow \infty\).

- We can transform the space into another space in a way that a Lee sphere will be transformed to a shape located inside another error-shape with a small volume which we know how to correct efficiently.

- We can find a coloring and perform correction of errors as explained in Section \(\text{IV}\).

In this section we will explain how we apply the last two methods.

A. Space transformation

The idea we are going to use is to transform the space into another space in such a way that a Lee sphere in one space will be transformed into a shape located inside a box in the second space. After that we will be able to use the encoding and decoding introduced in Section \(\text{IV}\).

We start with the two-dimensional transformation.

**Lemma 8:** Let \(M, M^*\) be infinite two-dimensional arrays and let \(T(i_1, i_2)\) be the transformation from \(M\) into \(M^*\) defined by \(T(i_1, i_2) = \left(\left\lfloor \frac{i_1 + i_2}{2} \right\rfloor, i_2 - i_1\right)\). Then a Lee sphere with radius \(r\) in the array \(M\) is located after the transformation \(T\) inside a rectangle of size \((R + 1) \times (2R + 1)\) in \(M^*\).

**Proof:** A Lee sphere of radius \(R\) with center at \((i_1, i_2)\) in the array \(M\) includes the set of positions

\[
B_R(i_1, i_2) = \{(t_1, t_2) : |t_1 - i_1| + |t_2 - i_2| \leq R\} = \{(i_1 + R_1, i_2 + R_2) : |R_1| + |R_2| \leq R\}.
\]

\(B_R(i_1, i_2)\) is transformed by \(T\) into the set of positions

\[
\left(\left\lfloor \frac{i_1 + R_1 + i_2 + R_2}{2} \right\rfloor, i_2 - i_1 - R_1\right)
\]

of \(M^*\). Denote, \(i_1^* = \left\lfloor \frac{i_1 + R_1}{2} \right\rfloor\), \(i_2^* = i_2 - 1 - R\), and we have that \(B_R(i_1, i_2)\) is located inside the rectangle

\[
\{(i_1^*, i_2^* + 2R) : 0 \leq t_1 \leq R, 0 \leq t_2 \leq 2R\}.
\]

The transformation \(T\) transforms a parallelogram into a rectangle (see Fig. \(3\) and \(4\) and hence we will need some adjustment in our encoding and decoding procedures if we want to correct Lee sphere clusters in a rectangular array rather than a parallelogram.

The construction is generalized to \(D\) dimensions. The transformation \(T\) will work between two \(D\)-dimensional arrays. For each entry \((i_1, i_2, \ldots, i_D)\) in the \(D\)-dimensional array \(M\), \(T(i_1, i_2, \ldots, i_D) = (i_1^*, i_2^*, \ldots, i_D^*)\).
of the coloring method. We choose two appropriate colorings \( \Psi_1 \) and \( \Psi_2 \). For a given position \((i_1, i_2)\) in the \( n_1 \times n_2 \) two-dimensional array let \( \Psi_1(i_1, i_2) = (R + 1)i_1 + Ri_2 \) and \( \Psi_2(i_1, i_2) = -Ri_1 + (R + 1)i_2 \) (see Fig. 5).

**Lemma 10:** If \( \Psi_1(i_1, i_2) = \Psi_1(t_1, t_2) \) then \( \Psi_2(i_1, i_2) - \Psi_2(t_1, t_2) \) is a multiple of \( 2R^2 + 2R + 1 \).

**Proof:** \( \Psi_1(i_1, i_2) = \Psi_1(t_1, t_2) \) implies that \((R + 1)i_1 + Ri_2 = (R + 1)t_1 + Rt_2\). Hence, \( R(i_2 - t_2) = (R + 1)(t_1 - i_1) \), i.e., \( (R + 1)(i_2 - t_2) = \frac{(R + 1)t_1 - i_1}{R} \).

Now, \( \Psi_2(i_1, i_2) - \Psi_2(t_1, t_2) = -Ri_1 + (R + 1)i_2 - (-Rt_1 + (R + 1)t_2) = R(t_1 - i_1) + (R + 1)(i_2 - t_2) = R(t_1 - i_1) + \frac{(R + 1)t_1 - i_1}{R} = 2R^2 + 2R + 1 \).

Since \( R \) and \( 2R^2 + 2R + 1 \) are relatively prime it follows that \( R \) divides \( t_1 - i_1 \) and hence \( \Psi_2(i_1, i_2) - \Psi_2(t_1, t_2) \) is a multiple of \( 2R^2 + 2R + 1 \).

The effect of these colorings of the two-dimensional arrays is best seen if we consider a tiling of the two-dimensional space with Lee spheres with radius \( R \). Such tiling is well known and given in [6], [10]. In this tiling each Lee sphere belongs to two diagonal strips. For the first coloring all relative positions of the Lee spheres in the same diagonal strip have the same number; and in the other direction they are congruent modulo \( b^* = 2R^2 + 2R + 1 \) which is the size of a sphere (see Fig. 5).

**Lemma 11:** For any given Lee sphere with radius \( R \) in a two-dimensional array, the color numbers assigned by \( \Psi_i, i = 1, 2, \) to the positions of the Lee sphere are \( 2R^2 + 2R + 1 \) consecutive integers.

**Proof:** Given a Lee sphere centered at the point \((i_1, i_2)\) it is readily verified that smallest color number assigned by \( \Psi_1 \) to a point in the Lee sphere is \( \Psi_1(i_1 - R, i_2) \) and the largest color number is \( \Psi_1(i_1 + R, i_2) \). Now, \( \Psi_1(i_1 + R, i_2) - \Psi_1(i_1 - R, i_2) = (R + 1)(i_1 + R) + Ri_2 - ((R + 1)(i_1 - R) + Ri_2) = 2R^2 + 2R \). Hence, to complete the proof we have to show that all the color numbers assigned by \( \Psi_1 \) to the positions inside a Lee sphere are distinct.

Let \((i_1, i_2)\) and \((t_1, t_2)\) be a pair of points for which \( \Psi_1(i_1, i_2) = \Psi_1(t_1, t_2) \). By the proof of Lemma 10 we have that \( R(i_2 - t_2) = (R + 1)(t_1 - i_1) \). Hence, \( i_2 - t_2 = \frac{R}{R+1}(t_1 - i_1) \) and \( t_1 - i_1 = \frac{R}{R+1}(i_2 - t_2) \). Since \( R \) and \( R + 1 \) are relatively primes it follows that \( R \) divides \( t_1 - i_1 \) and \( R + 1 \) divides \( i_2 - t_2 \). This implies that \( R \leq |t_1 - i_1| \) and \( R + 1 \leq |i_2 - t_2| \). Therefore, \( 2R + 1 \leq |t_1 - i_1| + |i_2 - t_2| \) and the two points \((i_1, i_2)\) and \((t_1, t_2)\) cannot be contained in the same Lee sphere.

Thus, all color numbers assigned by \( \Psi_1 \), to the positions contained in a Lee sphere are \( 2R^2 + 2R + 1 \) consecutive integers. The same proof holds for \( \Psi_2 \).

**Lemma 12:** The coloring matrix defined by \( \Psi_1 \) and \( \Psi_2 \) is an invertible matrix.

**Proof:** The coloring matrix defined by \( \Psi_1 \) and \( \Psi_2 \) is

\[
\begin{pmatrix}
R + 1 & R \\
-R & R + 1
\end{pmatrix}
\]

which is clearly an invertible matrix.

By Lemmas 10, 11, and 12 we have that (p.1), (p.2), and (p.3), are satisfied respectively. Hence, by Theorem 5 the code
We choose \( r + m + 1 \) appropriate redundancy bits similarly to the constructions in Section III. We use two component codes. One code is a \( b^* \)-burst-correcting code of length \( 2^{r-b^*+1} - 1 \), where \( 2^{r-b^*+1} \) is the least power of 2 greater than \((R + 1)(n_2 - 1) + R(n_2 - 1) + 1\) which is the number of colors needed to color the array with the first coloring. The second component code is a \( b^* \)-burst-locater code of length \( 2^m - 1 \) (such a code exists since \( b^* = 2R^2 + 2R + 1 \) is an odd integer). We take \( 2^m \) to be the least power of 2 greater than \((R + 1)(n_2 - 1) + R(n_2 - 1) + 1\) which is the number of colors needed to color the array with the second coloring (for the simplicity of the computations we will take \( 2^{r-b^*+1} > (R + 1)n_1 + Rn_2 \geq 2^{r-b^*} \) and \( 2^m > (R + 1)n_2 + Rn_1 \geq 2^{m-1} \)). The redundancy of the \( n_1 \times n_2 \) two-dimensional code is at most \( \lceil \log_2(n_1n_2) \rceil + b^* + [2\log_2(2R + 1)] + 2 \). If \( n_1 = n_2 = n \) then the redundancy of the two-dimensional code is at most \( \lceil \log_2(n^2) \rceil + b^* + [2\log_2(2R + 1)] \) and if each codeword is a rhombus of size \( n^2 \) then the redundancy is at most \( \lceil \log_2(n^2) \rceil + b^* + [\log_2 b^*] \).

### C. Multidimensional codes

A similar idea can be used for \( D \)-dimensional code of size \( n_1 \times n_2 \times \cdots \times n_D \) correcting Lee sphere error with radius one. We use different colorings of the array. For a position \((i_1, i_2, \ldots, i_D)\), \( 0 \leq i_\ell \leq n - 1 \), \( 1 \leq \ell \leq D \), the \( \ell \)-th coloring, \( 1 \leq \ell \leq D \), assigns the color \( \sum_{\ell' = 1}^{D} \ell' \cdot i_{\ell'} + i_{\ell-1} \), where indices are residues modulo \( D \) between 1 and \( D \) (note that each color in each coloring forms a perfect code [10] when we consider the coloring in \( \mathbb{Z}^D \) and not just in the array). Again, for each coloring, all the color numbers located in a Lee sphere of the \( D \)-dimensional array are \( 2D + 1 \) consecutive integers. Bit \( k \) of the \( D \)-dimensional code is the binary sum of all the bits colored with the integer \( k \), by the \( \ell \)-th coloring, in the \( D \)-dimensional codeword. It is easy to prove that the coloring matrix is invertible. But, property (p.3) does not hold in all dimensions. Therefore, if property (p.3) does not hold for the \( \ell \)-th coloring we need to take a \((2D + 1)\)-burst-correcting code instead of \((2D + 1)\)-burst-locator code for the \( \ell \)-th dimension. The consequence will be a code with larger redundancy. Clearly, there are many appropriate colorings for each dimension. Hence, we can try to replace each coloring by one for which property (p.3) holds. Of course we have to make sure that the coloring matrix will be invertible. The excess redundancy in this case is quadratic in \( D \), compared to exponential in \( D \) if we use the transformation \( T \) and the code which corrects \( D \)-dimensional box-error.

### VI. Bursts with Limited Weight

We now turn for a new kind of errors which are important in our final goal of correcting an arbitrary cluster-error. Assume we need to correct errors in a cluster of size \( b \), where the number of erroneous positions is at most \( t \). We wish to find one-dimensional and multidimensional codes which correct such errors. These codes have an obvious application as we can expect that in area that suffers from an event which caused errors, not all positions were affected. Another important observation is that any arbitrary cluster-error of size \( b \) is located inside a Lee sphere with radius \( \lfloor \frac{b}{2} \rfloor \). Hence, this cluster-error can be corrected if we can correct a Lee sphere error with radius \( \lfloor \frac{b}{2} \rfloor \), where the number of erroneous positions is at most \( b \).

#### A. One-dimensional codes

Throughout this subsection all codes are binary and \( b \) is an odd integer.

Let \( C_1 \) be a \( t \)-error-correcting code of length \( b \), and redundancy \( r \). Let \( H_1 \) be its parity-check matrix of size \( r \times b \),

\[
H_1 = [h_{0,1}, h_{1,1}, \ldots, h_{b-1,1}].
\]

Let \( C_2 \) be a \( b \)-burst-locator code, of length \( n = 2^m - 1 \), and redundancy \( m \). Its parity-check matrix, \( H_2 \), is of size \( m \times (2^m - 1) \),

\[
H_2 = [h_{0,1}, h_{1,1}, \ldots, h_{b-1,1}].
\]

Based on these two matrices, we construct a new parity-check matrix \( H \),

\[
H = \begin{bmatrix}
h_{0,1} & h_{1,1} & \cdots & h_{b-1,1} & h_{1,1} & \cdots & h_{(n-1)(mod \ b)} \\
h_{0,2} & h_{1,2} & \cdots & h_{b-1,2} & h_{2,1} & \cdots & h_{b-1,1} \\
\end{bmatrix}.
\]

The \( j \)-th column, \( 0 \leq j \leq n - 1 \), of the matrix \( H \) will be defined as the concatenation of the \( j \) (mod \( b \))-th column of the matrix \( H_1 \) and the \( j \)-th column of the matrix \( H_2 \).

**Lemma 13:** \( H \) is a parity-check matrix for a code \( C \) of length \( 2^m - 1 \), correcting every burst of length \( b \) with at most \( t \) erroneous positions.

**Proof:** It is sufficient to prove that there are no two bursts of length \( b \) and weight at most \( t \) that have the same syndrome. Assume the contrary, that there are two words, \( y^1 \) and \( y^2 \), of weight at most \( t \), with bursts of length \( b \), \( y^1 = (y_{i_0}^1, \ldots, y_{i_{b-1}}^1) \) and \( y^2 = (y_{i_0}^2, \ldots, y_{i_{b-1}}^2) \), which have the same syndrome, i.e. \( H(y^1)^T = H(y^2)^T \). This implies that

\[
\sum_{i=0}^{n-1} y_1^i h_{1,i}^1 = \sum_{i=0}^{n-1} y_1^i h_{1,i}^1 = \sum_{i=0}^{n-1} y_2^i h_{1,i}^1 , \quad (7)
\]

\[
\sum_{i=0}^{n-1} y_2^i h_{2,i}^2 = \sum_{i=0}^{n-1} y_2^i h_{2,i}^2 , \quad (8)
\]

where \( [j]_\ell \) is the unique residue of \( j \) (mod \( \ell \)) between 0 and \( \ell - 1 \). Let \( i_0^1, i_0^2 \) be the first nonzero bit in \( y^1 \), \( y^2 \), respectively. Therefore, (7) can be written as

\[
\sum_{i=i_0^1}^{i_0^1 + b - 1} y_{i}^1 h_{1,i}^1 = \sum_{i=i_0^2}^{i_0^2 + b - 1} y_{i}^2 h_{1,i}^1 .
\]

If we denote \( \ell^1 = b \left\lfloor \frac{b}{b} \right\rfloor \), \( \ell^2 = b \left\lfloor \frac{b}{b} \right\rfloor \), then the last equation can be written in the following way:

\[
\sum_{i=0}^{[i_0^1]_b} y_{[i_0^1]_b} h_{1,i}^1 + \sum_{i=[i_0^1]_b}^{[i_0^1]_b + b - 1} y_{[i_0^1]_b + i} h_{1,i}^1 = \sum_{i=0}^{[i_0^2]_b} y_{[i_0^2]_b} h_{1,i}^1 + \sum_{i=[i_0^2]_b}^{[i_0^2]_b + b - 1} y_{[i_0^2]_b + i} h_{1,i}^1 .
\]
This equation implies that for the words of length $b$

$$z^1 = \left( y_1^{\ell_1+b}, \ldots, y_1^{l_1+b+\lceil t \rceil_{b-1}}, \ldots, y_1^{l_1+b-1} \right),$$

$$z^2 = \left( y_2^{\ell_2+b}, \ldots, y_2^{l_2+b+\lceil t \rceil_{b-1}}, \ldots, y_2^{l_2+b-1} \right),$$

we have $H_1(z^1)^T = H_1(z^2)^T$. The weight of these words is at most $t$ and since $H_1$ is a parity-check matrix of a $t$-error-correcting code we have that $z^1 = z^2$. Therefore, the two different words $y^1$ and $y^2$ contain the same burst of length $b$ up to a cyclic permutation. By Lemma 13 we have that $H_2(y^1)^T \neq H_2(y^2)^T$, contradicting (b).

Thus, $H$ is a parity-check matrix for a code of length $2^m - 1$, correcting every burst of length $b$ with at most $t$ erroneous positions.

**Remark:** It is important to note that $H$ is acting similarly to the constructions of previous sections. The first part which is a concatenation of several copies of $H_1$ is a parity-check matrix of a $b$-burst-correcting code with at most $t$ erroneous positions. It finds the burst pattern up to a cyclic shift. The second part of $H$, $H_2$, is a parity-check matrix of a $b$-burst-locator which can find the location of a burst of length $b$ given up to a cyclic shift. Lemma 13 gives a formal proof for these facts in terms of the generated syndromes.

To summarize the parameters of the construction we need the parameters of $t$-error-correcting codes of length $b$. We can use BCH codes [13], [15] for this purpose. If $\ell$ is the least integer such that $b < 2^\ell - 1$ then there exists a $t$-error-correcting BCH code of length $2^\ell - 1$ and redundancy at most $t \ell$. By shortening we can obtain a $t$-error-correcting code of length $b$ and redundancy $t \lceil \log_2 b \rceil$. Now, we can summarize our construction in this section.

**Theorem 6:** The code $C$ has length $n = 2^m - 1$ and it corrects every burst of length $b$ with at most $t$ erroneous positions. If $b$ is an odd integer then the redundancy of the code is $m + t \lceil \log_2 b \rceil \geq \lceil \log_2 n \rceil + t \lceil \log_2 b \rceil$, and if $b$ is an odd integer then the redundancy of the code is $m + t \lceil \log_2 (b+1) \rceil \leq \lceil \log_2 n \rceil + t \lceil \log_2 (b+1) \rceil$.

**B. Multidimensional codes**

Now, we want to design a two-dimensional code of size $n_1 \times n_2$ capable of correcting a $(b_1 \times b_2)$-cluster with weight at most $t$, where $b_1 b_2$ is an odd integer. We use a construction similar to the one used in previous sections. In this construction we have to use two binary component codes. The vertical one is a $(b_1 b_2)$-burst-correcting code, of length $n_1 b_2$ in which the weight of the burst is at most $t$. Such a code was constructed in the previous subsection. The horizontal component code is a $(b_1 b_2)$-burst-locator code of length $n_2 b_1$. They are used in the same manner as they are used in previous sections to correct a burst of size $b_1 \times b_2$. Since the vertical code can find a burst only if the weight of it is at most $t$, it follows that the two-dimensional code can handle bursts of size $b_1 \times b_2$ only if their weight is at most $t$. If $b_1 b_2$ is an odd integer then by Theorem 6 we can take a vertical code of length $n_1 b_2$, $2^m \geq n_1 b_2 \geq 2^{m-1}$, with at most $m + t \lceil \log_2 (b_1 b_2) \rceil$ redundancy bits. The horizontal code has length $2^r - b_1 b_2 + 1$, with $r - b_1 b_2 + 1$ redundancy bits. Therefore we have.

**Theorem 7:** The redundancy of the $n_1 \times n_2$ code $C$ which is capable to correct a $(b_1 \times b_2)$-cluster, $b_1 b_2$ an odd integer, with weight less or equal to $t$, is at most $\lceil \log_2 (n_1 n_2) \rceil + (t + 1) \lceil \log_2 (b_1 b_2) \rceil + 3$.

The generalization for multidimensional codes is straightforward. If the size of the cluster is an even integer then we will use an appropriate coloring.

**VII. CORRECTION OF ARBITRARY BURSTS**

Finally, we want to design a code which corrects an arbitrary $D$-dimensional cluster-error of size $b$. If $b$ is odd then the
A related question is to find number of distinct clusters with redundancy bits in the codewords and to conduct the proper decoding. It is not difficult to see that all the multidimensional codes are linear, by noting that the bit by bit addition of two codewords is another codeword. In this section we will explain how to present similar codes with parity-check matrices. This will be done by considering all the component codes as binary codes.

**Remark:** When the component code is a linear burst-correcting code of length $n$ over $GF(2^b)$ we can consider it as a binary code of size $n \times b$, as we actually use it. We note that the bit by bit addition of two codewords of size $n \times b$ is also a codeword and hence the code is a binary linear code.

In these new codes, which will be constructed, we won’t need the redundancy bit of the third subset and hence the overall redundancy will be reduced by one. The idea is to use the technique of subsection VI-A. The parity-check matrix $H_1$, in subsection VI-A was used to find the pattern of the error, and the parity-check matrix $H_2$ was used to find the location of a burst given its pattern up to a cyclic shift.

This technique can be simply generalized for two-dimensional and multidimensional codes. We will describe it only for two-dimensional codes. Each of our constructions for two-dimensional codes uses two components codes $C_1$ and $C_2$. Assume that $C_1$ and $C_2$ are binary codes with $r_1 \times n_1$ parity-check matrix $H_1$ and $r_2 \times n_2$ parity-check matrix $H_2$, respectively. We construct a two-dimensional parity-check matrix $H$ for our two-dimensional code as follows. $H$ is a two-dimensional matrix whose shape is the shape of the two-dimensional codeword. In each position $\Upsilon$ in this two-dimensional shape, $H$ has a column vector of length $r_1 + r_2$ which is a concatenation of a column from $H_1$ and a column from $H_2$. The column from $H_1$ is $\xi_1$ if $\xi_1$ is the color given to position $\Upsilon$ by the first coloring (as mentioned before all our constructions can be represented by the coloring method). Similarly, the column from $H_2$ is $\xi_2$ if $\xi_2$ is the color given to position $\Upsilon$ by the second coloring (to avoid confusion, in the coloring method all positions are assigned with a color, by each coloring, including the redundancy bits). Now, we can use a proof similar to the proof of Lemma 13 to show that $H$ is a parity-check matrix for the required code. A generalization for multidimensional codes is straightforward.

Finally, note that the same method can be also applied to the three constructions presented in [8]. Hence, we can supply a parity-check matrix for each code constructed by these three constructions.

**IX. CONCLUSION AND OPEN PROBLEMS**

As we wrote in the abstract, the main results of the paper are summarized as follows:

1) A construction of small redundancy multidimensional codes capable to correct a box-error. These codes and the box-error have considerably more flexible parameters from previously known constructions.

2) A novel method based on $D$ colorings of the $D$-dimensional space for constructing $D$-dimensional codes correcting a $D$-dimensional cluster-error of various shapes.
3) A transformation of the $D$-dimensional space into another $D$-dimensional space in a way that a $D$-dimensional Lee sphere is transformed into a shape located in a $D$-dimensional box of a relatively small size. This transformation enables us to use the previous constructions to correct a $D$-dimensional error whose shape is a $D$-dimensional Lee sphere.

4) Applying the coloring method to correct more efficiently a two-dimensional error whose shape is a Lee sphere.

5) A construction of one-dimensional and multidimensional codes capable to correct a burst-error of length $b$ in which the number of erroneous positions is $t$.

6) Applying the construction for correction of a Lee sphere error and the construction for correction of a cluster-error with small number of erroneous positions, to correct a $D$-dimensional arbitrary cluster-error.

All the codes we have constructed are binary. We didn’t discuss cluster-correcting codes over GF($q$), but most of our results can be generalized straightforward for codes over GF($q$). We have omitted some tedious proofs. The interested reader is referred to [18] to see some of these proofs.

Clearly, our constructions do not cover all possible parameters. Moreover, the redundancy of our codes is close to optimal, but not optimal, so there is lot of ground for possible improvements with possibly new construction methods. In fact, the main disadvantage of our methods is that, for large $h$, the lengths of the known $b$-burst-correcting codes and $b$-burst-locator codes are very large.

Another question we didn’t discuss in this paper is constructions for cluster-correcting codes which correct a small cluster. This question was considered in [17]. The construction of $D$-dimensional cluster-correcting code which corrects a $D$-dimensional Lee sphere error with radius one is important in this connection. As we mentioned in subsection V-C, we don’t know the maximum number of $(2D + 1)$-burst-locator codes, among the $D$ component codes, that we can use.

The next question is how to implement the coloring method for correction of multidimensional Lee sphere errors with dimension greater than two and radius greater than two.

Finally, we still don’t know and even don’t have any indication what should be the excess redundancy of an optimum code which corrects an arbitrary multidimensional cluster-error. Even the two-dimensional case is far from being resolved.

The gap between the lower and upper bounds of Theorem 9 and Theorem 10, respectively, is quite large and we believe that both bounds can be improved.

ACKNOWLEDGMENT

The authors wish to thank Khaled Abdel-Ghaffar for providing [1]. They also thank Khaled Abdel-Ghaffar and Jack Wolf for helpful discussions.
