The idea that neutron stars (NSs) might be useful in determining the equation of state (EOS) of dense matter [1] precedes the discovery of the first NS in 1967 [2] by almost a decade. Until recently, the strongest observational constraints on the EOS came from NS mass measurements. These mass measurements all lay in a narrow range around 1.4 M⊙ [3] until the last decade, when NSs with masses near 2.0 M⊙ were discovered [4–8]. Measurements of NS radii, on the other hand, have been plagued with various systematic uncertainties [9]. The past decade has seen an increasing number of observations which constrain both the NS mass and radius with better-controlled systematic uncertainties, providing stronger EOS constraints. Quiescent low-mass X-ray binaries [10] (“QLMXBs”), NSs which exhibit photospheric radius expansion X-ray bursts [11] (“PREs”), and nearby isolated NSs [12, 13] all have been used to provide mass and radius measurements (see e.g. Refs. [14, 15] for recent reviews). Importantly, these measurements rely on data from various different instruments and connect the radius to the actual observables using different theoretical assumptions. These in turn all yield different underlying systematics. Finally, the recent observations of gravitational waves (GW) from binary NS mergers (GW170817 and GW190425) [16–18] by the LIGO Scientific- and Virgo collaborations (LVC) or X-ray observations of J0030+0451 by the NICER collaboration [19, 20] provide additional information on the EOS.

There are several recent works which analyze the data from GW170817 and/or GW190425 as well as NICER and its implication on the NS EOS [21–38], but very few (e.g., Ref. [31, 39]) directly combine the GW data with constraints on NS radii from QLMXBs and PREs. However, these additional observational sources add valuable information. Ref. [40] used QLMXBs and PREs observations to predict the NS tidal deformability which would be inferred from GW observations. They predicted the dimensionless tidal deformability of a 1.4 M⊙ NS, \( \Lambda_{M=1.4} \), was between 130 and 460 to 95% confidence. The recent analysis of GW 170817 [17] by the LVC found \( \Lambda_{M=1.4 \in [70,580]} \), to 90% confidence, matching the prediction to within errors.

In this letter, we present a Bayesian inference of the NS structure data, including both GW data as well as data from electromagnetic observation of QLMXBs and PREs, using less restrictive assumptions than made in previous works.

We build upon the method first described in Ref. [41, 42] (see also Ref. [43]), reviewed in Ref. [44], and detailed in the Supplemental Material. Ref. [45] first demonstrated that the choice of EOS parameterization has a significant impact on both the posterior mass-radius relation and the EOS, see also Ref. [46]. To estimate the impact of that choice, here as in Ref. [47], our prior distribution is built on two EOS parameterizations: (a) one which uses three polytropes (referred to as “3P”) and (b) one which uses four line segments in the space of pressure vs. energy density (referred to as “4L”). The latter parametrization has a stronger preference for strong phase transitions (regions where the pressure is nearly independent of the energy density).

At each point in our EOS parameter spaces, we solve

\[ \text{Equation} \]

\text{Result} 
\]
the Tolman-Oppenheimer-Volkov (TOV) equations [48, 49], compute the moment of inertia as a function of the central pressure, and use the Yagi-Yunes (YY) correlation [50] (as formulated in Ref. [51]) to compute the tidal deformability as a function of central pressure. This method of computing the tidal deformability is much faster than a direct computation, and while deviations from the exact result of up to 10% are possible [52, 53], the correlation is accurate to within a few percent for the typical EOS in our prior and posterior distributions. We construct the conditional probability for QLMXBs as in Ref. [47] and generalize it to include 3 PRE X-ray bursting sources [54, 55]. We also include the LIGO constraints on Λ from GW170817, using the SEOBNRv4T model for binary NS inspiral assuming low compact object spins [56]. GW observations are incorporated by tabulating and interpolating a marginal likelihood versus the masses for each object and the combined tidal deformability. Marginalization is performed via RIFT [57] over all extrinsic parameters and our fiducial low-spin prior assumptions. Finally, we also include mass and radius constraints on J0030+0451 from the NICER instrument [19, 20]. We reject all EOSs which are acausal or imply a maximum NS mass less than 2 M⊙. The mass cutoff does have a small uncertainty, but this uncertainty does not qualitatively impact our results. Also, we could have chosen to replace one of the high-density EOS parameters with $M_{\text{max}}$, but since neither the high-density part of the EOS nor the maximum mass is well-known, this prior choice is not necessarily better (or worse) than ours.

While it is often helpful to directly model systematic uncertainties, as was partially done in earlier works [47, 54, 55], these estimations require detailed models for the uncertainties which may not be perfect. Systematic uncertainties may result in intrinsic scattering (IS) which we model by convolving the probability distribution $D(R, M)$ for each star with a Gaussian kernel. This addition of an extra uncertainty to the observations allows us to quantify the possible level of systematic bias present in each measurement: the value of each IS parameter is expected to increase until the full dataset used in the inference is self-consistent. We emphasize that there is no reason to believe that a Gaussian is necessarily the correct distribution for additional unknown systematics, but we believe it is a reasonable first guess. The details of this procedure and the Markov Chain Monte Carlo (MCMC) method are given in the Supplemental Material.

We argue that neither of the two EOS parameterizations are more or less motivated by quantum chromodynamics (QCD), and thus we assign them equal prior probability. We present the posteriors for these two EOS parameterizations, 3P and 4L, separately to make the impact of a different EOS parameterization clear. We also present four different data sets: (i) GW170817 only (GW), (ii) GW170817+QLMXBs+PREs (GW, QLMXB, PRE), (iii) GW170817+QLMXBs+PREs+NICER (all), and (iv) GW170817+QLMXBs+PREs+NICER with an additional intrinsic scattering parameter added to each of the QLMXBs, PREs and NICER (all+IS). We thus performed 8 different sets of simulations.

Posterior for the radius of a 1.4 solar mass NS, $R_{1.4}$, are summarized in Figure 1. As might be expected, the limits for the GW data alone [(a) and (b)] are the least constraining. The 95% credible intervals are 11.3−13.9 km (3P) and 10.7−13.1 km (4L). Choosing a line segment-based EOS prior decreases the lower (upper) radius limit by 0.5 (1) km. The next four bar plots in the figure [(c) - (f)] show that the range shrinks significantly when adding the EM observations without IS. In addition, once the EM observations are added, these constraints are less sensitive to the EOS prior than the QLMXB observations alone [47]. Including the IS contribution [(g) and (h)] slightly broadens the constraints coming from the EM data.

Figure 2 shows the posterior distributions for the NS radius as a function of the gravitational mass. The shape of the M-R curve is more sensitive to the EOS prior than the radius of a 1.4 solar mass NS alone. The 4L EOS prior, because of the potential for phase transitions to modify the EOS at low densities, produces smaller radii for low-mass stars and larger radii for high-mass stars. This distinction may be particularly important in light of a possible 2.6 M⊙ NS in GW190814 [58–60].

Figure 3 shows the posteriors for the pressure as a function of the energy density. The combination of the EM and GW data strongly constrains the pressure until about 400-500 MeV/fm³. In order to more easily compare
the pressures between different models or data sets, Figure 4 shows an alternate version where, for each energy density, all 8 panels are rescaled and shifted by the same linear transformation which ensures that the 95% credible intervals for panel (a) lie exactly at 0 and 1. Thus, for panels (b) through (h), the orange dashed curves show the change in pressure of different models relative to that in panel (a). For reference, the energy density at nuclear saturation is $\epsilon_0 \approx 150 \text{ MeV/fm}^3$. The red dot-dashed curves show the probability that the central energy density of the maximum mass NS is smaller than the energy density from the x-axis. Most EOSs suggested by the data imply the central energy density is between about 900 and 1200 MeV/fm$^3$. In the 3P model, the EM data suggests a smaller pressure for small energy densities and almost unchanged at higher densities. In the 4L model, the effect is more dramatic: a smaller pressure at low densities is compensated for by an increase in the pressure at higher densities. For $\epsilon > 1200 \text{ MeV/fm}^3$, it is unlikely the data is strongly constraining the EOS, i.e. the EOS is strongly impacted by the prior distribution.

We compare our results to several other previous...
works in Table II. Our results on $R_{1.4}$ with the GW data alone are consistent with previous works which include only limited information from NS radius constraints [21, 23, 27–30, 37]. The variation in these results across the various references is consistent with our finding that these posterior distributions depend on the EOS prior distribution (as well as on the other details of the analysis).

Other works find, as we do, that the radius constraints are tighter when the EM data is included. Our results which include IS suggest (but do not definitively prove) that this result is not due to systematic uncertainties which are artificially constraining NS radii.

Gravitational wave observations have suggested other possible more indirect constraints on the EOS, and we summarize the impact of some of these constraints have on the radius of a $1.4 \, M_\odot$ NS in km with applied constraints on intrinsic scattering models.

| Model & constraints | $-2\sigma$ | $-1\sigma$ | med. | $+1\sigma$ | $+2\sigma$ |
