Magneto-transport of hard core bosons (HCB) is studied using an XXZ quantum spin model representation, appropriately gauged on the torus to allow for an external magnetic field. We find strong lattice effects near half filling. An effective quantum mechanical description of the vortex degrees of freedom is derived. Using semiclassical and numerical analysis we compute the vortex hopping energy \( t_V \), which at half filling is close to magnitude of the boson hopping energy. The critical quantum melting density of the vortex lattice is estimated at \( 6.5 \times 10^{-3} \) vortices per unit cell. The Hall conductance is computed from the Chern numbers of the low energy eigenstates. At zero temperature, it reverses sign abruptly at half filling. At precisely half filling, all eigenstates are doubly degenerate for any odd number of flux quanta. We prove the exact degeneracies on the torus by constructing an SU(2) algebra of point-group symmetries, associated with the center of vorticity. This result is interpreted as if each vortex carries an internal spin-half degree of freedom (‘vspin’), which can manifest itself as a charge density modulation in its core. Our findings suggest interesting experimental implications for vortex motion of cold atoms in optical lattices, and magnet-transport of short coherence length superconductors.

\section{I. INTRODUCTION}

Hard core bosons (HCB) are often used to describe superfluids and superconductors which are characterized by low superfluid stiffness and short coherence lengths. As such, HCB are relevant to cold atomic gases in optical lattices \cite{1, 2}, low capacitance Josephson junction arrays \cite{3–5}, disordered superconducting films \cite{6}, and cuprate superconductors \cite{7–13}.

At low densities, HCB can be treated by weak coupling (Bogoliubov) perturbation theory \cite{14}. Closer to half filling, lattice umklapp scattering and the hard core constraints become important. Recent calculations of the dynamical conductivity of HCB near half filling \cite{15} demonstrate the breakdown of weak-scattering Drude-Boltzmann transport theory in this regime. HCB exhibit so-called ‘bad metal’ phenomenology, (i.e. large resistivity, linearly increasing in temperature). Such behavior has been often observed in unconventional superconductors \cite{16}.

This paper also concerns dynamical correlations of HCB and their vortices near half filling. These will be exposed by including a weak orbital magnetic field in the Hamiltonian and studying the Hall effect.

Our primary results are as follows. Firstly, we apply a combination of semiclassical analysis and exact diagonalization to the gauged XXZ Hamiltonian on a finite lattice on the torus. We highlight the (sometimes overlooked) fact that a uniform magnetic field of one flux quantum penetrating the surface of the torus beaks translational symmetry. As a consequence, the semiclassical vortex center is subjected to a confining potential minimized at a well defined position. Fitting the low many-body spectrum to an effective single-vortex Hamiltonian, we determine the vortex hopping rate (effective mass).

Near half filling, the vortex mass is found to be similar in magnitude to the HCB mass. This allows us to estimate the critical field for quantum melting of the vortex solid (superfluid) phase at \( 6.5 \times 10^{-3} \) flux quanta per unit cell. Secondly, at half filling we find doublet degeneracies associated with an odd number of magnetic flux quanta penetrating the torus. We associate them with symmetries about the vortex position, and label the emergent degrees of freedom as ‘vortex spin’ (v-spin). Physically, these degrees of freedom correspond to the orientation of the charge density wave in the vortex cores.

Finally, we compute the Hall conductivity using thermally averaged Chern numbers. In stark contrast to continuum bosons, and to electrons in metallic bands, we find that the Hall conductivity of HCB reverses sign abruptly at half filling. The associated Hall temperature scale vanishes at half filling, signaling a possible quantum phase transition for the thermodynamic system in a magnetic field. Some of these results were briefly reported in a recent Letter \cite{17}.

This paper is organized as follows. In Section II the HCB Hamiltonian is introduced, with a discussion of its charge conjugation symmetry about half filling. Semi-classical approximations are derived in Section III, for the various regimes of filling. At low density, we recover the Gross-Pitaevskii theory with its Galilean invariant vortex dynamics and classical Hall effect. At half filling, the continuum limit corresponds to the anisotropic gauged non linear sigma model. Its vortices possess localized charge density waves in their cores. Section IV describes the mathematical peculiarities of the gauged torus, including translational symmetry breaking (elaborated in Appendix A). Definitions of null lines, null points and...
vorticity centers are provided. The point group symmetry generators $H_x^5$ and $H_y^6$ are constructed and their commutator is calculated. The proof of v-spin degeneracies at half filling is provided. Section V computes the vortex effective Hamiltonian by combining semiclassical and exact diagonalization calculations. The critical field for quantum melting of the vortex lattice is deduced from our value of vortex hopping rate. Section VII computes the Hall conductance on the torus as a function of density and temperature. We conclude in section VIII and discuss experimental implications of our results in cold atoms and cuprate superconductors.

II. HARD CORE BOSONS

The conventional Bose Hubbard model for interacting bosons is

$$\mathcal{H}_U = -2J \sum_{\langle ij \rangle} (e^{iqA_{ij}} a_i^\dagger a_j + a^{-iqA_{ij}} a_j^\dagger a_i) + 4V \sum_{\langle ij \rangle} (n_i - \frac{1}{2})(n_j - \frac{1}{2}) - \mu \sum_i n_i + \frac{1}{2}U \sum_i n_i(n_i - 1),$$

(1)

In the hard core limit $U \to \infty$, Eq. (1) reduces to the HCB Hamiltonian as $\mathcal{H} = \mathcal{P}\mathcal{H}_{U=0} \mathcal{P}$, where $\mathcal{P}$ is the projector onto the subspace where $n_i = 0$ or 1 for each site.

We use units where $\hbar = c = 1$. $\langle ij \rangle$ denotes a nearest neighbor link on the square lattice; the lattice constant is $a = 1$. $J$ is the Josephson coupling, $q$ is the boson charge and $A_{ij}$ the electromagnetic gauge field on a bond. $V$ is a nearest neighbor repulsive interaction. In the HBC limit, the chemical potential $\mu = 0$ corresponds to a density of half filling $\langle n \rangle = \frac{1}{2}$, with half a boson per site on average.

As is well-known, HCB operators obey an algebra corresponding to spin-$\frac{1}{2}$:

$$\hat{a}_i^\dagger = \mathcal{P} a_i^\dagger \mathcal{P} = S_i^+,$n_i = \hat{a}_i^\dagger \hat{a}_i = S_i^+ + \frac{1}{2}. $$

(2)

By $[S_i^+, S_j^-] = 2S_i^z \delta_{ij}$, HCB operators obey constrained commutation relations, $[\hat{a}_i, \hat{a}_j^\dagger] = (1 - 2n_i) \delta_{ij}$. The constraint effects of $-2n_i \delta_{ij}$ become important near half filling. $\lim_{U \to \infty} \mathcal{H}_U$ is thus represented by the gauged spin-half quantum $XXZ$ model,

$$\mathcal{H} = -2J \sum_{\langle ij \rangle} \left( e^{iqA_{ij}} S_i^x S_j^x + e^{-iqA_{ij}} S_i^y S_j^y \right) + 4V \sum_{\langle ij \rangle} S_i^x S_j^y - \mu \sum_i (S_i^z + \frac{1}{2}).$$

(3)

It is widely believed that the ground state of Eq. (4) exhibits magnetic order. In the regime of $V \ll J$, which is relevant to this paper, the ordered moment lies in the $XY$ plane, $\langle S_i^+ \rangle \neq 0$. That is to say, except for the limits $\mu = 0, 1$, the ground state of HCB exhibits long range superfluid order.

A. HCB charge conjugation symmetry

Another important distinction between the HCB Hamiltonian (4) and the finite $U$ Bose-Hubbard model of Eq. (1), is the emergence of charge conjugation symmetry in the infinite $U$ limit. One defines the unitary charge conjugation operator,

$$C \equiv \exp \left( i \pi \sum_i S_i^z \right).$$

(5)

$C$ transforms “particles” into “holes”, i.e. $C^\dagger \hat{n}_i C = 1 - \hat{n}_i$, and

$$C^\dagger H(qA, \mu) C = H(-qA, -\mu).$$

(6)

At half filling ($\mu = 0$), and $A = 0$, the Hamiltonian is invariant under charge conjugation on any lattice structure [18].

A consequence of (6) is that the Hall conductivity (which is linear in $q$) is antisymmetric in the deviation from half filling, i.e.

$$\sigma_{xy}(n, T) = -\sigma_{xy}(1-n, T).$$

(7)

In contrast, the superfluid stiffness $\rho_s(n)$ and longitudinal conductivity $\sigma_{xx}(n)$ are symmetric under $n \to (1-n)$.

In terms of vortex motion, (7) implies that below and above half filling vortices drift in opposite directions relative to the particle current.

III. SEMICLASSICAL THEORY

The partition function of HCB can be represented by the spin half coherent state path integral [19, 20],

$$Z = \int \mathcal{D} \hat{\Omega}(\tau) \exp \left( \int_0^\beta d\tau \left( iK - H^{cl} \right) \right),$$

(8)

where

$$K[\hat{\Omega}, \hat{\Omega}] = \frac{1}{2} \sum_i (1 - \cos \theta_i) \phi_i,$$

(9)

$$H^{cl}[\hat{\Omega}, A] = -J \sum_{\langle ij \rangle} \sin \theta_i \sin \theta_j \cos (\phi_i - \phi_j + qA_{ij}) + V \sum_{\langle ij \rangle} \cos \theta_i \cos \theta_j - \frac{U}{2} \sum_i \cos \theta_i.$$  

(10)
\( \hat{\Omega} = (\theta_i, \phi_i) \) are the polar angles on a sphere. The spin size \( S = \frac{1}{4} \) plays the role of the large parameter which controls the semiclassical expansion.

In the classical (saddle point) approximation, for \( A = 0 \), the ground state superfluid stiffness is

\[
\rho_s^{(1)} = q^2 \left. \frac{\partial^2 H^{(1)}}{\partial A^2_{r + \Delta t}} \right|_{A = 0} = J \langle \sin \theta \rangle = 4Jn(1 - n).
\]

which (in contrast to continuum bosons) exhibits a non-monotonic dependence on \( n \). At half filling (optimal density), \( \rho_s \) is maximized. Quantum corrections enhance \( \rho_s^{(1)}(n = \frac{1}{2}) \) further by about 7\% \([21, 22]\). The superfluid stiffness vanishes at the Berezinskii-Kosterlitz-Thouless (BKT) \([23]\) transition temperature, computed to be \( T_{BKT} \approx 1.41J \).

The kinetic term \( K \) of Eq. \( (8) \), determines the quantum dynamics. The harmonic spin-wave expansion of \( (10) \) yields a linearly dispersing phase fluctuations mode. The order parameter is suppressed to zero at all finite temperatures, in accordance with the Mermin-Wagner theorem.

### A. Low density, Gross-Pitaevskii limit

For large negative values of the chemical potential \( \mu \), the action in Eq. \( (10) \) can be expanded around the ferromagnetic (low density) state of \( \theta_i \approx \pi \),

\[
\cos \theta_i \rightarrow 2n_i - 1 \quad , \quad \sin \theta_i \approx 2\sqrt{n_i(n_i - 1)}.
\]

We define the continuous field

\[
\psi(x_i) = \sqrt{\frac{n_i}{a}} e^{i\phi_i},
\]

where \( a \) is the lattice constant, and replace the measure by

\[
\prod_i \mathcal{D} \cos \theta_i \mathcal{D} \phi_i \rightarrow \mathcal{D} \psi \mathcal{D} \psi \prod_i \Theta \left( 1 - \int d^2 x \, \psi^* \psi \right),
\]

up to an unnecessary normalization constant. The Heaviside functions enforce the hard core constraint \( n_i \leq 1 \) in the \( i^{th} \) unit cell at each time slice. In the low density limit, these constraints are ignored, and the action \( (10) \) is expanded to leading order in \( n_i \ll \frac{1}{2} \), and gradients \( \nabla \psi \).

This yields an effective Gross-Pitaevskii (GP) theory \([1]\),

\[
Z_{GP} = \int \mathcal{D} \psi^* \mathcal{D} \psi \exp \left( -S_{GP}[\psi^*, \psi, A] + \ldots \right)
\]

\[
S_{GP} = \int d^2x \int dt \left[ \psi^* (\partial_t - \mu) \psi \right.
\]

\[
+ \frac{1}{2m^*} \left[ (\pm \nabla - qA) \psi \right]^2 + g|\psi|^4 \right] \quad (15)
\]

where the effective mass and interaction parameters are given by

\[
m^* = \frac{1}{16J} \quad g = 16(J + V).
\]

In the presence of a magnetic field \( B\hat{z} \), a density of \( n_v = B/\phi_0 \) vortices is produced, where \( \phi_0 = 2\pi/q \) is the flux quantum. The core profile function \( f(r - R_j) \) near vortex \( j \) is well approximated by minimizing the GP energy, which yields \([1]\)

\[
f_{GP}(r) \approx \frac{\sqrt{n} r}{\sqrt{\xi^2 + r^2}},
\]

where \( \xi = 1/\sqrt{m^* n} \) is the coherence length. For \( n \ll \frac{1}{2} \), one has \( \xi \gg a \). The core density depletion is proportional to \( 1 - |f_{GP}|^2 \).

In the high density limit, \( n \rightarrow 1 \), the partition function can also be approximated by the same GP action \( (15) \) following a particle hole transformation \( (6) \). In this case, \(|\psi|^2 \) represents the density of holes.

By neglecting the higher order gradients, and the hard core constraints, the GP theory does not include lattice effects as it is completely Galilean invariant. Consider an externally induced uniform current density

\[
\mathbf{j} = qn \mathbf{v}_s.
\]

In the moving frame of velocity \( \mathbf{v}_s \) the vortices are stationary. Therefore, back in the lab frame, a purely transverse electromotive field is produced by the moving vortices,

\[
E = \frac{h}{q} \hat{z} \times \mathbf{j}_v
\]

\[
= \frac{h}{q} n_v \hat{z} \times \mathbf{V}_v
\]

\[
= \frac{h}{q^2} n_v \hat{z} \times \mathbf{j}.
\]

That is to say, in the pure GP theory, the longitudinal (dissipative) conductivity vanishes, and the Hall conductivity equals to the classical value,

\[
\sigma_{xx} = 0
\]

\[
\sigma_{xy} = \left( \frac{q^2}{h} \right) \left( \frac{n}{n_v} \right) = \frac{ne}{B}.
\]

Spoiling Galilean invariance by the presence of nonuniform potentials, boundary conditions, or by an underlying lattice can allow vortices to tunnel between different real space positions, resulting in a longitudinal conductivity \([24, 25]\).
B. Half filling, anisotropic $\sigma$-model

Toward half filling, lattice scattering modifies the vortex structure and dynamics. At half filling $\mu = 0$, the semiclassical theory of Eq. (10) is described by the anisotropic Non Linear $\sigma$-Model (NLSM) [26]. After a sublattice rotation $\prod_{i \in B} e^{iS_i^z}$ all the pseudo-spin interactions are antiferromagnetic. The spins $\hat{\Omega}_i$ are represented by

$$\hat{\Omega}_i = \eta_i \hat{n}(x_i) \sqrt{1 - (L(x_i)/S)^2} + L(x_i)/S ,$$

(21)

where $\eta_i = \pm 1$ on the A (+) and B (-) sublattices, respectively. The Néel vector $\hat{n}$ satisfies $\hat{n}^2 = 1$ and is orthogonal to the local magnetization $L$, i.e. $\hat{n} \cdot L = 0$.

The complex combination

$$n_\pm = n_x + in_y = |n_\pm| e^{i\phi},$$

(22)

defines the local superfluid order parameter, and $n_z$ corresponds to a bipartite charge density wave (CDW) with two possible signs. Following Refs. [19, 20, 26], we substitute Eq. (21) in the measure and action of (10), and expand them to quadratic order in $L$ and $\nabla \hat{n}$. Integrating out $L$ arrives at the anisotropic NLSM path integral,

$$Z_{NLSM} = \int \mathcal{D}\hat{n} e^{i\mathcal{Y}[\hat{n}]} e^{-S_E[\hat{n},A]} ,$$

(23)

where $S_E = \int_0^\beta d\tau \int d^2x \mathcal{L}_E$ is the Euclidean action, with

$$\mathcal{L}_E = \frac{1}{2} \chi_\perp |\hat{n}_\perp|^2 + \frac{1}{2} \chi_z \hat{n}_z^2$$

$$+ \frac{1}{2} \rho_s (|\nabla - i q A| n_\perp|^2 + \frac{1}{2} \rho_s^z |\nabla n_z|^2 + m_z^2 n_z^2 ,$$

and

$$\mathcal{Y} = S \sum_i \eta_i \int_0^\beta d\tau \left( 1 - n_z \right) \dot{\phi}_i ,$$

(25)

is the contribution from the geometric phase. The bare coupling constants are obtained directly from $H^{cl}$:

$$\chi_\perp = \frac{S^2}{2J} , \chi_z = \frac{S^2}{4(J + V)} ,$$

(26)

and

$$\rho_s = J , \rho_s^z = V , m_z^2 = 2(J - V) .$$

(27)

For $A = 0$, the isotropic (Heisenberg) limit is at $J = V, n_z = 0$. The Néel ground state implies degeneracy between superfluid and CDW order, and the existence of two massless Goldstone modes. At finite XY anisotropy, $m_z > 0$, and there is one massless (phase) mode, and a gapped CDW (roton) mode at the CDW ordering wavevector $(\pi, \pi)$.

Vortex configurations at half filling can be viewed as a localized meron (half skyrmion) of the Néel field. Since $|\hat{n}_{xy}| = 0$ at the vortex center, and $n_z^2 = 1 - |\hat{n}_{xy}|^2$, the semiclassical vortex has a CDW in its core, as illustrated in Fig. 1.

Due to the finite anisotropy ‘mass’ $m_z > 0$, $n_z(r)$ decays exponentially away from the center

$$n_{x}(r) = \sqrt{1 - n_z^2(r)} e^{i\phi(r)},$$

$$n_z(r) \sim e^{-r/\xi_z},$$

$$\xi_z = \sqrt{|\rho_s|/m_z} .$$

(28)

Indeed variational calculations have previously shown that at half filling CDW ordering is found in the localized vortex core [27]. In Section IV we shall show that the ‘orientation’ of the charge density wave is actually a continuous $SU(2)$ symmetry of the quantum Hamiltonian at half filling, which we name $v$-spin.

Since the system is charge conjugation symmetric at half-filling, there is no net charge depletion associated with the vortex core, and thus the statistical Berry phase for exchanging two vortices is zero. In other words, the vortices exhibit mutual Bose statistics. This is to be contrasted with GP vortices at low filling. As shown in (17), GP vortices involve a large density depletion (or accumulation, above half filling), which decays slowly away from their core [28].

In the limit where the number of lattice sites $N$ tends to infinity, the confining potential on the vortex vanishes, and the vortex energy is periodic on the lattice. Its minima lie in plaquette centers (i.e. at dual lattice sites).

When a vortex moves between dual lattice sites, the path dependent geometric phase $\mathcal{Y}$ yields $2\pi$ times the number of bosons enclosed by the path. At half filling, this amounts to an effective $\pi$ flux per dual plaquette. These phases can be incorporated in an effective hopping model by the dual lattice gauge field $A_{R,R+\mathbf{\eta}}$ along the link from site $R$ to $R + \mathbf{\eta}$. Thus for a single vortex on the infinite lattice, one can write an effective Harper

\[ FIG. 1: \text{Illustration of three static vortices with their v-spins. Arrows describe the v-spin directions, their z-component is the local charge density wave near the vortex core, illustrated as ripples in the surface. Current density is depicted by black field lines.} \]
A uniform magnetic field \( B \) is everywhere perpendicular to the surface, such that the total number of flux quanta penetrating the surface is \( N_\phi = NB/\phi_0 \), where \( \phi_0 = 2\pi/q \) is the flux quantum.

We construct a (piecewise differentiable) gauge field \( A(x) \) which interpolates the lattice gauge field on the surface of the torus, and obeys

\[
\hat{z} \cdot \nabla \times A = B, \quad \eta \cdot A(r + \mp \eta) = A_{r,r+\eta},
\]

where \( \eta = \pm \hat{x}, \pm \hat{y} \). \( A \) determines the magnetic fluxes which flow through vertical and horizontal circumferences of the torus. These are given by the gauge invariant Wilson loop functions,

\[
W_y(x) = q \oint dy A_y(x,y) \mod 2\pi, \\
W_x(y) = q \oint dx A_x(x,y) \mod 2\pi.
\]

The dimensionless AB parameters \( \Theta = (\Theta_x, \Theta_y) \) are defined by the Wilson loops at \( x = 0 \) and \( y = 0 \),

\[
\Theta_y = W_y(x = 0), \\
\Theta_x = W_x(y = 0).
\]

\( \Theta \) lives on the reciprocal torus \([0, 2\pi) \times [0, 2\pi)\).

\( W_y = 0 \), \( \alpha = x, y \) define the null lines on the torus. For \( N_\phi = 1 \), there is one null line in each direction \( x = X_0 \), \( y = Y_0 \), as depicted in Fig. 2. Their intersection is the null point \( R_\circ = (X_0, Y_0) \), which constitutes a gauge invariant symmetry point on the torus.

\[
X_0(\Theta) = -\frac{L_x \Theta_y}{2\pi}, \\
Y_0(\Theta) = \frac{L_y \Theta_x}{2\pi}.
\]

The existence of a special point \( R_\circ \) on the torus, demonstrates the unintuitive fact that a uniform magnetic field necessarily destroys lattice translational symmetry. This fact is closely related to the quantization of Dirac monopoles in three dimensions. We elaborate further on this fact in Appendix A. Eq. (34) shows that \( R_\circ(\Theta) \) can be moved continuously on the torus by changing the AB parameters \( \Theta \) [29, 30].

As we shall see in Sec. V, semiclassical analysis and exact diagonalizations find that the center of vorticity \( R_V \) is located at the antipodal position of the null point on the torus,

\[
R_V(\Theta) = (\frac{1}{2}L_x + X_0(\Theta), \frac{1}{2}L_y + Y_0(\Theta)).
\]

For larger magnetic fields, \( N_\phi > 1 \), there are \( N_\phi \) null lines in each of the \( x \) and \( y \) directions. This introduces a set of \( N_\phi^2 \) null points which form an evenly spaced square lattice (which may or may not coincide with the original lattice sites). These are indexed by \( m, n = 0, \ldots, N_\phi - 1 \)

\[
R^{mn}_\circ(\Theta) = R_\circ(\Theta) + \frac{1}{N_\phi}(mL_x, nL_y),
\]
Correspondingly there are $N^2_\Phi$ vorticity centers,

$$R^m_n(\Theta) = R^m_n(\Theta) + \frac{1}{2}(L_x, L_y). \quad (37)$$

### A. Choosing a gauge

The uniform magnetic field must integrate to an integer number of flux quanta $N_\Phi$,

$$B = \frac{2\pi N_\Phi}{q L_x L_y} \quad (38)$$

The gauge field is given by

$$A^x_{r,r+x} = - \text{mod} \ (y - Y_0, L_y) B L_x H(X_0, x)$$

$$A^y_{r,r+y} = \text{mod} \ (x - X_0, L_x) B \quad (39)$$

Note that for $0 < m < n$, $\text{mod} \ (-m, n) = n - m$. The function $H(X_0, x)$ ensures that $A^x_{r,r+x}$ vanishes unless $r$ is immediately to the left ($-\hat{x}$) of the null line $x = X_0$. It is defined by

$$H(X_0, x) = \begin{cases} 1 & 0 < \text{mod} \ (X_0 - x, L_x) \leq 1 \\ 0 & \text{otherwise}. \end{cases} \quad (40)$$

For a continuous position $r$ we define $A^a(r)$ to be the linearly interpolated gauge field between the two enclosing links in the $a$ direction.

For $\Theta = (0, 0)$ the null point $R_0$ is at $R_0 = (0, 0)$, and the vorticity center is therefore at $R_\chi = (\frac{1}{2}L_x, \frac{1}{2}L_y)$.

Our gauge choice is shown in Fig. 3. The gauge invariant content of $A$ consists of the uniform magnetic field with flux $B = N_\Phi \Theta_0 / L_x L_y$ in each plaquette, and the two Wilson loop functions

$$W_y(x) = xqB + \Theta_y,$$

$$W_x(y) = -yqB + \Theta_x. \quad (41)$$

### B. V-spin degeneracies

In the process of calculating the Hall conductance (see Section VII), we computed the spectrum at half filling, for an even number of sites, with one total flux quantum of magnetic field. We encountered a sequence of AB fluxes $\Theta_i$, where the whole spectrum becomes two-fold degenerate. These degeneracy points are demonstrated in Fig. 4 for $N_\Phi = 1$, for the lowest two multiplets. The level crossings indicate the existence of a non-commuting symmetry generators [31], which act on the wavefunctions of vortices introduced by the external magnetic field. We now construct these symmetry operators and compute their commutation relations.

As discussed earlier, for a finite magnetic field ($N_\Phi > 0$), $\mathcal{H}$ does not possess the lattice translational symmetry. Nevertheless, with respect to the vorticity center $R_\chi(\Theta)$ we can define two reflection operators

$$P^0_y(x, y) = (\text{mod} \ (2X_\chi - x, L_x), y),$$

$$P^0_y(x, y) = (x, \text{mod} \ (2Y_\chi - y, L_y)) \quad (42)$$

which by (35) are equivalent to reflections about $R_0$.

Now, by appropriately tuning $\Theta$ using Eq. (34), the vorticity center $R_\chi$ can be chosen to coincide with a symmetry point of the square lattice, such as any lattice site.
FIG. 5: Figuring out \(N_{\text{null}}\) for two cases of even size lattices. The parity of the number of lattice sites (black dots) which lie precisely on the null lines (red color online), determines the commutation rule of \(\Pi^\alpha\) and \(\Pi_\alpha\), according to Eq. (53). The two examples explain why \(N_{\text{null}}\) is odd whenever the vorticity center \(R_0\) is positioned precisely on a lattice site.

The gauge invariant content of \(\tilde{\Delta}^\alpha\) describes an inverted uniform magnetic field \(\tilde{B} = -B\), and a reversed sign of the Wilson loop functions (32).

The reversal of the fields in \(\tilde{\Delta}\) can be undone, at half filling, by applying the charge conjugation transformation \(C\) (5), and a pure gauge transformation \(U^\alpha\). Thus, we construct two operators,

\[
\Pi^\alpha = U^z \, C \, P^\alpha, \\
\Pi_\alpha = U^y \, C \, P^\alpha
\]

where,

\[
U^\alpha = \exp \left( i \sum_r \chi^\alpha (r) \, S^z_R \right),
\]

and

\[
\chi^\alpha (r) = \int_{R_0}^{r} \, d r' \cdot \left( A (r') + \tilde{A}^\alpha (r') \right).
\]

In the line integral we use the interpolated gauge field defined after Eq. (39). Since \(A\) and \(-\tilde{A}^\alpha\) describe the same magnetic fields, they obey,

\[
\nabla \times (A + \tilde{A}^\alpha) = 0.
\]

This implies that \(\chi^\alpha\) is independent of which continuous path (of zero winding number) is chosen between \(R_0\) and \(r\).

It is easy to verify by this construction that for all \(\Theta_i\), such that \(R_0(\Theta_i)\) is a symmetry point the \(\Pi^\alpha\) operators become symmetries of the Hamiltonian:

\[
[\mathcal{H}[A], \Pi^\alpha] = 0, \quad \alpha = x, y.
\]

Now we calculate the commutation relation between \(\Pi_\alpha\) and \(\Pi^\alpha\). This is a straightforward but slightly tedious procedure. Using the gauge choice (39), and (46),

\[
\chi^x (r) = \frac{2 \pi N_\phi}{L_y} \text{mod} (y - Y_0, L_y) \left( 1 - \delta_x, X_0 \right), \\
\chi^y (r) = 0.
\]

Note that \(\chi^y\) vanishes on the null lines. Multiplying the two \(\Pi^\alpha\) operators yields

\[
\Pi_\alpha \Pi^\alpha = \exp \left( i \sum_r \left( \chi^y (P^\alpha [r]) - \chi^y (P^\alpha [r]) \right) \right) P^\alpha \, P^\alpha,
\]

\[
\Pi_\alpha \Pi^\alpha' = \exp \left( i \sum_r \left( \chi^y (P^\alpha [r]) - \chi^y (P^\alpha [r]) \right) \right) P^\alpha \, P^\alpha'
\]

where we have used \([P^\alpha, P^\alpha'] = 0\). The overall phase is given by the operator

\[
\Upsilon = \sum_r \omega_r \, S^z_r,
\]

\[
\omega_r = \chi^x + \chi^y (P^\alpha [r]) - \chi^y - \chi^y (P^\alpha [r]).
\]

It can be directly verified from (49) that

\[
\omega_r = \begin{cases} 
0 & \text{if } r \in \text{null lines} \\
2 \pi N_\phi & \text{otherwise.}
\end{cases}
\]

Since \(\exp (i 2 \pi m S^z_r) = (-1)^m\),

\[
e^{-i \Upsilon} = (-1)^{N_\phi (N - N_{\text{null}})} = (-1)^{N_\phi N_{\text{null}}}.
\]

where \(N_{\text{null}}\) is the number of sites which sit precisely on the two null lines. For even \(N_\phi\), \(e^{i \Upsilon} = 1\) and \([\Pi_\alpha, \Pi^\alpha] = 0\).

For odd \(N_\phi\), and odd \(N_{\text{null}}\), one obtains \(e^{-i \Upsilon} = -1\). Let us prove a simple lemma concerning the parity of \(N_{\text{null}}\).

**Lemma:** For even size lattices, if \(R_0\) is tuned to be precisely on a lattice site, then \(N_{\text{null}}\) is odd. The proof is illustrated in Fig. 5.

**Proof:** Since we assume that \(N\) is even (to describe precise half filling), there are two cases to consider:

(i) For an even by even lattice, \(L = (2m, 2n)\), if we choose \(R_0\) on a lattice site, it is easy to see that \(R_0\) must also sit on a lattice site. The number of sites which contribute to \(N_{\text{null}}\) are the sum of lattice sites in the \(x\) and \(y\) directions minus the null point itself which is counted twice:

\[
N_{\text{null}} = 2m + 2n - 1.
\]
Hence \( e^{i\tau} = -1 \).

(ii) For the odd by even lattice, e.g. \( L = (2m + 1, 2n) \), we choose \( R_y \) to be in the middle of a bond in the \( x \) direction. The null line includes only the sites on the \( x \)-null line which is odd:

\[
N^\text{null} = 2m + 1
\]  

(55)

Thus, here too \( e^{-i\tau} = -1 \). Note that in both (54,55), the vorticity center is situated on lattice sites \( R_y = (m, n) \).

QED.

Thus we conclude that for an odd number of fluxes \( N_\alpha = 2n + 1 \), if \( R_y(\Theta) \) is located precisely on any lattice site, then \( \Pi^x \) and \( \Pi^y \) anticommute.

Under these conditions, all states of \( \mathcal{H}[\Theta] \) must be at least two-fold degenerate. This follows the standard proof: Since

\[
[\mathcal{H}, \Pi^x] = 0,
\]  

(56)

and \( \Pi^x \) has eigenvalues \( \pm 1 \), then each common eigenstate of \( \mathcal{H} \) and \( \Pi^x \), can be labelled by \( |E_n, \pi^z = \pm 1 \rangle \). Now,

\[
\Pi^x \Pi^y |E_n, 1 \rangle = -\Pi^y \Pi^x |E_n, 1 \rangle \propto |E_n, -1 \rangle,
\]

(57)

that is to say each eigenenergy \( E_n \) is associated with a degenerate pair of eigenstates with opposite quantum numbers of \( \Pi^y \).

\( \Pi^x \) and \( \Pi^y \) are point group symmetries about the vorticity center. We can also construct a third symmetry operator \( \Pi^z \) as

\[
\Pi^z = -i \Pi^x \Pi^y.
\]

(58)

The three operators \( \Pi^x, \Pi^y, \Pi^z \) are unitary and Hermitian,

\[
\Pi^\dagger = (\Pi^\dagger)^{-1} = (\Pi^\dagger)^2 = 1.
\]

(59)

Therefore their eigenvalues are \( \pm 1 \). The \( \Pi \) operators behave as Pauli matrices and can be used to construct an SU(2) algebra of spin half,

\[
\tau^z = \frac{1}{2} \Pi^z, \quad \alpha = x, y, z.
\]

(60)

We note that for multiple number of magnetic fluxes \( N_\alpha > 1 \), degeneracies appear for any odd number of vortices. This is consistent with the Kramers doublets associated with an odd number of interacting spin half particles.

C. V-spin and meron density

The semiclassical analysis of HCB vortices at half filling, shown in Eq. (28) finds that the vortex has a CDW in its core. This is signalled by the local order parameter \( \langle n^z(r) \rangle \neq 0 \), as illustrated in Fig. 1.

We define the modified ‘meron density’ operator as

\[
\tau^z(r) = \hat{n} \cdot D_\alpha \hat{n} \times D_\beta \hat{n},
\]

\[
D_\alpha = \partial_\alpha - iqA_\alpha,
\]

(61)

where \( \hat{n} \) were defined in (21) and \( D_\alpha \) are gauge invariant derivatives in the \( xy \) plane. In the absence of a gauge field \( A = 0 \), a single meron (half a skyrmion) of a continuos classical field has topological charge

\[
Q = \frac{1}{4\pi} \int d^2r \tau^z(r, \mathbf{A} = 0) = \pm \frac{1}{2}.
\]

(62)

A HCB representation of \( \tau^z \) is constructed spin-half operators. In the presence of one flux quantum, we define the modified topological charge operator as

\[
\hat{Q} = \frac{1}{4\pi} \sum_r \tau^z_r(\mathbf{A}).
\]

(63)

\( \hat{Q} \) is not expected to be quantized at \( \pm \frac{1}{2} \). However, we have found that in the low lying eigenstates of (4), its sign correlates with the eigenvalues of \( \Pi^z \):

\[
\text{sign} \left( \left( E_n, \pi^z \right| Q | E_n, \pi^z \right) \right) = \pi^z.
\]

(64)

We conclude that \( \pi^z \) of a single vortex measures the sign of the CDW in its core, with respect to sublattice \( A \).

V. THE HAMILTONIAN OF QUANTUM VORTICES

A. Vortex confining potential

The current density operator is given in the pseudospin representation by

\[
j_{\eta}(r) = -2iJq \left( e^{iqAr \cdot \eta} S^+_{r+\eta} S^-_{r-\eta} - \text{H.c.} \right).
\]

(65)

By choosing \( A \) to describe one flux quantum of uniform magnetic field through the whole lattice one vortex is introduced into the low energy eigenstates. Indeed, we verified that the exact ground state exhibits a vortex pattern of the current density \( j_{\eta} \), defined in (65). Also, the center of vorticity is agrees with the value of \( R_y(\Theta) \) as defined in Eqs. (34,35).

We determine the effective confining potential on the vortex variationally. We choose the square geometry \( L^2 = N \), and define a vortex coherent state centered at \( R \) by a spin coherent state \( |R_y(R)\rangle \). All the unit vectors \( \hat{R}_y \) lie in the \( xy \) plane with the azimuthal angles \( \phi_r \) given by a Jacobi theta function [32]:

\[
\phi_r(R) = -\text{Im} \log \theta \left( \left( i(z - Z) - \frac{1}{2} - \frac{r}{2} \right) \right)
\]

\[
+ \pi \left( y - \left( \frac{1}{2} - Y \right) x \right)
\]

(66)

\[
\theta(z) = \sum_{n=\infty} e^{-\pi n^2} e^{2\pi inz}.
\]

(67)

Here we use scaled complex coordinates \( z = (x + iy)/L \) and \( Z = (X + iY)/L \) for the position and vortex center \( r \) and \( R \), respectively.
FIG. 6: A variational vortex configuration with its center located at $\mathbf{R} = (0.5, 0.6)L$. The black dots mark the center of vorticity $\mathbf{R}_V$, where the variational energy is minimized. a) Phase field marked by directions of the arrows. b) Current density distribution where the colors correspond to the local current magnitude. Note the excess currents flowing around the torus in the negative $x$ direction: a consequence of the vortex being displaced from variational minimum.

FIG. 7: The energy as a function of vortex position, for a single vortex on the torus of dimensions $L \times L$. The vorticity center is located at $\mathbf{R}_V = \frac{1}{2}L$.

While $\phi_r$ is discontinuous on the torus at $x, y = L$, the gauge invariant current density

$$
(\hat{\Omega}_V | j_{n\eta} \hat{\Omega}_V) = qJ \sin (\phi_r - \phi_{r+\eta} - A_{r,r+\eta}),
$$

is continuous. An example for the phase and current distributions is given in Fig. V A.

The effective confining potential on the vortex is given by the classical energy defined in (10). By semiclassical estimates [33], its curvature at $\mathbf{R}_V$ scales as $1/N$. For lattices of size $L \geq 4$ we fit the variational potential by a two dimensional quadratic function, which scales as $1/N$ as,

$$
U_N = \frac{1}{2}K|\mathbf{R} - \mathbf{R}_V|^2 / N, \quad K = 39.2J.
$$

$U$ is minimized at the vorticity center $\mathbf{R}_V$, which was defined in (35). Fig. 7 depicts the confining potential as a function of vortex center for the choice of $\Theta = (0, 0)$.

FIG. 8: Fitting the single vortex energies of the effective Harper Hamiltonian (70), to the many-body spectrum of HCB (4). The HCB Hamiltonian is defined on a $4 \times 4$ lattice at half filling, which is embedded on a torus which is penetrated by one flux quantum. The parameters $J = 1$, and $V = 0$ are chosen for this figure. Up and down arrows denote the v-spin magnetic quantum number $\tau^z$. The confining potential of the vortex in the Harper Hamiltonian is calculated by a variational calculation, Eq. (69). The effective vortex hopping rate is fit to be $t_V = 4J$. The lowest three doublets of the two models agree within 2% of the first energy gap.

We can now combine the single vortex hopping terms of Eq. (29) with the confining potential to obtain the Harper hamiltonian on the finite torus

$$
H_N^V = -\frac{1}{2} \sum_{\mathbf{R}, \eta} \left( e^{iA_{\mathbf{R}, \mathbf{R}+\eta}} b^\dagger_{\mathbf{R}+\eta} b_{\mathbf{R}} + \text{H.c.} \right) + U_N(\mathbf{R}) b^\dagger_{\mathbf{R}+\eta} b_{\mathbf{R}}.
$$

B. Vortex hopping Amplitude

For a quantitative quantum theory of vortices we need to evaluate the effective hopping $t_V$. Since vortex tunneling between lattice sites depends on short range many-body correlations, we extract $t_V$ from exact numerical diagonalizations of $\mathcal{H}$ on 16 – 20 sites clusters, in the presence of a single flux quantum.

By tuning $t_V$, we fit the lowest three eigenenergies $E_n$ of $\mathcal{H}$ to those of the effective Harper Hamiltonian (70). The fit is shown in Fig. 8.

Our primary concern is that the low eigenstates will not be exclusively described by $H_N^V$, since there are also
low energy superfluid phonons (phase fluctuations) [34–37]. However, we can estimate the phonons lowest excitation to be gapped by the finite lattice with the energy scale $2\pi J/L$, which is larger than the energies we have fitted to (70).

Our results for $t_V(n_b, V/J)$, for $N = 20$ can be described by the fitting formulas,

$$t_V(n, 0) = 4J - 50.4J(n - \frac{1}{2})^2 + 5056J(n - \frac{1}{2})^4,$$

$$t_V(\frac{1}{2}, V) = 4J + 6V + 10.8 \frac{V^2}{J}.$$  

(71)

The system parameters were varied throughout the range $|n - \frac{1}{2}| \leq 0.2$, and $V/J < 0.5$. We find that at half filling, the vortex hopping rate $t_V$ varies very little between the $N = 16$ and $N = 20$ lattices. This indicates that the bare vortex kinetic energy is determined by short range correlations, and thus does not require a large lattice to be computed with acceptable accuracy.

To further test the association of the many body lowest eigenstates with vortex center fluctuations, we measure the vorticity density defined on the dual lattice,

$$\rho^{(n)}(\mathbf{R}) \equiv \sum_{r, \eta} \langle \Psi^{(n)} | \mathbf{j}_r \cdot \eta \rangle | \Psi^{(n)} \rangle,$$

(72)

for each of the low lying states $| \Psi^{(n)} \rangle$. We compare $\rho^{(n)}$ to the single particle probability density of the corresponding wavefunctions of $H^c_N$. As shown in Fig. 9, for the fitted value of $t_V$, the corresponding distributions increase in width in a qualitatively similar fashion. This demonstrates that the low lying eigenstates of $\mathcal{H}$ correspond to quantum fluctuations of the vortex position.

VI. QUANTUM MELTING OF THE VORTEX LATTICE

At half filling, for $N_\phi > 1$ semiclassical evaluation of vortex interactions at distances larger than the core radius is

$$U^{\text{int}}_{ij} = -\pi J \log(|\mathbf{R}_i - \mathbf{R}_j|).$$  

(73)

Integrating out the phonon fluctuations, produces an instantaneous logarithmic (2D Coloumb) interaction between vortices, plus retarded (frequency-dependent) interactions [35, 36]. Since we are interested in the short wavelength fluctuations which are responsible for quantum melting of the vortex lattice, we ignore these retardation effects.

Thus in the large lattice limit, at a finite magnetic field $B$, the multi-vortex quantum Hamiltonian is given by the Harper boson plasma (HBP)

$$H_{\text{HBP}} = -\frac{1}{2} t_V \sum_{\langle \langle ij \rangle \rangle} \left( e^{iA_{ij}} b_i^\dagger b_j + \text{H.c.} \right)$$

$$-\pi J \sum_{i,j} n_i n_j \log(|\mathbf{R}_i - \mathbf{R}_j|)$$

$$+ \pi^2 J B \Phi_0 \sum_i n_i |\mathbf{R}_i|^2.$$  

(74)

At half filling the continuum limit of (75) can be taken as follows. The single vortex dispersion exhibits a two-fold degeneracy of the ground states of the Harper Hamiltonian at $\pi$ flux per plaquette. This implies the degeneracy $E_k = E_{k+(0, \pi)}$, at low $|k| << \pi$. Since we wish to expand the hamiltonian at long wavelength, we retain the degeneracy by the $v$-spin label $s = \uparrow, \downarrow$. The vortex effective mass is defined as

$$M_v = \left( \frac{\partial^2 E_k}{\partial k^2} \right)^{-1} = 1/t_V.$$  

(75)

This leads to the continuum spin-half Coulomb Bosons (CB) Hamiltonian for the vortices as half filling:

$$\mathcal{H}_{\text{CB}} = \sum_{i,s = \uparrow, \downarrow} \frac{P_i^2}{2M_v} + \pi J \sum_{i \neq j} \log(|\mathbf{R}_i - \mathbf{R}_j|)$$

$$- \frac{B}{\Phi_0} \pi^2 J \sum_i |\mathbf{R}_i|^2.$$  

(76)

At low vortex densities, interactions clearly must dominate over the kinetic energy, and vortices form a vortex lattice. This a superfluid phase with $v$-spin correlations. At a finite temperature $T_m$, if we ignore the quantum effects of the kinetic term, the classical melting temperature $T_m$ is independent of vortex density (magnetic
where a be studied by Magro and Ceperley (MC) [40] by diffusion.

Quantum melting is reached at a critical vortex density \(B\) / Eq. (76), increase with the vortex density variant). Since the continuum approximation is expected to fail near half filling, we resort to a numerical computation of corrections relative to the particle current. In the following we shall study the transition between these two regimes. In terms of vortex motion, this relation implies that below and above half filling vortices drift in opposite directions relative to the particle current. In the following we shall study the transition between these two regimes. Since the continuum approximation is expected to fail near half filling, we resort to a numerical computation of \(\sigma_{xy}\).

MC used the dimensionless parameter to describe the CB density \(n_v\),

\[
\sigma_{xy}^2 = \pi n_v a_0^2, \tag{77}
\]

where \(a_0\) is the Bohr radius. We set the Bohr radius to be

\[
a_0 = \left( \frac{\hbar^2}{\pi J M_V} \right)^{1/2} \tag{78}
\]

to match between the model of MC and our \(\mathcal{H}_{CB}\) of Eq. (76).

MC found that below \(r_s \approx 12\) the boson lattice undergoes quantum melting, i.e. they found the critical quantum melting density of

\[
n_{cr}^V = \frac{1}{144\pi a_0^2}, \tag{79}
\]

Above this density, the CB looses translationally symmetry breaking and becomes a quantum liquid, which will be discussed in Section VIII. Using our values of \(M_v\) from Eqs. (71,75), this translates into a critical vortex number per lattice site of of

\[
n_{cr}^V \leq \left( 6.5 - 7.9 \frac{V}{J} \right) \times 10^{-3} \text{ vortices per site.} \tag{80}
\]

This is a suprisingly low vortex density, above which a vortex quantum liquid (QVL) is created.

**VII. HALL CONDUCTIVITY**

We have shown earlier by Eqs. (20 , 7) that the Hall conductivity in the low and high density obey the effective Galilean invariant limits,

\[
\sigma_{xy} = \left\{ \begin{array}{ll}
\frac{ne}{2\pi^2} & \text{if } n \ll \frac{1}{2} \\
\frac{e}{2\pi^2 (1-n)q} & \text{if } 1 - n \ll \frac{1}{2}
\end{array} \right. \tag{81}
\]

In terms of vortex motion, this relation implies that below and above half filling vortices drift in opposite directions relative to the particle current. In the following we shall study the transition between these two regimes. Since the continuum approximation is expected to fail near half filling, we resort to a numerical computation of \(\sigma_{xy}\).

The zero temperature Hall conductance of a finite lattice embedded on a torus is defined by the Chern number [41]:

\[
\sigma_{xy}(N) = \frac{q^2}{\hbar^2} \frac{2\pi}{\partial \Theta_y} \int_0^{2\pi} d\Theta_x \text{Im} \langle \frac{\partial \Psi_0}{\partial \Theta_y} \rangle, \tag{82}
\]

where \(|\Psi_0(\Theta)\rangle\) is the exact ground state of (4), in the presence of AB fluxes \(\Theta\). \(q^2/\hbar^2\) is the quantum of conductance. In the absence of degeneracies and level crossings, the Chern number \(\sigma_{xy}(N)h/q^2\) is an integer. We compute Eq. (82) for a sequence of finite lattices. In Figure 10 we plot \(\sigma_{xy}(N)\) for a square lattice of size 4 x 4 with a single flux quantum \(N_b = 1\), as function of boson numbers \(N_b = [0, 1, 1, 16]\). We find that the Hall conductance follows two straight lines as given by Eq. (81), with an abrupt jump to zero at half filling. The same behavior was found for all smaller lattices, and reflects a sharp change in vortex dynamics around half filling.

We extend Eq. (82) to finite temperatures by thermally averaging over all eigenstates \(|\Psi_n\rangle\),

\[
\sigma_{xy}(T) = \frac{q^2}{\hbar^2} \sum_{n=0}^{\infty} \int_0^{2\pi} d\Theta_x \int_0^{2\pi} d\Theta_y e^{-E_n/T} \times \text{Im} \langle \frac{\partial \Psi_n}{\partial \Theta_x} \rangle \langle \frac{\partial \Psi_n}{\partial \Theta_y} \rangle. \tag{83}
\]

\(E_n(\Theta)\) and \(|\Psi_n(\Theta)\rangle\) are the exact spectrum and eigenstates of (4). The results obtained with Eq. (83) are matched at high temperatures with the the conductivity calculated using the Lehmann representation of the...
FIG. 11: $\sigma_{xy}$ of hard core bosons, as a function of temperature (in units of $t_V$), for 4 to 7 bosons on a $4 \times 4$ lattice. For low temperatures, we calculate $\sigma_{xy}$ using Eq. (83), while for $T > 1$ we use Eq. (84). The dashed line is an interpolation between the two calculations. The points where $\sigma_{xy}$ drops to half its value at $T = 0$ are indicated. The inset shows the temperature scale $T_H$ as a function of density difference from half filling.

Kubo formula [42],
$$\sigma_{xy}(T) = \lim_{\omega \to 0^+} \frac{i}{NZ\omega} \sum_{m,n} e^{-\beta E_m - \beta E_n} e^{\beta E_n - \beta E_m + \omega} \times \langle \Psi_n | \sum_r j_x(r) \Psi_m \rangle \langle \Psi_m | \sum_r j_y(r') \Psi_n \rangle,$$

where the current operator $j_n$ is defined by (65).

The Kubo expression for $\sigma_{xy}$ is evaluated at high enough temperatures where the $\omega \to 0$ limit is well behaved. In Figure 11 we plot $\sigma_{xy}$ as a function of temperature at different HCB densities, by interpolating between Eq. (83) at low temperatures and Eq. (84) at high temperatures.

We see that in general, the magnitude of $\sigma_{xy}(T, n_b)$ decreases with temperature, and the discontinuity as a function of filling at zero temperature smoothens at finite temperatures. As the temperature is lowered, the reversal of the Hall conductance takes place in a narrower region around half filling. A characteristic Hall temperature $T_H(n_b)$ can be defined by,
$$\sigma_{xy}(T_H) = \frac{1}{2} \sigma_{xy}(0).$$

In the inset of Fig. 10, we show that $T_H$ increases with $|n_b - \frac{1}{2}|$, although we cannot estimate the critical exponent from the small cluster calculation.

FIG. 12: Different vortex drift directions (purple arrows) in the presence of a bias current (red arrows), for regions of boson density $n$ which is lower (blue online) and higher (green online) than half filling.

VIII. DISCUSSION AND EXPERIMENTS

In this paper, we have determined the vortex effective hopping rate $t_V$, in Eq. (71), and the Hall conductivity $\sigma_{xy}$, in Fig. 10 from the eigenstates of 16 site clusters on the torus. We emphasize that these quantities serve only as short wavelength "bare parameters", to be used in the single vortex Harper Hamiltonian Eq. (75) and the multi-vortex Bose Coulomb liquid model (75). The charge transport coefficients depend on the thermodynamic phases of the latter model.

**Vortex Solid** – The vortex solid phase, expected for vortex densities lower than $n_{cr}^v$ of Eq. (80), has superfluid (i.e. superconducting) order. Vortices are pinned to their lattice positions and therefore $\sigma_{xx} = \infty$ and $\sigma_{xy} = 0$. The role of $t_V$ is to produce quantum zero point motion and effective v-spin super-exchange interactions, which are ferromagnetic (since vortices have Bose statistics). Below the v-spin ordering temperature $T_{v\text{spin}}$, charge density waves might be expected with significant magnitude in the vortex cores. This phase is a weak supersolid. Incidentally, density modulations have been observed near vortex cores of High Tc cuprate superconductors [43] and analyzed within bosonic models [44, 45].

At low vortex density, the superexchange interactions decay rapidly, which reduces $T_{v\text{spin}}$. For $T > T_{v\text{spin}}$ the v-spins will contribute an extra entropy density given by
$$S_{v\text{spin}} = \frac{B}{\Phi_0} \log 2.$$  \hfill (86)

**Quantum Vortex Liquid** – At vortex densities which exceed $6.5 \times 10^{-3}$ vortices per lattice site, we expect the vortex lattice to melt and give way to the Boson Coulomb Liquid studied by MC [40]. Superfluidity of the CB translates into a Mott insulating behavior of the original bosons [34]. However, MC have found that the liquid phase Eq.(76) is incompressible and hence exhibits vanishing condensate fraction [46]. Furthermore, retardation effects act to suppress dual superfluidity [47]. The value
of the transport coefficients of the QVL phase is therefore left as an important open question. Away from half filling, our results for $\sigma_{xy}$ show that the vortices are subject to a strong magnetic field, which further suppresses their condensation. At low boson fillings and large vortex density, $n_b/n_\phi < 1$, there is evidence for fractional quantum hall phases [48, 49].

The QVL phase discussed above is distinct from the vortex-antivortex condensate (VC) phases which were predicted at rational boson filling fractions, $n_b = p/q$, in the absence of a magnetic field [45, 50–52]. These are expected at strong longer range interactions $V \approx J$, and corresponds to Mott-insulating commensurate CDW phases.

**Hall coefficient** – The abrupt reversal of Hall coefficient was found for 16 and 20 site lattices. This effect correlates with the rapid change in the semiclassical vortex core profile at half filling, since we know by the GP equation (17) that vortices have a diverging density depletion (accumulation) in the low and (high) filling regime, while they have a localized charge density wave in their small core at half filling. The sign of $\sigma_{xy}$ determines the drift direction of a vortex with respect to a bias current. This rapid reversal of $\sigma_{xy}$ may be relevant to the rapid change in Hall resistivity as a function of doping, which was observed in ($\text{La}_{1-x}\text{Sr}_x$)$_2\text{CuO}_4$ [53, 54].

In Fig. 12 we propose a set-up to observe the Magnus action reversal for cold bosonic atoms on a rotating optical trap [55]. If the density of bosons is allowed to vary slowly in space across half filling, we expect a rapid change of the vortex drift directions at the half filling line. The vortices would drift downstream with the boson current for $n < \frac{1}{4}$ and upstream for $n > \frac{1}{4}$.

**Soft core interactions** – We have not considered relaxing the hard core constraints of the bosons, which would be described by the Bose Hubbard model (1). For $U/J < \infty$, the charge conjugation operator ceases to be an exact symmetry at half filling, and Eq. (6) is not valid. Therefore the Hall coefficient will not be precisely zero at half filling, and the v-spin degeneracies will be lifted by the finite $U/J$ corrections. A full determination of the Hall conductivity in the $U/J$ versus $n$ phase diagram, is an interesting open question. In particular, one would like to find out how the zeros of the Hall conductivity connect between the HCB limit and the free bosons limit.

FIG. 14: The radial component of the magnetic field in the plane \( y = 0 \), containing the ring \( N = 20 \) monopoles and \( N = 19 \) anti-monopoles on the line \( y = 0 \), as shown in Fig. 13, as a function of the azimuthal coordinate \( x \). The oscillations magnitude decays as a function of \( N \) leading to a uniform radial field.

The magnetic field of \( N_\phi = 1 \) enters the torus and must end in a magnetic charge. By Dirac quantization [56], \( \) ‘magnetic charge’ density must be quantized as \( \rho_m = g_m \delta(r - r_m) \) where,

\[
g_{\text{mon}} = 1/(2q). \tag{A2}
\]

Therefore the physical reason for the TSB is the point-like discreteness of the magnetic charge. Consider an embedding of the torus in three dimensions. Dirac quantization forces one to choose a special location \( r_m \) inside the torus which breaks the translational symmetries.

A possible counter argument is raised: Could TSB be avoided by somehow smearing the monopole charge inside the torus? This would presumably restore translational symmetry, at least for the direction in which the embedding has axial symmetry. It is somewhat surprising that the answer is negative, as the particular construction below demonstrates.

Ady Stern [57] has suggested the following construction. Consider a large number \( N \) of positive Dirac monopoles and \( N - 1 \) negative monopoles placed on the middle circle inside the torus, as shown in Fig. 13. One arranges both positive and negative monopoles to be at equal distances between them such that their mean density is uniform. Let us calculate the magnetic fields and their effects on bosons on the torus surface, and then take \( N \) to infinity.

For large \( N \), the distribution of monopoles approaches a uniform density with total monopole charge of \( g_m \). We compute numerically the magnetic field created by \( N = 20 \) monopoles situated on rings of radius \( R \), as given by Coloumb’s law

\[
B = \frac{r}{2qr^3}. \tag{A3}
\]

The radial magnetic field penetrating the surface of the torus in the plane \( y = 0 \), becomes increasingly closer to a constant, with decreasing oscillatory component as shown in Fig. 14. This behavior is precisely analogous to the electric field from a ring with uniform charge density.

Now let us examine the function \( W_y(x) \), evaluated for the same monopole configuration as Fig. 15. By Gauss’s law, it exhibits discontinuous jumps of size \( 2\pi \) \((-2\pi)\) at each position where the cross section of the torus at \( x \) cross through a monopole (anti-monopole). Note that \( W_y(x) \) exhibits \( N \) positive jumps and \( N - 1 \) negative jumps, corresponding to the number of positive and negative monopoles. Therefore, in order for \( W_y(x) \) to be periodic in \( x \rightarrow x + L_x \), the continuous part of \( W_y(x) \) needs to compensate for the extra positive jump. Indeed, as can be seen by Fig. 15, between the \( 2N - 1 \) jumps \( W(x) \) decreases linearly, as demanded by Eq (A1).

This increasingly discontinuous function does not converge to a well defined limit function in the large \( N \) limit. However, the physically relevant function which effects the dynamics of our bosons of charge \( q \) on the surface is the unimodular phase function

\[
\zeta(x) = e^{iW_y(x)} = \zeta_0 e^{iqBL_yx}, \quad x \in [0, L_x], \tag{A4}
\]

which is perfectly continuous and periodic on the circle. Here we see that \( \zeta(x_0) = 1 \) uniquely defines a special position \( x_0 \) which breaks lattice translational symmetry.

We note that the values of \( \zeta(x) \) have physical consequences on the current distribution. In the ground state, the loops in the region of \( \zeta \approx 1 \) feel a weak AB flux, and thus a relatively weak persistent current is induced in these regions. Similarly, the persistent currents are expected to be maximized around loops with \( \zeta \approx -1 \).

Thus we learn that a static configuration of monopoles leads translational symmetry breaking. However, if one considers the possibility of an extended quantum wave-function of a monopole, the magnetic field will be in a
A boson field can be restored in the entangled state of the matter quantum superposition. In this case, translational symmetry can be restored in the entangled state of the matter.

[17] We note that in the case of half filled fermion bands, particle-hole conjugation is obtained by sending \( f_i \to f_i^\dagger \). However, due to the anticommutation of fermion operators, Hamiltonians can realize this symmetry only on bipartite lattices. In contrast, particle-hole symmetry of half filled HBC models occurs on any graph.
