Smooth muscle cell recruitment to lymphatic vessels requires PDGFB and impacts vessel size but not identity

ABSTRACT
Tissue fluid drains through blind-ended lymphatic capillaries, via smooth muscle cell (SMC)-covered collecting vessels into venous circulation. Both defective SMC recruitment to collecting vessels and ectopic recruitment to lymphatic capillaries are thought to contribute to vessel failure, leading to lymphedema. However, mechanisms controlling lymphatic SMC recruitment and its role in vessel maturation are unknown. Here, we demonstrate that platelet-derived growth factor B (PDGFB) regulates lymphatic SMC recruitment in multiple vascular beds. PDGFB is selectively expressed by lymphatic endothelial cells (LECs) of collecting vessels. LEC-specific deletion of Pdgfb prevented SMC recruitment causing dilation and failure of pulsatile contraction of collecting vessels. However, vessel remodelling and identity were unaffected. Unexpectedly, Pdgfb overexpression in LECs did not induce SMC recruitment to capillaries. This was explained by the demonstrated requirement of PDGFB extracellular matrix (ECM) retention for lymphatic SMC recruitment, and the low presence of PDGFB-binding ECM components around lymphatic capillaries. These results demonstrate the requirement of LEC-autonomous PDGFB expression and retention for SMC recruitment to lymphatic vessels, and suggest an ECM-controlled checkpoint that prevents SMC investment of capillaries, which is a common feature in lymphedematous skin.

INTRODUCTION
The lymphatic vasculature in mammals controls homeostasis by transporting liquid from tissue back to the blood circulation. It is also part of the immune system and filters the lymph through lymph nodes for immune surveillance. The lymphatic vasculature is organised in a hierarchy of capillaries, pre-collectors and collecting lymphatic vessels, each with specific functional and morphological features (Lutter et al., 2012; Ulvmar and Mäkinen, 2016). Lymphatic capillaries lack mural cell coverage and are blind-ended vessels with permeable button-like cell junctions, which allow fluid uptake and immune cell entry from the tissue (Baluk et al., 2007; Pflicke and Sixt, 2009). Downstream of the capillaries are the pre-collectors, which are sparsely covered by smooth muscle cells (SMCs) and drain into the collecting vessels with more extensive SMC coverage. Here, valves and continuous zipper-like endothelial cell junctions ensure an efficient unidirectional lymph transport (Alitalo, 2011; Baluk et al., 2007; Kołowska et al., 2013; Schulte-Merker et al., 2011; Ulvmar and Mäkinen, 2016).

Impaired lymphatic drainage causes accumulation of fluid in the tissue and leads to swelling, referred to as lymphedema. Long-term symptoms include discomfort, pain and an increased incidence of infections (Williams et al., 2005). Lymphedema can be caused by genetic mutations (primary), or trauma, infections, cancer surgery and/or irradiation (secondary); however, knowledge of the pathological mechanisms is still limited (Szuba and Rockson, 1998). Collecting lymphatic vessels and their valves are known to be crucial for proper lymph drainage but the role of SMCs in this process is only partly understood. For example, SMC contraction has been shown to promote lymph drainage in the larger collecting vessels, such as the popliteal vessels (Kunert et al., 2015; Liao et al., 2011), but its importance for the function of smaller collecting vessels like those present in the skin, a tissue commonly involved in lymphedema, is not known. Nevertheless, deficient SMC function has been suggested to be an integral part of chronic lymphedema in humans (Ogata et al., 2015). In individuals suffering from lymphedema distichiasis (LD), which is caused by mutations in the forkhead transcription factor FOXC2, lymphedema is accompanied by valve agenesis but also by aberrant recruitment of SMCs to lymphatic capillaries (Petrova et al., 2004). Genetic deletion of Foxc2 as well as of Ang2 or Ephb2 in mice recapitulates this disease phenotype and leads to profound lymphatic remodelling defects that are characterised by defective valve formation, SMC recruitment and establishment of collecting vessel and capillary lymphatic endothelial cell (LEC) identities (Gale et al., 2002; Makinen et al., 2005; Normén et al., 2009; Petrova et al., 2004; Sabine et al., 2015). Altogether, these studies suggest an important role for SMC and LEC interplay in lymphatic morphogenesis and function, but precisely how SMCs regulate these processes is not known.

The successive steps of SMC recruitment to the lymphatic vasculature during development have been characterized in both dermal and mesenteric lymphatic vessels (Lutter et al., 2012; Normén et al., 2009). In the mouse ear, SMCs start to colonize the collecting vessels at postnatal day (P) 14, which coincides with downregulation of lymphatic vessel hyaluronan receptor 1 (LYVE-1). From P16, only lymphatic capillaries maintain Lyve1 expression and also remain devoid of SMCs throughout life. The reciprocal cellular interaction between SMCs and LECs has thus been suggested to regulate the establishment of capillary versus collecting vessel identity. Supporting this notion, SMC-LEC
contact induces secretion and activation of the extracellular matrix glycoprotein reelin (Reln) specifically in LECs of collecting vessels, which in turn promotes further SMC recruitment (Lutter et al., 2012). In Reln 

PM mice, reduced SMC coverage is accompanied by sustained LYVE-1 expression in collecting vessels. Platelet-derived growth factor B (PDGFB), which is central for mural cell (SMCs) sustained LYVE-1 expression in collecting vessels. Platelet-derived growth factor B (PDGFB), which is central for mural cell (SMCs) recruitment to collecting vessels, but overexpression is insufficient to mediate recruitment to lymphatic capillaries. We find that in addition to PDGFB expression the ligand relies on its binding and retention to the local extracellular matrix to promote SMC recruitment. We also show that although SMCs are crucial for pulsatile contraction of collecting vessels, they are not required for dermal lymphatic vessel remodelling, valve morphogenesis and establishment of capillary versus collecting vessel identity.

**RESULTS**

**PDGFB is selectively expressed by LECs of SMC covered collecting vessels but not by capillary LECs**

SMCs cover arteries and veins of the blood vasculature, as well as the collecting lymphatic vessels (Fig. 1A). PDGFB is known to regulate mural cell recruitment to blood vessels but its potential involvement in the analogous process in the lymphatic vasculature has not been demonstrated. To characterize the precise cellular source of PDGFB within the developing vasculature, we used a double transgenic mouse (Pdgfb-CreERT²-ires-eYFP;R26R-eYFP) carrying a Pdgfb-promoter-driven tamoxifen-inducible Cre-recombinase, a Pdgfb-driven GFP, as well as a conditional allele (loxP flanked stop) for Pdgfb in situ. Analyses of SMC coverage and proliferation at P21 (Fig. 1F-K) showed EdU+ SMCs along the entire length of collecting vessels. Although SMC coverage was higher in the proximal than in the distal ends of vessels, the proximal regions showed a relatively lower degree of SMC proliferation (Fig. 1I-K), suggesting that proliferation ceases as vessels mature. Interestingly, within the distal parts of the vessels EdU+ SMCs were confined to regions near vessel branches (Fig. 1L). Together, these data suggest that SMCs not only populate the lymphatics by initial recruitment but also by subsequent proliferation.

**Postnatal LEC-specific deletion of Pdgfb prevents SMC recruitment to dermal collecting lymphatics, causing vessel dilatation without affecting vessel hierarchy**

To investigate the role of LEC-autonomous PDGFB in the recruitment of SMCs, we generated Prox1-CreERT²; PdgfbiLECKO mice (henceforth denoted PdgfbiLECKO). These mice allowed for tamoxifen-induced LEC-specific deletion of Pdgfb, as well as the identification of recombination by YFP expression. Daily tamoxifen administration from P4 to P7 and staining of the ear skin of P21 mice revealed recombination (YFP+) in both blood and lymphatic vessels (Wang et al., 2010). Tamoxifen induction and analysis of Cdh5(PAC)-CreERT²; PdgfbiLECKO mice revealed recombinant expression of GFP (here denoted PdgfbiLECKO-GFP). Staining of the ear skin of P21 mice revealed colocalisation of GFP and α-smooth muscle actin (α-SMA), indicative of Pdgfb-expressing SMCs in collecting vessels (Fig. 1D,D'). No GFP signal was observed in LYVE-1+ lymphatic capillaries, indicating the absence of other potential α-SMA`; PdgfbiLECKO-GFP` mural cells, such as pericytes (Fig. 1E,E'). These results demonstrate that, unlike the ubiquitous expression of Pdgfb in the blood vasculature, Pdgfb is restricted to collecting vessels within the lymphatic vasculature. The spatial correlation between LECs producing PDGFB and mural cells expressing PDGFRβ suggests that this ligand-receptor pair is involved in lymphatic SMC recruitment.

In addition to recruitment, SMC in situ proliferation may contribute to the final coverage of developing collecting lymphatic vessels. To investigate this, we administered EdU to wild-type mice, starting at the time of initial SMC recruitment (P14), and continued at P16 and P18 to cover the time period of collecting vessel maturation. Analyses of SMC coverage and proliferation at P21 (Fig. 1F-K) showed EdU+ SMCs along the entire length of collecting vessels. Although SMC coverage was higher in the proximal than in the distal ends of vessels, the proximal regions showed a relatively lower degree of SMC proliferation (Fig. 1I-K), suggesting that proliferation ceases as vessels mature. Interestingly, within the distal parts of the vessels EdU+ SMCs were confined to regions near vessel branches (Fig. 1L). Together, these data suggest that SMCs not only populate the lymphatics by initial recruitment but also by subsequent proliferation.
thereby recapitulating the observations from the PdgfbLECKO mice. The lack of an obvious effect on blood vessel SMC coverage may reflect a higher degree of maturation of the blood vasculature compared with the lymphatic vessels at the time of induction. Together, these data provide direct genetic evidence for the requirement of LEC-derived Pdgfb in the recruitment of mural cells to the lymphatic collecting vessels and indicate that SMCs are not required for lymphatic vessel remodelling into a hierarchy of collecting vessels and capillaries.

Establishment of collecting versus capillary LEC identities does not require SMC interaction

The basement membrane (BM) of collecting vessels is continuous, whereas that of capillaries is described as discontinuous (Pflicke and Sixt, 2009). To further investigate the potential involvement of SMCs in the maturation of collecting vessels, we studied the abundance of BM proteins in lymphatic vessels of the PdgfbLECKO mice. Immunostaining for laminin (Fig. 3A-B’) and collagen IV (Fig. 3C-D’) revealed no differences between dermal lymphatic vessels with antibodies against ERG 1 (blue), EdU (green) and α-SMA (red). (I,) Distribution of EdU+ SMCs (I, arrows in upper panel; I’, schematic green ellipse in lower panel) in a complete collecting vessel. (J,K) Quantification of EdU+ and α-SMA+ cells (K) relating to SMC coverage (J) in the proximal and distal part of the entire collecting vessel (n=3). Data are mean±s.e.m. P value is calculated using Student’s t-test. Scale bars: A, 200 µm; B-E’, 50 µm; F-H, 20 µm; I,I’, 200 µm.
lymphatic vessel identity and vascular hierarchy is independent of SMC interaction but that such interaction affects cellular size. They furthermore indicate that the contribution of SMCs to the major constituents of the BM of collecting vessels is minor.

### PDGFB is required for SMC recruitment to the large-diameter collecting vessels of the hind limb and mesentery

Recruitment of mural cells to larger diameter collecting vessels, such as the popliteal and mesenteric collecting vessels, occurs during embryogenesis. To study the involvement of PDGFB in these tissues, we deleted PDGFB in *Pdgfb<sup>LECKO</sup>* embryos by administration of 4-OHT to pregnant females at embryonic day (E)15, E16 and E17, and analysed the embryos at E18.5. SMC coverage in the *Pdgfb<sup>LECKO</sup>* mice was reduced in both popliteal (Fig. 4A-C) and mesenteric lymphatic vessels (Fig. 4E-G) compared with controls. Although the diameter of popliteal lymphatic vessels was unaltered (Fig. 4D), mesenteric vessels were enlarged (Fig. 4H), suggesting tissue-specific consequences of SMC reduction. To investigate whether PDGFB is also required for expansion and maintenance of SMCs after their initial recruitment, PDGFB deletion was induced at P1 and P2 and lymphatic vessels were compared between *Pdgfb<sup>LECKO</sup>* and control mice at P12. SMC coverage of the popliteal vessels was reduced to 73.8% compared with 93.1% in the control (Fig. 4I-K), while it remained unchanged in the mesenteric vessels (Fig. 4M-N'). Interestingly, local regions lacking SMC coverage in the popliteal vessels of *Pdgfb<sup>LECKO</sup>* were bulging, demonstrating local effects of SMCs in constriction of the vessel (Fig. 4J', arrowheads). Nevertheless the average vessel diameter remained unchanged (Fig. 4L). Together, these data reveal the strict requirement of LEC-derived PDGFB in SMC recruitment to large diameter collecting vessels of the hind limb and mesentery.

### Loss of SMCs causes impaired contraction of dermal collecting vessels

Despite the near-complete absence of dermal lymphatic SMC coverage in the *Pdgfb<sup>LECKO</sup>* mice, no obvious lymphedema could be observed. Although contraction of large diameter vessels, such as popliteal and mesenteric lymphatic vessels, has been previously documented, dermal vessel contraction remains poorly studied and has not been correlated with SMC function or presence (Liao et al., 2011; Sabine et al., 2015). To further assess potential effects of mural cell loss on lymphatic properties, we studied lymphatic vessel contraction and drainage following tracer injection, using non-invasive *in vivo* live imaging of the ear skin. Using high-frequency non-invasive imaging, pulsatile vessel contraction was recorded...
Dermal collecting vessels displayed a wide range of contraction frequency and amplitude (Fig. 5A-D). Notably, only a subpopulation of collecting dermal lymphatic vessels was seen to contract under the experimental conditions applied. To investigate the dependence and role of SMCs on this contractile behaviour, *Pdgfb*LECKO mice (*n*=6) and control mice (*n*=10) at an age of 1 month were imaged and compared. The number of contraction sites per ear was significantly lower in *Pdgfb*LECKO mice compared with control mice (*P*<0.05, Mann–Whitney Test; Movies 2 and 3). Out of 10 control mice analysed, 32 contraction sites were observed in seven mice and the contraction sites were associated with SMC coverage, indicated by immunofluorescence staining of the same ear after live imaging (Fig. 5E,E'). None of the above proteins were altered following *Pdgfb* deletion. (M–N') Immunostaining of mouse ear skin with antibodies against CD31 (blue), VE-CAD (green) and α-SMA (red). Individual LEC size is enlarged on the collecting vessel of *Pdgfb*LECKO mice compared with the control mice. (O) Quantification of individual cell area of LECs (*n*=72) from two *Pdgfb*LECKO mice and LECs (*n*=55) from two control mice. Data are mean±s.e.m. and *P* value is calculated using Student’s *t*-test. Scale bars: A–L', 50 µm; M–N', 10 µm.

vasculature, a fluorescent tracer was subcutaneously injected into the ear of PdgfbiLECKO and control mice. However, live imaging did not reveal any difference in the clearance of the injected tracer from tissue over time (Fig. S3).

Postnatal LEC-specific overexpression of PDGFB does not induce ectopic SMC recruitment to lymphatic capillaries

To investigate whether aberrant PDGFB expression within lymphatic capillaries is sufficient to induce SMC recruitment, we crossed Prox1-CreERT2 mice with R26hPDGFB^{+/-} mice (Armulik et al., 2010), allowing for inducible LEC-specific overexpression of human PDGFB. Endothelial cell-specific expression of the R26hPDGFB^{+/-} allele has been demonstrated to rescue embryonic lethality and mural cell recruitment of Pdgfb^{-/-} mice (Armulik et al., 2010). Prox1-CreERT2; R26hPDGFB^{+/-} mice (PdgfbLECOE) and controls received three doses of tamoxifen between P2 and P8, followed by analysis of the dermal ear lymphatic vasculature at 4 weeks of age. Prox1-CreERT2-mediated recombination driving expression of the human PDGFB was observed throughout the lymphatic vasculature, as indicated by visualisation of the conditional reporter (data not shown; see Fig. 2A). Ectopic expression in lymphatic capillaries was confirmed by detection of human PDGFB transcripts in FACS-sorted LYVE-1+ LECs from dermal ear skin of PdgfbiLECOE mice (Fig. S4A). SMC coverage of the collecting vessels of PdgfbiLECOE mice was modestly increased compared with littermate controls (Fig. 6A) (44.5% versus 33.4%, P<0.05) illustrating functionality of induced overexpression, as well as a PDGFB dose effect on SMC recruitment. Collecting vessels in PdgfbiLECOE mice further showed a trend towards reduced average diameter (Fig. 6B). However, despite aberrant PDGFB expression in capillary LECs, no α-SMA+ or PDGFRβ+ cells were recruited to lymphatic capillaries (Fig. 6C-F). These data demonstrate that, although PDGFB is essential for SMC recruitment to the lymphatic...
vasculature, LEC expression is not sufficient to mediate recruitment of SMCs to lymphatic capillaries.

**Deficient interaction between PDGFB and extracellular matrix causes defective SMC recruitment to dermal collecting lymphatic vessels**

Mural cell recruitment to the blood vasculature relies not only on endothelial cell production of PDGFB but also on its binding to the extracellular matrix. To investigate whether such interaction is important also for the lymphatic vasculature, we studied mice with a genetically modified PDGFB that lack its heparan sulphate-binding domain (Pdgfb<sup>ret/ret</sup>) (Lindblom et al., 2003). Here, heterozygote Pdgfb<sup>ret/wt</sup> served as controls as they showed no alterations of collecting vessels (Fig. 7A). Similar to the situation in Pdgfb<sup>LECKO</sup> mice, Pdgfb<sup>ret/ret</sup> mice displayed reduced SMC coverage and dilation of dermal ear lymphatic collecting vessels (Fig. 7A-D), without affecting density or number of branch points of the lymphatic capillaries (Fig. 7E-H). These results show that interaction between extracellular matrix and PDGFB is required for correct recruitment of SMCs to the lymphatic collecting vessels of the skin. Differential composition of the collecting versus capillary BMs, with respect to PDGFB-binding molecules, may thus contribute to the inability of ectopically expressed PDGFB to induce mural cell recruitment to the lymphatic capillaries. To investigate this, we assessed lymphatic vascular expression and deposition of heparan sulphate proteoglycan perlecan, as well as collagen IV, which are known to bind PDGFB either via the heparan sulphate chains or directly via the core protein (Gohring et al., 1998). Immunostaining for perlecan, collagen IV and laminin revealed high levels of both proteins in dermal collecting vessels (Fig. 7I-I′,K,K′,M,M′) but strikingly lower levels in capillaries (Fig. 7J,J′,L,L′,N,N′). These data suggest that, in the absence of PDGFB-binding BM proteins, PDGFB may not be sufficiently retained in close proximity to the LECs of capillaries to allow for recruitment of mural cells, even following ectopic PDGFB expression.

**Fig. 5. Pulsatile contraction of dermal lymphatic collecting vessels requires SMC coverage.** (A-C) Lymphatic collecting vessels of ears of living mice, highlighted by subcutaneous injections with Tritc-dextran (grey). Snap shots from live-imaging of lymphatic collecting vessels analysed as two regions of interest (A, red box and green box). Snap shots of vessels contracting (arrowheads) and relaxing in the respective region of interests (ROIs) (ROI1, red box, magnified in B; ROI2, green box, magnified in C). (D) Relative change in vessel diameter over time for ROI1 (B) and ROI2 (C) reflects regional contraction patterns. (E,F) Snap shots from movies of contracting vessels in ears of control (E) or Pdgfb<sup>LECKO</sup> (F) mice. (E,F) Whole-mount immunofluorescent staining of the live-imaged vessels in E and F. Areas of contraction (dashed line) were covered by SMCs in control mice (arrows, green in E; intensity adjustments were applied specifically to the vessel area in order to enhance the visibility of perivascular SMCs) as well as in the only two areas of the Pdgfb<sup>LECKO</sup> mouse (arrows, green in F). Scale bars: A, 20 μm; E,F, 500 μm; E′,F′, 200 μm.
DISCUSSION

Here, we generated novel mice allowing for inducible LEC-specific deletion of PDGFB. PDGFB deletion rendered the dermal lymphatic vasculature of the ear completely devoid of SMCs and led to reduced SMC coverage of mesenteric and popliteal vessels, in turn revealing a strict requirement for LEC-derived PDGFB in SMC recruitment to collecting vessels. Using this model, we provide the first description of the direct role of SMCs in lymph vessel morphogenesis and function, independent of other factors. The data indicate that several key aspects of lymphatic vascular development do not rely on SMCs, in contrast to previous suggestions.

SMC recruitment to the collecting vessels has been shown to coincide with vessel remodelling and maturation. Several studies have, in addition, revealed abnormal SMC coverage on lymphatic vessels in disease as well as in genetic mouse models. Some of these investigations have inferred an inverse correlation between SMC coverage and LYVE-1 expression (Dellinger et al., 2008; Lutter et al., 2012). In none of the previous studies could the contribution of potential secondary and systemic effects be ruled out. Here however, we have found that collecting vessels in Pdgfb<sup>LECKO</sup> mice displayed normal (low) LYVE-1 levels despite the near-complete absence of SMCs. This indicates that SMC contact per se does not lead to downregulation of LYVE-1, which is considered a hallmark of establishment of collecting vessel identity. Together with the inability of ectopic expression of PDGFB in lymphatic capillaries to induce recruitment of SMC, these data suggest that lymphatic capillary- versus collecting-vessel identities are not directly dictated by SMC interaction.

The degree of SMC proliferation during the process of SMC coverage within lymphatic vessels had not been investigated. Our analysis revealed a higher ratio of proliferating SMCs in the ‘younger’ distal collecting vessels than in the ‘older’ proximal half, suggesting that proliferation mainly occurs during the collecting vessel maturation process. Although PDGFB also likely contributes to proliferation, the near total absence of SMCs in collecting vessels of Pdgfb<sup>LECKO</sup> shows the strict requirement for PDGFB in the recruitment of the initial pool of SMCs. Furthermore, the reduced coverage seen in the Pdgfb<sup>RECO</sup> mice, in which the signalling of the mutant PDGFB is not altered but only its ability to be retained within the local extracellular matrix, further suggests that the initial recruitment is dependent on LEC-derived PDGFB.

Pulsatile contraction of perivascular SMCs in major collecting vessels is known to contribute to the efficiency of lymph drainage (Kunert et al., 2015; Zawieja, 2009). However, whether such contractions are required during normal physiology, or even in pathology, has not been thoroughly assessed. Furthermore the functional impact of a similar contraction in the skin had not been studied. Here, Pdgfb<sup>LECKO</sup> mice displayed severely impaired dermal lymphatic vessel contraction, owing to loss of SMCs, but with no apparent lymphedema and no recordable change in lymphatic vessel morphology.
lymphatic drainage in the applied experimental setup (Fig. S3). It should be noted that even genetic mouse mutants that display severe lymphatic vessel defects, such as hypoplasia of lymphatic capillaries in the mouse model of Milroy disease, a form of primary lymphedema (Karkkainen et al., 2001), do not show as severe tissue swelling as humans with the corresponding genetic defect. It is therefore likely that loss of dermal SMCs would have more dramatic consequences in humans.

Ectopic SMC coverage of the lymphatic capillaries has been observed in both primary and secondary lymphedema (Yu et al., 2016), and is postulated to inhibit lymphatic drainage function. In individuals with primary lymphedema, owing to FOXC2 loss-of-function mutations, the cause of ectopic SMC recruitment was suggested to be a consequence of induction of PDGFB expression within the capillaries. Indeed dermal lymphatic capillaries of Foxc2<sup>−/−</sup> embryos displayed abnormal PDGFB expression, but whether this alteration was sufficient or required in this pathology is not clear. Our data show that genetically induced LEC-specific overexpression of PDGFB is not sufficient to drive recruitment of SMCs to lymphatic capillaries. These data, together with the increased SMC coverage in individuals with secondary lymphedema, indicate that other alterations are required in

**Fig. 7.** Impaired PDGFB retention in the extracellular matrix causes defective SMC recruitment to collecting vessels without affecting lymphatic capillaries. addition to induced PDGFB expression. Our results demonstrate that PDGFB requires the binding to heparan/chondroitin sulfate chains to mediate normal SMC recruitment to the collecting vessels. Whereas collecting vessels have a continuous BM, lymphatic capillaries display only discontinuous BMs and, as shown here, with very low levels of the PDGFB-binding perlecan and collagen IV, thereby potentially limiting PDGFB retention to LECs. Interestingly, Foxc2<sup>−/−</sup> mice display increased deposition of BM components within the defective lymphatic capillaries, which may act together with PDGFB to mediate ectopic SMC recruitment (Petrova et al., 2004). Extracellular matrix alterations may also influence integrin-mediated SMC migration and adhesion, adding to the complexity. In addition the retention motif of PDGFB can be cleaved by proteases, with potential differential abundance or activity in capillaries and collecting vessels. Finally, it is possible that SMC recruitment to lymphatic capillaries is actively inhibited under normal physiological conditions. It has been shown that Sema3-Nrp1-plexin A1 signalling prevents recruitment of SMCs to the valve regions of collecting vessels to ensure normal valve morphogenesis and function (Bouvree et al., 2012; Juriscic et al., 2012); a similar mechanism may exist in lymphatic capillaries.

Precisely how the lymphatic vasculature acquires and maintains its hierarchical structure of capillaries and collecting vessels is not well understood (Schulte-Mmerker et al., 2011). Here, we demonstrate that the establishment of vessel identity is mainly unaffected by a complete inhibition of lymphatic mural cell recruitment – a process here shown to be strictly dependent on lymphatic endothelial PDGFB expression and pericellular retention. We also clarified that erroneous spatial expression of PDGFB is unlikely to be the single cause of ectopic recruitment of SMCs to lymphatic capillaries in disease. The genetic mouse model of lymph vessel-specific mural cell deficiency provides a novel and specific tool for further studies on the importance of SMCs in lymphatic development and lymphedema.

**MATERIALS AND METHODS**

**Mice and treatments**

All animal experiments included male and female mice. *Pdgfb<sup>eGFP</sup>* mice ([Gensat.org line name: Tg(Pdgfb-eGFP)JN169.Gsat/Mmucd]) express GFP under the control of the Pdgfb promoter and hence function as mural cell reporter. *Pdgfb-CreERT<sup>2</sup>* and *R26-mTmG* mice have been previously described (Claxton et al., 2008; Muzumdar et al., 2007), and here were combined with inter-crosses to generate *Pdgfb-CreERT<sup>2</sup>*; *R26-mTmG* mice. To evaluate differential Pdgfb expression within the dermal lymphatic vasculature, 4-hydroxytamoxifen (4-OHT) was injected into the abdominal cavity at P14 and mice were sacrificed at P21. Ear samples were then fixed in 4% PFA. *Prox1-CreERT<sup>2</sup>* and *Pdgfb<sup>fllox/fllox</sup>* mice have been previously described (Bazigu et al., 2011; Enge et al., 2002) and were herein crossed with the so-called *Ai3* reporter mice ([B6.Cg-Gt(Rosa26)Sor<sup>tm1(CAG-EYFP)Hze</sup>/J, Stock Number 007903, The Jackson Laboratory, here denoted with the so-called *Ai3* reporter mice [B6.Cg-Gt(Rosa26)Sor<sup>tm1(CAG-EYFP)Hze</sup>/J, Stock Number 007903, The Jackson Laboratory]). In order to specifically delete *Pdgfb* in the mouse endothelium, these mice received 50 µl tamoxifen (20 mg/ml) at P17 and were sacrificed at 4 months.

Animal experiment protocols were approved by the Stockholm North Ethical Committee on Animal Research (permit number N14/13, N16/18) and the Uppsala Ethical Committee on Animal Research (Permit number: C224/12, C225/12, C130/15). All animal experiments were carried out in accordance with their guidelines.

**Whole-mount immunofluorescence staining**

Ears and hind limbs were fixed in 4% PFA at room temperature for 2-4 hours and then either stored in PBS with 0.01% NaN<sub>3</sub> or immediately processed for immunofluorescence staining. To dissect the ear and expose lymphatic vasculature, hair was removed with fine surgical forceps and scissors (Agnthos), and two layers of superficial skin were separated to expose the dermal layer of the ear. Muscles and fat were carefully trimmed away. To isolate the popliteal vessels from the hindlimb of pups at P12, the skin was removed and the exposed blood and lymphatic vessels were dissected together with the underlying muscles. Dissected ears or tissues from hind limbs were then washed with PBS 3×10 min on a rocking table at room temperature. Samples were then blocked in PBS with 1.5% BSA and 0.5% Triton X-100 for 3 h at room temperature followed by addition of primary antibodies and incubation overnight at 4°C. Samples were then washed in PBS with 0.25% Triton X-100 at room temperature on a rocking table followed by secondary antibody incubation overnight at 4°C. After three washes (1 h each) in PBS with 0.25% Triton X-100 at room temperature on a rocking table, ear samples were flattened on a glass slide and mounted with Prolong Gold (Life Technologies). Mesenteries were fixed in 4% paraformaldehyde at room temperature for 2 h. Samples were washed in PBS, permeabilized in 0.3% Triton X-100 in PBS (PBSTx) and blocked in 3% BSA in PBSTx. Primary antibody incubation was performed at 4°C overnight, followed by washing in PBSTx and incubation with secondary antibodies at room temperature for 2 h. Samples were then washed in PBSTx and mounted in Prolong Gold for imaging. Primary antibodies included goat anti-podocalyxin (1:400; AF1556, R&D Systems), goat anti-CD31 (1:400; AF3628, R&D Systems), rat anti-CD31 (1:1000; 553370, BD Pharmingen), rabbit anti-ERG (1:400; ab92513, Abcam), chicken anti-GFP (1:1000; ab13970, Abcam), mouse anti-α-smooth muscle actin (1:200; α-SMA) (1:250; e6198, Sigma), rabbit anti-PDGFRβ (1:200; ab32570, Abcam), rat anti-PDGFRβ (1:200; 14-1402-82, ebioscience), rabbit anti-PROX1 (1:200; Martinez-Corral et al., 2015), goat anti-NRP2 (1:200; AF567, R&D Systems), rat anti-LYVE-1 (1:400; 0117, R&D Systems) rabbit anti-LYVE-1 (1:400; ab14917, Abcam), goat anti-CCL21 (1:200; AF457, R&D Systems), goat anti-VEGFR3 (1:200; AF743, R&D Systems), rat anti-VE-Cadherin (1:200; 550548, BD Pharmingen), rabbit anti-collagen IV (1:400; 2105-1470, Bio-Rad), rat anti-perlecan (1:200; ab17848, Abcam) and rabbit anti-laminin (1:400; L9393, Sigma Aldrich). Secondary antibodies conjugated with Alexa fluorophores were from Jackson ImmunoResearch Laboratories and Life Technologies (1:300 for staining of mesenteric vessels; 1:400 for staining of other tissues).

**Assessment of SMC proliferation**

To assess proliferation of SMCs, mice received three intraperitoneal injections of 5-ethyl-2-deoxyuridine (EdU, 100 µg/mouse) at P14, P16 and P18, and were sacrificed at P21 for immunofluorescence staining of the ear. EdU staining was performed using the Click-it EdU imaging kit (Life Technologies) apart from a 3 h incubation of reaction cocktail at room temperature.

**In vivo imaging of dermal ear lymphatic vessel contraction**

For evaluation of dermal lymphatic vessel contraction, mice were anaesthetized with isoflurane and hair on the dorsal side of the ears was removed using a sharp blade. The head and nose of the mouse was fixed to a customized head holder device and the left ear was glued to a customized...
plastic plate to prevent movement. TRITC-Dextran (1 μl of 10 mg/ml, 500 kDa, Sigma-Aldrich) was injected subcutaneously with a (30G) insulin syringe (BD Biosciences) or a Hamilton syringe. Mice were then immediately transferred to the imaging stage for time-lapse epifluorescence imaging using either the 20×/0.1 objective on a Leica SP8 laser confocal microscope system (Movie 1, images acquired every 1 s) or a Leica M205FA microscope with a PLANAPO 1.0× objective (Leica Microsystems) (Movies 2,3,4,5, images acquired with an interval of less than 1 s).

**Imaging acquisition of immunofluorescence stained specimens**

Confocal images of lymphatic vessels of the ear skin, the popliteal lymphatic vessels or mesenteric lymphatic vessels were acquired using a Zeiss LSM 700 system (Carl Zeiss) with a 20×/0.8 objective or a Leica SP8 laser confocal microscope system (Leica Microsystems) with either of 25×/1.0, 25×/0.95, 20×/0.75 or 10×/0.3 objectives. The images represent maximum intensity projections of z stacks that, in the case of overviews, were stitched from multiple tile scan images, either manually using Adobe Photoshop (Adobe) or automatically by the Leica LAF software. Images were processed with FIJI (Schindelin et al., 2012) or Adobe Photoshop software (Adobe). Intensity Adjustments in Fig. 5E were applied specifically to the vessel area (dashed line) in order to enhance the visibility of perivascular SMCs. Tiled epifluorescence images showing the entire capillary network were acquired using an Axio Observer Z1 system (Carl Zeiss) with a 5×/0.13 objective and images were automatically aligned by Zen blue 2012 software (Carl Zeiss).

**Image analysis**

To quantify EdU+ cells/mm² SMC surface area, pictures of complete lymphatic collecting vessels were created using manual alignment (Adobe Photoshop) of individual high resolution images. Cells double positive for EdU and α-SMA were manually counted and SMC surface area of a complete collecting vessel was measured using Volocity (Perkin Elmer). To quantify collecting vessel width and SMC coverage, regions with excessive branches and intersecting blood vessels were excluded and vessel width was measured along the vessel and averaged by number of measurements. SMC coverage was quantified using Volocity (Perkin Elmer) (dermal ear skin, popliteal lymphatic vessels) or FIJI (Schindelin et al., 2012) (mesenteric lymphatic vessels) and indicated as percentage of vessel area covered by capillaries in the complete region of interest. Branch points/mm² lymphatic capillaries within a defined region of interest were measured using ImageJ. Lymphatic vessel contraction was analysed in Volocity (Perkin Elmer) and plotted as vessel area against time in GraphPad Prism 5 (GraphPad Software).

**Flow cytometry and PCR**

Dermal lymphatic endothelial cells were sorted as previously described (Martinez-Corral et al., 2016). Ear skin from adult mice were dissected in ice-cold PBS and digested in collagenase IV (BD Biosciences) and DNaseI (Roche, 0.2 mg/ml in PBS). All digestions were incubated for 30-40 min at 37°C, quenched by adding 2 ml EDTA and filtered through a 70 μm nylon filter (BD Biosciences). Cells were washed with FACS buffer (PBS, 0.5% FBS, 2 ml EDTA) and immediately processed for immunolabelling in 96-well plates. FC receptor binding was blocked with rat anti-mouse CD16/CD32 (eBioscience). Immune cells and erythrocytes, as well as dead cells, were excluded using anti-CD45 (30-F11), anti-CD11b (M1/70) and anti-TER-119 (TER-119) e450 (eBioscience), together with the cell death dye Sytox Blue (Life Technologies), all detected by the violet laser as one dump channel. (Capillary) LECs were excluded using anti-podoplanin e660, anti-LYVE-1 (eBioscience) and Carina Ho Hammes, H. P., Fassler, R. and Betsholtz, C.

**Statistics**

Statistical analysis was performed using GraphPad Prism (GraphPad Software) and all differences were determined by unpaired Student's t-test, except for the comparison of the number of contraction sites between Pdgfp+/+ and Pdgfp−/− mice and control mice, for which a Mann-Whitney test was applied. All differences were defined as significant by P<0.05. Investigators were not blinded to the group allocation when performing experiments and assessing outcomes.

**Acknowledgements**

We thank Ralf Adams for providing the Cd31(SPAC)-CreER², Mikhail Burmakin and Sofie Wagensi for technical assistance, and Jana Chmielniakova, Pia Peterson and Carina Hörnsten for animal maintenance.
