ABSTRACT

An atlas of the Galactic plane (−4.7° < b < 4.7°), along with the molecular clouds in Orion, ρ Oph, and Taurus-Auriga, has been produced at 60 and 100 μm from IRAS data. The atlas consists of resolution-enhanced co-added images with 1′−2′ resolution and co-added images at the native IRAS resolution. The IRAS Galaxy Atlas, together with the Dominion Radio Astrophysical Observatory H line/21 cm continuum and FCRAO CO (1−0) Galactic plane surveys, which both have similar (≈1′) resolution to the IRAS atlas, provides a powerful tool for studying the interstellar medium, star formation, and large-scale structure in our Galaxy. This paper documents the production and characteristics of the atlas.

Subject headings: atlases — Galaxy: structure — infrared: ISM: continuum — radio lines: ISM

1. INTRODUCTION

In 1983, the Infrared Astronomical Satellite (IRAS) fundamentally changed our view of the infrared sky when it conducted the first infrared all-sky survey. The IRAS data have proved important to the study of many astrophysical phenomena, including star formation, the interstellar medium, Galactic structure, late-type stars, supernova remnants, external galaxies, infrared cirrus, and debris disks around nearby stars (Beichman 1987). Newer infrared spacecraft missions such as the Infrared Space Observatory, the Midcourse Space Experiment (MSX), and the Infrared Telescope in Space now provide higher sensitivity and spatial resolution (Kessler 1995; Matsumoto 1995; Price 1995; Mill & Guilmain 1996). However, by design these instruments surveyed only a small fraction of the sky, thus ensuring that the IRAS data will provide a fundamental archive for many years to come.

The native spatial resolution of the IRAS co-added data is a few arcminutes by 5′. Various image reconstruction techniques have been applied to the IRAS data in the quest to extract higher spatial resolution (Terebey & Mazzarella 1994). These include maximum entropy techniques, among them the HIRAS package developed at Groningen (Assendorp et al. 1995; Bontekoe, Koper, & Kester 1994). Making use of an alternate approach, the production of the IRAS Galaxy Atlas is based on the well-known HIRES processor, first developed in 1991 and made available to the scientific community by the Infrared Processing and Analysis Center (IPAC). HIRES implements the iterative maximum correlation method (MCM; Aumann, Fowler, & Melnyk 1990), a variant of the Richardson-Lucy algorithm that has been optimized for IRAS data. The advantages of HIRES include flux conservation, speed of processing, and the ability to work reliably on faint sources. HIRES images have been successfully used for a variety of Galactic and extragalactic studies (Rice 1993; Surace et al. 1993; Terebey & Mazzarella 1994).

The parallel supercomputing facilities available at Caltech and the development of new artifact reduction algorithms made possible a large-scale high-resolution IRAS mapping of the Galactic plane (Cao et al. 1996, hereafter Paper I; Cao 1997). The new IRAS Galaxy Atlas (IGA) maps have 1′−2′ resolution. This represents a threefold improvement in linear resolution, for a total factor of 10 improvement in areal resolution over the IRAS Sky Survey Atlas (ISSA; Wheelock et al. 1994). The IGA incorporates several important features that differ from standard HIRES processing at IPAC. Foremost is improved destriping and zodiacal emission subtraction, which lead to reduction of artifacts, enhancement of faint structure, and the ability to mosaic images without edge discontinuities. The IGA is well suited to high-resolution studies of extended structure and will be valuable for a wide range of scientific studies, including studies of the structure and dynamics of the interstellar medium (ISM), cloud core surveys within giant molecular clouds, detailed studies of H II regions and star-forming regions, determination of initial mass functions (IMFs) of massive stars, and the study of supernova remnants (SNRs). The IGA will be especially useful for multiwavelength studies using the many Galactic plane surveys that have similar (~1′) resolution. These include the new FCRAO CO (1−0) spectral line (Heyer et al. 1997) and DRAO H line/21 cm continuum surveys (Normandeau, Taylor, & Dewdney 1997).

All image reconstruction algorithms have their quirks. This paper describes and characterizes the IGA so that it will be useful for quantitative scientific study. Section 2 describes the geometry and information content of the atlas images. Section 3 gives a description of the various processing stages, namely, the basic algorithm, the subtraction
of zodiacal emission, and coordinate transformation and reprojection. Section 4 discusses the characteristics of the images, including resolution, photometric and positional accuracy, mosaic properties, and calibration. Section 5 details the various image artifacts.

The IGA images are available on-line from IPAC at http://www.ipac.caltech.edu or through the NASA National Space Science Data Center (NSSDC). The complete archive comprises 10 8-mm tapes. Casual users should direct requests for specific images to IPAC.

2. DESCRIPTION OF THE ATLAS

The atlas consists of images (first and 20th iterations) and ancillary maps in Flexible Image Transport System (FITS; Wells, Greisen, & Harten 1981) format in the 60 and 100 μm wavelength bands. The Galactic plane images cover 0° ≤ l ≤ 360° in Galactic longitude and −4°7 ≤ b ≤ 4°7 in latitude. The field of view for each image is 1°4 × 1°4 on 1° centers in both the Galactic longitude and latitude directions; the pixel size is 15°, and Galactic coordinates and Cartesian projection are used. The molecular cloud fields (Orion, ρ Oph, and Taurus-Auriga) are rectangular, about 20° on a side, with boundaries selected to encompass the diffuse infrared emission of each cloud. The images are 2°5 × 2°5 on 2° centers with 15° pixels and use equatorial coordinates (B1950) and Cartesian projection. The boundaries are given by [5°8′8″, 6°12′] and [−13°0′, 18°0′] for Orion, [15°31′, 17°00′] and [−33°0′, −17°0′] for ρ Oph, and [3°48′, 5°12′] and [12°0′, 33°30′] for Taurus-Auriga. The Cartesian projection used with equatorial coordinates is a relatively new FITS combination that may cause trouble for some FITS reading software. For individual images or small mosaicked fields, the FITS header keyword -SIN can be used in place of -CAR (see § 3.4).

The first-iteration images are co-added IRAS images (i.e., Full-Resolution Coadder [FRESCO] images) with no resolution enhancement. They have the native IRAS resolution of approximately 2.0 × 4.7 at 60 μm and 3.8 × 5.4 at 100 μm. After MCM processing to 20 iterations, the typical spatial resolution improves to 1.0 × 1.7 at 60 μm and 1.7 × 2.2 at 100 μm (see § 4.1). The images at 60 and 100 μm have inherently different resolutions. Ratio or color maps should only be attempted by expert users, and only after correcting the images to a common resolution.

Aperture photometry is accurate to about 25% (see § 4.4). Most of the uncertainty is due to background measurement uncertainties. The images are on the same absolute flux level as the ISSA images, except for a constant AC/DC factor (see § 4.3).

The ancillary maps include the correction factor variance (CFV) map, the photometric noise (PHN) map, coverage (CVG) map, the detector track (DET) map, and the beam-sample map (BEM). See Table 1, referenced in § 3.2, for the quantities they represent and the figures referenced in § 6 for example images. The FWHM.txt text file gives Gaussian beam sizes derived from the corresponding BEM map.

3. DESCRIPTION OF PROCESSING

An overview of the HIRES processing developed at IPAC is available on-line from IPAC at http://www.ipac.caltech.edu. This section details the unique problems encountered in the production of the IGA.

3.1. Overview of the Production Pipeline

IRAS detector data, known as CRDD (Calibrated Reconstructed Detector Data), grouped in 7° × 7° plates, reside in the “Level 1 Archive” at IPAC. The first step in the pipeline for mass production of HIRES images is to extract data covering a specific field from the archive and then to perform calibration and various other preprocessing operations. We take the 7° × 7° preprocessed and calibrated plates and use the algorithm described in § 3.3 to subtract the zodiacal background emission. This step requires the corresponding ISSA image as supplemental input (“SmLAUN” in Fig. 1; see § 3.3).

Following the calibration and zodiacal subtraction, the detector files are broken into 1°4 × 1°4 fields, and reprojected into Galactic coordinates (from equatorial) if required, with field centers separated by 1° (“BrkDet” in Fig. 1; see § 3.4). The factor of 2 overlap is a conservative insurance

**TABLE 1**

| Name | Type | Quantity Mapped |
|------|------|-----------------|
| IMG  | Image| f_j |
| PHN  | Photometric noise| \[
\left(\sum r_{ij}/\sigma_{ij}\right)^{-1/2}, \text{ where } \sigma_{ij} = \sigma_f \sum (r_{ij} f_j) \]
| CFV  | Correction factor variance| \[
\left(\sum (r_{ij}/\sigma_{ij})^2\right)^{1/2}/\left|\sum (r_{ij} f_j)\right| - c_j^2 \]
| CVG  | Coverage| \[
\sum r_{ij} \]
| DET  | Detector track| index of detector whose center falls at pixel j |
| BEM  | Beam sample map| reconstructed image from data made from spiked scene |
against discontinuity across field boundaries (§ 4.7), as local
destriping and different flux bias (§ 3.5) will be applied to
each small field. The 1' 4 × 1' 4 size is also the maximal field
size with complete coverage allowed within one Level 1
plate, given the two degrees of redundancy of the plates and
the arbitrary location and orientation of the small field rela-
tive to the Level 1 plate. Figure 2 illustrates the overlapping
IGA fields and the geometry and orientation of the Level 1
plates that determine the allowed IGA field size.

All operations described above are carried out on work-
stations. The small-field (1' 4 × 1' 4) detector files are then
processed into HIRES images, which is done on an Intel
Paragon supercomputer. The basic algorithm for image
reconstruction is described in § 3.2. For parallelization
strategy and details of the destriping algorithm, see Paper I.

3.2. The Maximum Correlation Method

Starting from a model of the sky flux distribution, the
HIRES MCM algorithm folds the model through the IRAS
detector responses, compares the result track by track to
the observed flux, and calculates corrections to the model.
One important characteristic of the standard MCM algo-
rithm is that it conserves flux. We give a brief description of
the MCM algorithm following the formalism and notations
of Aumann et al. (1990).

Given an image grid f_j, with n pixels j = 1, ..., n and m
detector samples (or footprints) with fluxes D_i, i = 1, ..., m,
whose centers are contained in the image grid, an image can
be constructed iteratively from a zeroth estimate of the
image, f_j^0 = const > 0 for all j. In other words, the initial
guess is a uniform, flat, and positive definite map. For each
footprint, a correction factor C_i is computed as

\[ C_i = D_i / F_i, \]  

(1)

where

\[ F_i = \sum_j r_{ij} f_j \]  

(2)

and r_{ij} is the value of the ith footprint’s response function at
image pixel f_j. Therefore F_i is the current estimate of the ith
footprint’s flux given an image grid f_j.

A mean correction factor for the jth image pixel is com-
puted by projecting the correction factor for the footprints
into the image domain:

\[ c_j = \frac{\sum_i (r_{ij}/\sigma_i^2) C_i}{\sum_i (r_{ij}/\sigma_i^2)}. \]  

(3)

The weight attached to the jth correction factor for the jth
pixel is r_{ij}/\sigma_i^2, where \sigma_i is the a priori noise assigned to the
jth footprint.

The kth estimate of the image is computed by

\[ f_j^{(k)} = f_j^{(k-1)} c_j. \]  

(4)

In practice, when the footprint noise \sigma_i is not easily esti-
imated, an equal noise value for all footprints is assumed,
and the MCM is identical to the Richardson-Lucy algo-
rithm (Richardson 1972; Lucy 1974).

Table 1 shows the quantities represented by the ancillary
maps (Aumann et al. 1990). More detailed information on
the HIRES ancillary maps is available on-line from IPAC.
The correction factor variance (CFV) map gives an estimate
of the level of convergence at a certain pixel, measuring the
agreement of correction factors projected onto it from dif-
ferent detector footprints. The photometric noise (PHN)
map signifies the photometric noise at a pixel, propagated
from noise in the detector measurements. The coverage
(CVG) map is the sum of the response function grids of all
footprints within the field. The detector track (DET) map
registers the footprint centers and helps visualize the detec-
tor scanning pattern. Artifacts due to low coverage may be
diagnosed using the coverage maps. The remaining ancil-
ary maps provide diagnostics for other less frequent arti-
facts.

The effective beam size in HIRES images depends on the
response function and sample density in a complicated
fashion, and may vary by a factor of 3 over distances of
several arcminutes (Fowler & Aumann 1994). In order to
estimate the beam size at any given position and to see
typical variation over the field, “beam-sample maps”
(BEMs) are provided. These are produced from simulated
detector data based on actual coverage geometry, with the
simulation scene being a collection of spike sources against
a smooth background. An image of the reconstructed spikes
beam-sample map is generated with all the same pro-
cessing options as the actual image.

3.3. Subtraction of Zodiacal Emission

Zodiacal dust emission is a prominent source of diffuse
emission in the IRAS survey. The zodiacal contribution to
the observed surface brightness depends on the amount of
interplanetary dust along the particular line of sight, an
amount that varies with Earth’s position within the dust
cloud. Consequently, the sky brightness of a particular loca-
tion on the sky as observed by IRAS changes with time as
Earth moves along its orbit around the Sun. The different zodiacal emission level in different scan lines, if not subtracted out, can cause step discontinuities in the images for adjacent patches of sky observed at different times.

A physical model of the zodiacal foreground emission based on the radiative properties and spatial distribution of the zodiacal dust was developed by Good (1994). The IRAS Sky Survey Atlas (ISSA; Wheelock et al. 1994) made use of this model and subtracted the predicted zodiacal emission from the detector data before co-adding.

However, the IRAS detector data that serve as input to the IGA and other IRAS image products still contain zodiacal emission. A preprocessing method has been developed to bring the raw detector data flux to a common level with the ISSA images, effectively subtracting the zodiacal emission component. Nearby ISSA images (Paper I) were reprojected and mosaicked to cover the same field of view as a Level 1 plate ($7\arcmin \times 7\arcmin$, 1' pixels). A set of simulated data is then calculated from the mosaicked image by running the actual IRAS scan pattern through this image:

$$F_{i}^{\text{ISSA}} = \sum_{j} r_{ij} F_{j}^{\text{ISSA}}.$$  \hspace{1cm} (5)

The difference between these simulated data and the real data is then used to determine the local zodiacal emission

$$D_{i}^{\text{ZODY}} = \text{median} \ (D_{i} - F_{i}^{\text{ISSA}}),$$  \hspace{1cm} (6)

where the median is taken for nearby footprints in the same scan line with a total spatial range of $1\arcmin$. The zodiacal component is then subtracted,

$$D_{i}^{\text{NEW}} = D_{i} - D_{i}^{\text{ZODY}},$$  \hspace{1cm} (7)

and the new data are given as output for use in image construction. Because of the large spatial scale used in equation (6), the resulting zodiacal emission flux, $D_{i}^{\text{ZODY}}$, varies smoothly with a characteristic scale of $\sim 1\arcmin$. Therefore the zodiacal subtraction process does not interfere with the high spatial frequency information inherent in the raw data, which is needed for the image reconstruction and resolution enhancement.

3.4. Coordinate Transform and Reprojection

Each Level 1 plate covers a field of view of $7\arcmin \times 7\arcmin$, using a projection center local to the plate. The positions of detector footprints are stored in B1950 equatorial coordinates using Cartesian projection (Greisen & Calabretta 1997; FITS keywords RA-CAR, DEC-CAR):

$$x = \phi, \quad y = \theta,$$  \hspace{1cm} (8)

where $\theta$ and $\phi$ are angles in the native coordinate system (Euler angles with respect to local great circles). Each Level 1 plate has its own projection center (point C in Fig. 3).

For the IGA, the Cartesian projection (FITS keywords GLON-CAR and GLAT-CAR) with reference point at the Galactic center is convenient, in which case $l$ and $b$ map linearly to $x$ and $y$.

To transform the equatorial coordinates of footprints stored in the Level 1 archive to Galactic coordinates, the following steps are done in BrkDet: For each footprint centered at $P$, a unit vector OP is computed in the equatorial system, using the right ascension and declination of the projection center C and the $x$- and $y$-values of $P$ in the Cartesian projection system centered at C. Then the unit vector is rotated to the Galactic system, and $l$ and $b$ are obtained (see Fig. 3). Coordinates and fluxes of footprints falling in each $1.4\arcmin \times 1.4\arcmin$ field of view are grouped together and written out for the final image reconstruction step.

The tilt angle for each scan line, which is necessary for calculating the response function grid during image reconstruction, also needs to be redetermined in the Galactic coordinate system. For a scan line with $n$ footprints located at $(x_{i}, y_{i}), \ i = 1, \ldots, n$, this was done by fitting a straight line through the $x$- and $y$-values by minimizing $\sum_{i} \Delta_{i}^{2}$, where $\Delta_{i}$

Fig. 3.—Reprojection of footprint coordinates. **Left:** Right ascension and declination are known for the Level 1 plate center C, and $x$ (negative as shown here) and $y$ are known for the footprint P. The components of the unit vector OP are then computed in the equatorial system. **Right:** The vector OP is rotated to the Galactic system, from which $l$ and $b$ of the footprint are obtained.
is the distance from footprint $i$ to the line. This gives an estimate for the tilt angle $\Phi$ measured relative to the $x$ axis of

$$\Phi = \frac{1}{2} \arctan \frac{2 \sum (x_i y_i - \bar{x} \bar{y})}{\sum (x_i^2 - \bar{x}^2 - y_i^2 + \bar{y}^2)}, \tag{9}$$

where

$$\bar{x} = \frac{\sum x_i}{n}, \quad \bar{y} = \frac{\sum y_i}{n}. \tag{10}$$

For the molecular cloud fields (Orion, $\rho$ Oph, and Taurus-Auriga), B1950 equatorial coordinates were used (FITS keywords RA-CAR and DEC-CAR), and the Level 1 archive geometry was retained (no reprojection of the footprint data was performed). Each Level 1 plate ($7^\circ \times 7^\circ$ on $5^\circ$ centers) was divided into $3 \times 3$ subfields of $2.5 \times 2.5$ each on $2^\circ$ centers, with the projection center the same as the Level 1 plate center. Therefore the subfield images belonging to the same Level 1 plate are mosaicable without the need of reprojection, but special care needs to be taken when mosaicking subfields from different Level 1 plates. The use of Cartesian projection for equatorial coordinates is closest to the native format of the IRAS data, but differs from the more commonly used -SIN projection by about 0.5 pixel at the edge of a Level 1 plate.

3.5. Issues Related to Flux Bias

Astronomical images often contain backgrounds that need to be subtracted from the source of interest, such as instrumental offsets, sky backgrounds, or, in the case of the IRAS data, zodiacal light or diffuse Galactic backgrounds. This means that the zero level of an image depends on the application, which specifies what part of the signal is considered source or background. Taking advantage of this arbitrary nature of the background level, many resolution enhancement schemes add a constant value to the image, chosen to optimize the performance of the algorithm.

Because of the nonlinear nature of the MCM algorithm, the spatial resolution achieved by HIRES processing is not invariant under application of an additive flux bias

$$D_i \rightarrow D_i + F_{\text{BIAS}}. \tag{11}$$

Generally, the closer to zero the data, the higher the resolution obtained. Alternatively, the more iterations, the higher the resolution obtained. However, the MCM algorithm is unstable to negative data values. The optimum performance is obtained by using data with small but non-negative values. Therefore, to maximize both spatial resolution and throughput, a flux bias is computed and applied before the image reconstruction step to bring the data close to zero, in order to achieve higher resolution at a given iteration. Since the flux bias is only important during the image-processing step, the applied flux bias is subtracted from the result image so that the surface brightness of the output image matches the original data. For IGA processing, the flux bias is calculated in the BrkDet step, using the negative of the first percentile from the flux histogram in each $1^\prime 4 \times 1^\prime 4$ field. In other words, the first percentile is used as the zero point in subsequent HIRES processing. The detector data having fluxes below the first percentile are discarded, since negative data cause instabilities in the algorithm.

4. CHARACTERISTICS OF THE IMAGES

In this section “IGA(1)” denotes the first-iteration IGA images and “IGA(20)” the 20th-iteration images. The resolution, photometric accuracy, positional accuracy, surface brightness accuracy, mosaic property, and residual hysteresis effect of the images are discussed and quantified.

4.1. Resolution

The diffraction limit of the IRAS 0.6 m telescope is 50" and 84" at 60 and 100 $\mu$m, respectively. The effective beam size of the co-added IRAS data is much larger, typically $20 \times 4.7$ at 60 $\mu$m and $3.8 \times 5.4$ at 100 $\mu$m, because of the large and rectangular IRAS detectors. The MCM algorithm makes use of the geometric information in the large number of redundant tracks with differing scan angles to extract higher spatial resolution, which in some cases can approach the diffraction limit of the telescope (Rice 1993). The effective beam size in HIRES images depends on the response function and sample density in a complicated fashion. The resolution also depends on the magnitude of the point source relative to the effective background (see also § 3.5).

The spatial resolution of a given field can be estimated from the corresponding BEMs produced from simulated data (see also § 3.2 and Table 1). To generate the BEMs, artificial point sources are added to the smoothed data, which then undergo HIRES processing. Specifically, point sources are identified and removed from the IGA(20) image: the image, further smoothed, provides a model background to which regularly spaced (12") point sources are added. The magnitude of the planted point-source spikes is adjusted according to the dynamic range of the IGA(20) image: the pixel intensity is set to 20(99% quantile — 50% quantile) of the IGA image histogram (plus the background). The numerical value of 20 approximately converts from flux per unit beam to flux per unit pixel. This arbitrary choice of flux is meant to represent a typical point source that is strong enough with respect to the local Galactic background to benefit from high-resolution processing. A set of simulated data is then generated from the artificial image, from which the BEM is reconstructed through HIRES. A Gaussian profile is fitted to the reconstructed point sources in the BEMs, and the FWHM values along the major and minor axes are taken as the measure for the resolution achieved.

The typical resolution of the IGA(20) images is $1.0 \times 1.7$ at 60 $\mu$m and $1.7 \times 2.2$ at 100 $\mu$m, which represents a substantial improvement over the co-added images. Figure 4 demonstrates the dependence of the resolution on longitude across the Galactic plane. The plotted major- and minor-axis FWHMs were averaged over latitude. Two obvious dips are seen in the major-axis curves, both in 60 and 100 $\mu$m, near $l = 10^\circ$ and $l = 280^\circ$. These two areas in the Galactic plane featured near-perpendicular intersecting scan lines in the IRAS survey, and the extra geometric information in the data gives rise to the increased resolution.

To investigate the dependence of resolution on source strength relative to background level, BEMs were generated for simulated point sources ranging from 1 to 10,000 Jy in strength. The background intensity levels determined for the test field near $l = 120^\circ$ were 53.94 and 165.05 MJy sr$^{-1}$ at 60 and 100 $\mu$m, respectively. Integrated over the effective solid angles of the IRAS detectors, $6.25 \times 10^{-7}$ and $13.54 \times 10^{-7}$ sr, the detector fluxes from the local background become 33.7 and 223 Jy, respectively. To find the
Fig. 4a—Dependence of beam size on Galactic longitude for (a) 60 $\mu$m and (b) 100 $\mu$m. The top and bottom curves in each figure are the FWHM of the Gaussian fitted beam along the major and minor axes, respectively. The regions in the Galactic plane that had intersecting scan lines in the IRAS survey are seen as two dips in the major axis curves (better resolution obtained from the extra geometric information).

Effective background during HIRES processing, the flux bias value from the FITS header (see § 3.5) can be converted from W m$^{-2}$ to Jy through division by the conversion factors $2.58 \times 10^{-14}$ and $1.00 \times 10^{-14}$ at 60 and 100 $\mu$m, respectively, and then subtracted from the corresponding local background flux. In this test case, zero flux bias was used, giving simply 33.7 and 223 Jy for the processing background at 60 and 100 $\mu$m, respectively. We emphasize that the spatial resolution depends on the effective background level during HIRES processing, namely, the local background minus the flux bias value. A quick way to estimate the processing background in IGA images is to find the minimum intensity value in the image (which will be close to the flux bias value) and then subtract it from the local background. If necessary, convert from intensity to flux in janskys using the detector solid angles given above.

The results plotted in Figure 5 show that the IGA(20) resolution is at least a factor of 2 better than the co-added IGA(1) resolution. Also, the resolution significantly improves for point sources stronger than the processing background of 33.7 and 223 Jy at 60 and 100 $\mu$m, respectively. Furthermore, when the source-to-background contrast reaches about 20, the achieved resolution becomes insensitive to the background. The resolution in other fields/regions should behave in the same qualitative fashion when the local processing background is computed as above.

Figure 5 shows the additional effect that offset compensation destriping (Paper I; see also § 5.1) gives comparable but slightly poorer resolution than standard HIRES destriping, especially along the major axis (cross scan) direction.

The number of iterations also affects the spatial resolution, although in practice most of the improvement in spatial resolution is gained within the first 10 iterations. For IGA processing, 20 iterations was chosen in a trade-off between speed of processing and artifact development versus spatial resolution. However, for strong sources, regions of high coverage, or regions with favorable scan-line geometry, data reprocessing with additional iterations

Fig. 5b—Dependence of beam size on source flux. Resolution significantly improves for sources stronger than the local processing background of 33.7 Jy at 60 $\mu$m and 223 Jy at 100 $\mu$m in the test field. Results with destriping (solid lines) and without destriping (dashed lines) show that the IGA destriper has resolution comparable to that of the standard HIRES routine, with the most notable difference along the 100 $\mu$m major axis.
yields better spatial resolution (Rice 1993; Hurt & Barsony 1996).

In addition, note that the beams of the IGA images are not Gaussian. The most prominent deviation of the beam from a two-dimensional Gaussian is due to the ringing artifact (§ 5.2). Rice (1993) gives a detailed account of the HIRES beams.

4.2. Photometric Accuracy

To test the photometric accuracy, 35 relatively isolated point sources (with a well-defined background) were selected. All sources have flux of more than 10 Jy and are spatially unresolved, as measured by the correlation coefficient (CC) flag in the IRAS Point Source Catalog, Version 2 (1988). Fluxes were measured using an aperture photometry program developed at IPAC, in which the median pixel intensity within an annulus (radius 5”–7”) centered at the point-source position (taken from the PSC) is taken as the background intensity. Two estimates of the point-source flux are then made, using the total fluxes within 5” and 7” radius from the PSC position (minus the background intensity times the number of pixels). For sources chosen for the photometry test, these two values are usually sufficiently close to each other to indicate a well-defined background level. The average of these two values is taken as the point-source flux from the IGA image and compared against the value from the PSC. The computed fluxes are given in Table 2, while Table 3 summarizes the statistical correlation between IGA and PSC flux values.

An overall offset (12%) between the IGA(1) and PSC fluxes is seen at 60 μm that is, however, not present at 100 μm (1%). One possible explanation for the 60 μm offset is the different data calibration used, specifically, the hysteresis correction. The IGA and other recent IRAS image products are based on the final IRAS Pass 3 calibration, described in detail in the ISSA Explanatory Supplement (Wheelock et al. 1994). This calibration includes hysteresis correction at both 60 and 100 μm (see § 4.8). The PSC, however, is based on IRAS Pass 2 calibrated raw detector

### Table 2

| IRAS Designation | PSC Galactic Position | PSC Flux 60 μm | IGA Flux 60 μm |
|------------------|-----------------------|----------------|----------------|
|                  | 0.500 | 1.000 | 0.990 | 0.980 |

### Table 3

| Photometry Comparison Statistics | Ratio | Mean | Standard Deviation |
|----------------------------------|-------|------|--------------------|
| 60 μm band:                      |       |      |                    |
| IGA(1)/PSC .................. | 1.12  | 0.11 |
| IGA(20)/PSC .................. | 1.14  | 0.13 |
| IGA(20)/IGA(1) ................| 1.02  | 0.07 |
| 100 μm band:                     |       |      |                    |
| IGA(1)/PSC .................. | 1.01  | 0.16 |
| IGA(20)/PSC .................. | 1.11  | 0.19 |
| IGA(20)/IGA(1) ................| 1.10  | 0.15 |
data that were later corrected to the Pass 3 calibration. One significant difference is the way in which hysteresis was treated: the PSC applied a hysteresis correction only at 100 μm (IRAS Explanatory Supplement 1988). The lack of hysteresis correction at 60 μm for PSC sources, which is particularly important for the Galactic plane, where hysteresis is strongest, provides one explanation for why there is a systematic offset at 60 μm, but not at 100 μm, between the IGA(1) and PSC fluxes.

In addition, Table 3 shows that there is a growth in flux from the first to the 20th iteration that is small (2%) for the 60 μm band but significant (10%) for the 100 μm band. Analysis shows that the effect is caused by the depression of the background by the ringing artifact. In the Galactic plane, where the background emission is strong and structured, the largest contributor to the flux uncertainty is the background level systematically to source flux is 1.8 at 60 μm and 1.8% at 100 μm. In addition, the background level systematically decreases on average by 1.7% for 60 μm and 1.8% at 100 μm because of ringing in the 5′–7′ annulus. This leads to an apparent flux increase from one to 20 iterations of 1.8 × 1.7% ~ 3% at 60 μm and 6.7 × 1.8% ~ 12% in the 100 μm band, which agrees with the results of Table 3.

To compensate for the systematically low background levels, we recomputed the IGA(20) source fluxes using IGA(1) background levels. The resulting fluxes show no systematic offset [mean of IGA(20)/IGA(1) = 0.99] and better correlation with IGA(1) fluxes (standard deviation = 0.10). This technique of using IGA(1) backgrounds to calculate IGA(20) fluxes is recommended whenever the most stable and accurate photometry is required.

The growth in flux found for IGA point sources is not a universal property of HIRES processing. In a HIRES study of interacting Galaxy pairs, Surace et al. (1993) found that HIRES fluxes systematically decreased by 20% from iteration 1 (FRESCO) to iteration 20, a result they attributed to the small, extended nature of the sample. Since the MCM algorithm fundamentally conserves flux, the effect appears because of either a systematic increase in the background or a redistribution of flux outside the photometric aperture. The use of the IGA(1) background to compute the IGA(20) flux is a technique that can help determine the cause of such systematic trends.

Figure 6 plots the dependence of the IGA(20)/PSC flux ratio on the PSC flux. There is no trend with source flux, apart from the previously discussed offsets.

4.3. Size-dependent Flux Correction

The estimation of the flux for extended sources ( > 4′–40′) may involve a size-dependent flux correction, also known as the AC/DC correction. The IRAS detectors have a dwell-time–dependent responsivity change. Hence, the gain changes as a function of source size: at the IRAS survey speed of 3.85 s⁻¹, the gains leveled off for structure on the order of 40′ in extent. This effect was band dependent and was largest at 12 μm. Thus, there are two calibrations for the IRAS data, the calibration appropriate for point sources, known as the AC calibration, and the calibration appropriate to very extended structure, known as the DC calibration. To bring point-source fluxes measured from DC-calibrated products to the AC (same as the PSC) calibration, the fluxes must be divided by 0.78, 0.82, 0.92, and 1.0 at 12, 25, 60, and 100 μm, respectively. The IGA uses the AC calibration, while the ISSA images are on the DC scale.

Point-source fluxes obtained by aperture photometry with appropriate background subtraction on AC-calibrated images such as the IGA should be consistent with the PSC. However, neither calibration is strictly correct for structure on spatial scales intermediate between point sources and 30′ in size. Intermediate-scale corrections and uncertainties can be estimated from the plots in the IRAS Explanatory Supplement (1988).

4.4. Calibration Uncertainty

The flux measurement uncertainties derived from point sources (Table 3) for the IGA(1) images are 11% and 16% at 60 and 100 μm, respectively. Given the isolated nature of the sources, these uncertainties represent a best case. A better estimate of the measurement uncertainty in more complex regions is given by Fich & Terebey (1996), who find 17% and 18% for the flux measurement uncertainty at

---

**Fig. 6a**

**Fig. 6b**

**Fig. 6a**—IGA(20)/PSC flux ratio vs. PSC flux. There is no trend with source strength. Offsets are discussed in the text. Thirty-five sources are plotted in each wavelength band.
60 and 100 μm, respectively, for a sample of outer Galaxy star-forming regions.

In some cases, systematic instrumental effects also contribute significantly to the flux uncertainty. The IRAS calibration for point sources is accurate, albeit affected by residual hysteresis at 60 and 100 μm in the Galactic plane. As described in the previous section, there is a 12% systematic uncertainty at 60 μm between the IGA(l) and PSC. At 100 μm the uncertainty due to residual hysteresis is less than 5% over most of the Galactic plane, but it approaches a maximum of 20% near the Galactic center.

For small but extended (5°–20°) sources, the situation is complex. The size but extended flux correction, the so-called AC/DC effect (see § 4.3) is typically about 10% or less. However, the detector response is not well behaved for bright, extended sources: above 100 Jy the IRAS Explanatory Supplement quotes uncertainties of 30% at 60 μm and 70% at 100 μm (IRAS Explanatory Supplement 1988).

Prominent in the IGA is diffuse Galactic emission associated with H I, which varies on a scale of a few degrees. The IRAS/Cobe comparison gives an indication of the calibration uncertainty. Over angular scales larger than 10°, the IRAS calibration differs systematically from that of COBE by 13% and 28% at 60 and 100 μm, respectively (Wheelock et al. 1994).

The ISSA survey was used as a large-scale surface brightness truth table for the IGA. This implies that defects or uncertainties introduced by the ISSA processing extend to the IGA as well (see § 5.4). At 60 and 100 μm, residuals associated with zodiacal emission model can approach 1–2 MJy sr−1 in the ecliptic plane (Galactic center and anticenter directions) but are typically far less (see, e.g., Fich & Terebey 1996). For more information consult the ISSA Explanatory Supplement (Wheelock et al. 1994).

4.5. Positional Accuracy

IRAS Point Source Catalog positions were used as truth tables for a positional accuracy test of the IGA. Positions were computed for the same sample of 35 sources used in the photometry comparison. For each source, a circular area with radius 5° was defined (centered at the PSC position), and the area’s flux-weighted centroid was taken as the point-source position implied by the IGA image to be compared against the PSC position.

Table 4 shows the result of the comparison. For the 60 μm band, the distances between the IGA position and PSC position have an average of 7.6 and a standard deviation of 5.6, while for 100 μm there is a 7.1 ± 4.1 difference.

The PSC reports error ellipses corresponding to the 95% confidence level for source positions. The major and minor axes of the error ellipse correspond approximately to the cross scan and in-scan directions. For each source, we projected the IGA position along the major and minor axes of the error ellipse centered at the PSC position. The mean

| IRAS DESIGNATION | PSC l | PSC b | IGA 60 μm l | IGA 60 μm b | IGA 100 μm l | IGA 100 μm b | 60 μm DISTANCE (arcsec) | 100 μm DISTANCE (arcsec) |
|------------------|-------|-------|------------|------------|------------|------------|-----------------------|-----------------------|
| Table 4          |       |       |            |            |            |            |                       |                       |
| Note:—Latitudes and longitudes (l, b) measured in degrees.
deviations from the PSC position were found to be similar along the major- and minor-axis directions, and do not scale with the length of the major and minor axes. This indicates the positional errors produced by the MCM algorithm come from nonsystematic effects unrelated to the IRAS scan pattern and detector geometry.

4.6. Surface Brightness Accuracy

To test the surface brightness of the zodiacal light-subtracted IGA images, they were rebinned to match the ISSA geometry and compared pixel by pixel against the ISSA images. The standard deviation of the 1.5 pixel-by-pixel difference is less than 6% for IGA(1) versus ISSA and less than 12% for IGA(20) versus ISSA. No systematic offset was found between the IGA and ISSA data. See Paper I for details.

4.7. Mosaic Property

The geometry of the IGA images allows them to be mosaicked without any reprojection; hence no smoothing is required, and the original resolution can be retained in the mosaicked images. To reduce edge discontinuities, the images should first be cropped to 1° × 1° from 1°4 × 1°4 with the centers unshifted before mosaicking. No offset needs to be applied to the different subfields. In most cases the mosaicked image is seamless to the human eye.

Quantitatively, within a chosen Level 1 plate in the W3, W4, and W5 region, pixel intensity ratios were calculated for edges of width 1 pixel covered by neighboring subfields, after cropping the subfields to slightly larger than 1° × 1°. Table 5 summarizes the intensity-ratio statistics for both the first- and 20th-iteration images. A total of 10122 pixels in 42 1° edges were used in the calculation. For 20th-iteration images, the standard deviation of the ratio amounts to 0.51% and 0.23% for bands 3 (60 μm) and 4 (100 μm) respectively. Intensity ratio statistics were also calculated for boundaries that cross Level 1 plates, using a total of 8194 pixels in 34 1° edges. Again, for 20th-iteration images, the standard deviations are 1.5% and 0.46% for band 3 and 4. The match is worse than that of intraplate edges, since the zodiacal subtraction was done separately for each Level 1 plate (see § 3.3).

The better boundary match (smaller deviation) in band 4 can be understood from the poorer resolving power of HIRES in band 4 than in band 3, which decreases the resolution difference between subfields caused by the different flux bias levels used in the image reconstruction process (see § 3.5).

| Wavelength (μm) | Cross Level 1 Plate? | Number of Pixels | Standard Deviation of Ratio (%) |
|-----------------|----------------------|------------------|--------------------------------|
| First iteration:|                      |                  |                                |
| 60 ........ yes  | 10122                | 0.14             |
| 60 ........ no   | 8194                 | 0.52             |
| 100 ....... no   | 10122                | 0.08             |
| 100 ....... yes  | 8194                 | 0.18             |
| Twentieth iteration:|                   |                  |                                |
| 60 ........ yes  | 10122                | 0.51             |
| 60 ........ no   | 8194                 | 1.5              |
| 100 ....... no   | 10122                | 0.23             |
| 100 ....... yes  | 8194                 | 0.46             |

Fig. 7.—Illustrations of the hysteresis effect. (a) Internal flashes of known magnitude were used at the starting and ending points of a scan line in an effort to determine the responsivity change (dashed line, assumed responsivity). The true responsivity, including the photon-induced responsivity enhancement, is shown by the dotted curve. (b) Deviation of computed fluxes for ascending and descending scans from the true values. (c) Variation of the ascending scan/descending scan flux ratio with Galactic latitude. (Adapted with changes from Fig. VI.B.2, IRAS Explanatory Supplement 1988.)

4.8. Residual Hysteresis

The IRAS detectors showed photon-induced responsivity enhancement, known as the hysteresis effect, especially in the 60 and 100 μm bands. The effect is prominent when the scan lines pass the Galactic plane (e.g., IRAS Explanatory Supplement 1988) and thus a concern for the IGA survey. The final IRAS Pass 3 calibration, on which both the IGA and ISSA are based, employed a physically based detector model to correct for the hysteresis. However, the technique could not correct variations that were more rapid than ~ 6° in spatial scale (Wheelock et al. 1994). This section quantifies the residual hysteresis near the Galactic plane in the ISSA data, which should also describe the residual hysteresis present in the IGA.

In the IRAS survey, a given region can be covered by up to three scans carried out at different times, known as hours-confirming (HCON) scans. HCON 1 and HCON 2 were separated by up to several weeks, while HCON 3 was taken roughly 6 months later. This meant HCON 3 usually passed the Galactic plane while going in the direction opposite to that of HCON 1 and 2, since IRAS followed a Sun-synchronous orbit and the telescope always pointed approximately 90° away from the Sun.

Figure 7 illustrates the effect on computed flux values from the different HCONs that is caused by the photon-induced responsivity change. At the starting and ending points of a scan, IRAS detectors were lit up by an internal calibration flash, which anchored the responsivity of the detectors at these two points. In the early calibration

3 Most (96%) of the sky was covered by at least two HCONs, and two-thirds of the sky was covered by three HCONs.
schemes, the response was assumed to change linearly between the two calibration flashes. This scheme tracks the true detector response imperfectly when the scan passes through bright regions like the Galactic plane (Fig. 7a).

Figure 7b illustrates the resulting deviation of the computed fluxes from the true values. For example, the computed flux of a 1 Jy source differs from 1 Jy in a systematic way that depends both on Galactic latitude and the scanning direc-

Hysteresis may also be present in the $l = 60^{\circ}$ and $300^{\circ}$ graphs but is below the 5% level. Other small (<5%) but systematic variations in the ISSA ratio are likely due to destriping differences.

**Fig. 8.**—Residual hysteresis in the IGA. **Left:** Average intensity vs. Galactic latitude at $l = 0^{\circ}$, $60^{\circ}$, and $120^{\circ}$. **Right:** Ratio of ISSA intensities from oppositely directed scans. The hysteresis signature (Fig. 7c) is clearly seen near $(l = 0^{\circ}, b = 0^{\circ})$ with an amplitude of about 20% at 100 $\mu$m (top right).
Figure 7c shows the ratio of fluxes determined from descending and ascending scans; the ratio should equal unity for perfectly calibrated data.

To quantify the residual hysteresis effect in the ISSA images, ISSA images made from HCON 1 and 3 were compared at $l = 0^\circ, 10^\circ, 20^\circ, 60^\circ, 120^\circ, 180^\circ, 240^\circ, 300^\circ, 340^\circ$, and $350^\circ$. Images covering $\pm 5^\circ$ latitude and $\pm 2.5^\circ$ longitude were first smoothed with a $4.5$ (3 pixel) boxcar kernel to simulate roughly the ISSA resolution and then averaged over $5^\circ$ longitude intervals for each latitude, which gives the average intensity with increased signal-noise ratio. Pixel intensity ratios (HCON 1/HCON 3) were computed and averaged over each $5^\circ(l) \times 4.5(b)$ box.

Figures 8 and 9 plot the average intensity (left) and...
HCON1/HCON3 intensity ratio (right) versus Galactic latitude. Plots made versus Galactic latitude are sufficient for our purpose, although, strictly speaking, ecliptic latitude better represents the IRAS scanning direction. The hysteresis signature is seen clearly near \( l = 0^\circ \) with an amplitude of about 20\% at 100 \( \mu \)m. As expected, the peak of the average-intensity plot corresponds to the appearance of the hysteresis signature in the ratio plot. Hysteresis may also be present in the \( l = 60^\circ \) and \( 300^\circ \) graphs, but below the 5\% level. Other small (<5\%) but systematic variations in the ISSA ratio are likely due to destriping differences. Figure 10 shows the maximum and minimum HCON 1/HCON 3 intensity ratio found at each longitude. At 100 \( \mu \)m and within 60° of the Galactic center, residual hysteresis becomes larger than systematic differences from destriping and noise.

5. ARTIFACTS

A general description of artifacts produced by HIRES processing is available on-line from IPAC.

5.1. Stripping Artifacts

Stripes were formerly the most prominent artifacts in HIRES images. HIRES takes the IRAS detector data as input, and if the detectors were not perfectly calibrated, HIRES would try to fit the gain differences in the detector scans by a striped image. The striping builds up in amplitude and sharpness during the HIRES iterations, as the algorithm refines the “resolution” of the stripes.

An algorithm was developed to eliminate the striping artifacts. The basic technique involved is to estimate gain variations in the detectors and compensate for them within the image reconstruction process. Observation of the Fourier power spectrum of the resulting images shows that the algorithm eliminates the striping signal after roughly 10 iterations. Therefore, striping artifacts have been virtually eliminated from the IGA images. See Paper I for details and examples.

5.2. Ringing Artifacts

“Ringing” is a prominent artifact in the IGA images. When a point source is superposed on a nonzero background, the artifact known as ringing or ripples appears in many image reconstruction algorithms. In Fourier language, the reconstruction process tries to make the image agree with the true scene in the low spatial frequency components (data constraint), without access to the infinitely high spatial frequencies inherent in the point-source scene. The magnitude of the ringing depends on the strength of the point source, the level of the residual background intensity (after the application of flux bias), and the detector scan pattern. For nonlinear algorithms (such as MCM), the dependence is complicated and difficult to quantify.

The ringing artifact adds uncertainty to the level of background emission around point sources, thus hindering photometric accuracy (see § 4.2). The ringing may also interfere with the lower intensity structures present in the background. Numerous approaches have been developed in the field of astronomical image reconstruction to overcome the difficulty (Frieden & Wells 1978; Lucy 1994; Bontekoe et al. 1994).

At the time when IGA image production started, no satisfactory algorithm was found for the purpose of ringing suppression for the atlas (see Paper I) that preserved photometric integrity and did not require extra prior knowledge (such as the positions and fluxes of point sources) as input. Therefore the IGA images were produced with the standard MCM algorithm (along with gain-compensation destriping), which has the advantage of proved flux conservation. Ringing thus remains as the only major artifact in the IGA images.

Figure 11 demonstrates the ringing artifact around several point sources. At the first iteration, the point sources are poorly resolved and no ringing is seen. At the 20th iteration, low-intensity rings (the shape of which is roughly elliptical and determined primarily by the detector response functions) surround the point sources. Farther away from each point source, a brighter ring is usually visible.

An iterative algorithm was later developed (but too late for IGA production) that aims to maximize the relative Burg entropy between modeled and measured data (Cao 1997; Cao et al. 1997). The algorithm was run on several test fields and was found to suppress ringing effectively and give good photometry. A partial-convergence proof has also been found. The algorithm has been applied to the bright infrared star \( \alpha \) Ori with good results (Noriega-Crespo et al. 1997). At 60 \( \mu \)m, the morphology of a 7' bow shock...
shows dramatic improvement. On a smaller scale the ringing is suppressed to the level at which diffraction spikes surrounding the star become visible.

5.3. Glitches

Glitches are caused by hits on individual detectors by cosmic rays or trapped energetic particles. The IPAC utility LAUNDR passes the flux values in each scan line through two filters, one detecting point sources and one glitches. If the ratio of the power in the point-source filter to that in the glitch filter is greater than a certain threshold (default is 1), the phenomenon is taken to be a point source, otherwise a glitch.

In a few regions, found by visual inspection, glitches were mistaken for point sources and leaked into the image reconstruction stage. In such cases, reprocessing with a higher point-source-to-glitch power threshold in LAUNDR sufficed to eliminate the artifact. However, it is not guaranteed that all such artifacts have been uncovered.

Remaining glitches in the IGA are rare but fairly easy to identify. In first-iteration images, a glitch traces out the shape of a single detector response function and has a different profile from that of a point source (a glitch being narrower than a point source). At the 20th iteration, a glitch takes on a "broken up" shape, showing structures finer than the physically achievable resolution, as shown in...
Demonstration of the glitch artifact. The elongated feature to the upper left of the field center is a glitch. The glitch is shown at the first and the 20th iteration by (a) and (b), respectively. At the 20th iteration, the glitch takes on a "broken up" shape. Black is brighter in the images. Field center is $l = 7\degree$, $b = 1\degree$; field size is 1¿ on each side.

Figure 12, while a point source is usually characterized by the ringing artifact. These differences provide a way to distinguish between real point sources and glitches in the images.

5.4. Discontinuities

The ISSA images employed both global and local destriping techniques, and the local destriping left some amount of intensity discrepancy between adjacent ISSA plates (Wheelock et al. 1994).

When reprojecting and mosaicking the ISSA images to the Level 1 geometry (against which the detector data are calibrated and zodiacal emission removed), care was taken to adjust the cropping of neighboring ISSA plates to minimize the discontinuity. In a small number of cases, however, some discontinuity remained that eventually affected the final IGA image. The discontinuity is not seen in the first iteration but is sharpened and visible in the 20th. Less than
Fig. 14—IRAS Galaxy Atlas images of the Galactic plane at 60 μm. Longitudes 0°–40° show a variety of star-forming regions, H II regions, and the diffuse IR emission associated with the Galactic H I layer. Each panel covers 11° in longitude and −1°7 < b < 1°7 in latitude, with the logarithmic stretch chosen to emphasize structure. Black is brighter in the images.

0.5% of all the 1°4 × 1°4 subfields are affected by this artifact. Figure 13 shows one instance of the discontinuity across a subfield (60 μm, 20th iteration). The difference in intensity is approximately 5 MJy sr⁻¹.

The different flux-bias values used in different 1°4 × 1°4 fields also affects the mosaicking property of nearby images, since different resolutions are achieved in the overlap region from the two images. See §4.7 for a detailed discussion.
5.5. Coverage Artifacts
After the processing of the minisurvey ($-1^\circ.7 < b < 1^\circ.7$), it was found that the data-processing window was too small, causing coverage depletion and unreliable structure near window boundaries. A border of at least 5' should be cropped from images within the minisurvey. For the extended survey ($1^\circ.3 < |b| < 4^\circ.7$), a larger window ($1^\circ.67 \times 1^\circ.67$) was used in BrkDet to avoid coverage depletion.

The use of a flux bias (see § 3.5) to bring the data closer to zero during processing, and thereby increase throughput,
was necessary but led to a subtle artifact. The IGA processing subtracted a flux bias from the data corresponding to the first percentile from the flux histogram. Data below the threshold were discarded. This procedure effectively assumes that the lowest 1% of the data represent noise which is not always justified. In fields that had structured backgrounds, particularly at 100 μm, it was found that discarding data resulted in severe coverage depletion at the intensity minimum of an image. All images for which the coverage fell below a value of 5 in the coverage map

**Fig. 16.**—Galactic plane at 60 μm, longitude 280°–320°
were reprocessed with a smaller flux bias. However, problems such as anomalous structure near the image intensity minimum may remain. The ancillary CVG map can help diagnose problems associated with inadequate coverage.

The HIRES algorithm can cause systematic positional shifts if the coverage changes abruptly. In cases for which positional accuracy is important, the CVG maps should be checked for the presence of discontinuities or steep (less than $5'$) coverage gradients. The sense of the artifact is to shift source positions systematically down and along the coverage gradient.
6. EXAMPLE IMAGES

To illustrate the image quality of the IGA, mosaics at 60 μm of a restricted latitude range (-1°7 < b < 1°7) were made for regions between Galactic longitude 280° and 80° (approximately 16% of the total area covered by the atlas) and are shown in Figures 14–17. Most of the emission is from star-heated dust and shows a wealth of star-forming regions, H II regions, and diffuse infrared cirrus (see, e.g., Fich & Terebey 1996). Extended Galactic infrared emission, long associated with the Galactic H I layer, is readily apparent as enhanced emission near the midplane (e.g., Terebey & Fich 1986; Sodroski et al. 1989). Each panel covers 11°5 in longitude. The dynamic range is much larger than can be displayed; therefore the stretch is logarithmic, with the range chosen separately for each panel to emphasize as much structure as possible.

The complete set of available images and ancillary maps is illustrated for an individual 1°4 × 1°4 field near IC 1805 in the second Galactic quadrant. Figure 18 shows the co-added and resolution-enhanced images, as well as beam-sample maps. Figure 19 shows the associated diagnostic
ancillary maps (see § 2). The source IC 1805, an OB cluster exhibiting strong winds and ionizing radiation, is located near the brightest FIR emission. To the north, a cloud suffering erosion from the IC 1805 cluster appears in the infrared as a comet-shaped arc (Heyer et al. 1996). An \textit{H}\textsubscript{i} survey of the region shows that the OB cluster appears to fuel a Galactic chimney (Normandeau, Taylor, & Dewdney 1996).

7. SUMMARY

The \textit{IRAS} Galaxy Atlas, an atlas of the Galactic plane ($4.7 < b < 4.7$) and the molecular clouds in Orion, $\rho$ Oph, and Taurus-Auriga, has been produced at 60 and 100 $\mu$m from \textit{IRAS} data. The HIRES processor, which incorporates the MCM resolution enhancement algorithm, was ported to the Caltech parallel supercomputers for this CPU-intensive task.

At 60 $\mu$m the typical resolution is $20 \times 4.7$ for co-added IGA(1) (1 iteration) images and $10 \times 1.7$ for resolution-enhanced IGA(20) images, which compares favorably with the 50' diffraction limit of the \textit{IRAS} telescope and the 5' resolution of the previously released \textit{IRAS} Sky Survey Atlas (ISSA). At 100 $\mu$m, where the diffraction limit is 84', the
typical IGA(1) resolution is $3.8 \times 5.4$ and IGA(20) resolution is $1.7 \times 22$, again good compared with the 5' ISSA resolution.

The IGA contains images, beam-sample maps to assess local resolution, and ancillary diagnostic maps in FITS format. Field sizes are $1.4 \times 1.4$ in the Galactic plane and $2.5 \times 2.5$ in the Orion, $\rho$ Ophiuchus, and Taurus-Auriga molecular clouds.

Zodiacal emission has been removed from the images. The result is images that are easily mosaicked by simple cropping and contain negligible seams. Stripes in the images, long the limiting artifact of standard HIRES processing, have been eliminated by algorithmic improvements to the destriping procedure. "Ringing" around point sources is the major artifact remaining in the IGA images.

Photometry on the IGA images is accurate to roughly 25%, depending on the wavelength and size scale, while positions agree with the IRAS Point Source Catalog to better than an 8" standard deviation.

The IGA, combined with other Galactic plane surveys of similar (~1') resolution, provides a powerful tool for multi-wavelength studies of the interstellar medium, star formation, and the large-scale structure of our Galaxy.

We are indebted to Ron Beck and Diane Engler, who carried out the production and recurring rounds of reprocessing of the IGA. We thank John Fowler for his help with the YORIC software. The project received support from the Astrophysics Data Program of the National Aeronautics and Space Administration under contract NAS 5-32642. This work was performed in part at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration. The atlas production was performed in part using the Intel Paragon operated by Caltech on behalf of the Concurrent Supercomputing Consortium.
