We investigate the ratchet dynamics of nonlinear Klein-Gordon kinks in a periodic, asymmetric lattice of point-like inhomogeneities. We explain the underlying rectification mechanism within a collective coordinate framework, which shows that such system behaves as a rocking ratchet for point particles. Careful attention is given to the kink width dynamics and its role in the transport. We also analyze the robustness of our kink rocking ratchet in the presence of noise. We show that the noise activates unidirectional motion in a parameter range where such motion is not observed in the noiseless case. This is subsequently corroborated by the collective variable theory. An explanation for this new phenomenon is given.

I. INTRODUCTION

The study of transport mechanisms at the mesoscale level is of great importance nowadays. Specifically, the so-called ratchet systems have shown to be proper candidates for explaining unidirectional motion to biological systems [1], and have important physical applications for nano- and micro-scale technologies [2–4]. Many of these models have been developed in the simple picture of point-like particles [5–7] (see the reviews [8–10] for details). Such scenario has been subsequently generalized to spatially extended systems [11–13], where much attention has been paid to situations where the net motion arises through time-symmetry breaking [14–16]. This kind of ratchet phenomenon has been recently observed in long Josephson junction (LJJ) devices [17]. Another possibility that has been considered in the literature is that of nonlinear Klein-Gordon system where the on-site potential is ratchet-like [16]. Notwithstanding, to our knowledge the case of spatial-symmetry breaking by inhomogeneities has not been studied in depth. One such study has been done by Carapella et al. who used an inhomogeneous magnetic field to create an effective inhomogeneous junction profile for fluxons to propagate [18]. Recently an alternative to the generation of motion for extended systems with a disorder in the chain has been proposed [19]. The novelty of the procedure is the design of a ratchet device from a lattice of point-like inhomogeneities. For this system, net motion arises from the interplay between disorder and nonlinearity of the nonlinear systems [20].

In this paper we elaborate on the preliminary results reported in [18]. Our aim is to carry out an in-depth analysis of the system, including a careful comparison to related point-like ratchets [21] and an extension of our results, originally obtained for the sine-Gordon (sG) model, to other nonlinear Klein-Gordon models such as the $\phi^4$ equation. Additional motivation for this work arises from research on models of energy propagation along microtubule filaments inside the cells [21]. This application is specially interesting in view of the possible connection with the dynamics of transport in molecular motors in biological systems, with features similar to those of solitons as extended objects. In this context, the present work sheds light on the role played by the length scale competition between the point-like inhomogeneities (disorder) and the size of kinks in the transport dynamics. For this purpose, we use the framework of collective coordinates (CC) in order to gain insight in the cause of the motion and the degrees of freedom that take part in it. Emphasis will be given to the kink width oscillations and their role in the transport properties: Indeed, in general, the width of the nonlinear topological excitations is crucial for the movement of these coherent excitations. The coupling between the translational and kink width degrees is such that motion takes place [14]. In particular, in the present work we will see that the oscillation range of the kink width is determined by the interplay with the inhomogeneities. An additional, relevant issue is the analysis of the motion dynamics under thermal fluctuations. In ratchets, the noise is an important source of energy and, for some biological systems, it is regarded as the main cause of transport. Here we will consider the robustness of our rocking ratchet system under thermal fluctuations. In this case, activation of unidirectional motion was observed for a certain range of frequencies in the simulations as well as in the CC.

In order to achieve the above mentioned goals, our paper is organized as follows: In Sec. II we formulate the basis for the ratchet device and explain the origin and
physical reasons of the rectification process. A discussion in the CC framework is devoted to the length scale competition between the inhomogeneities and the kink width, and its influence on the motion dynamics. In the same context, we establish an analogy with a simple model used for describing unidirectional motion in molecular motors \[21\], pointing out the relevant role of the kink width for the ratchet dynamics and its application in biological systems. Subsequently, an analysis of the efficiency in terms of the quantization of the transport is done for the relevant parameters of our ratchet system, including the interference effects among the inhomogeneities. An example is given for the \(\phi^4\) model, not only for its known rich internal dynamics reinforced by the presence of an internal mode, but also for its potential application to macromolecules (e.g., in transfer of energy in microtubules \[21\]). Next, in Sec. III, we analyze the kink dynamics subject to noise. In particular, a new phenomenon of activation of motion induced by noise is described. In order to explain this new behavior, different collective coordinate approaches are implemented and thoroughly discussed. Finally, in the last Section we summarize the main contributions of our work and make a discussion about the perspectives on this line. We include appendices where we detail the CC approaches for one and two collective variables, extending the \textit{Generalized Traveling Wave Ansatz} (GTWA) to the case where inhomogeneities and noise act together with damping and ac forces.

II. RATCHET MODEL AND TRANSPORT

A. Model

Kink dynamics in the presence of inhomogeneities can exhibit different and interesting behaviors, depending on the interplay between those inhomogeneities and the nonlinearity \[22, 23\] among other factors. The generation of net motion using a lattice of point-like inhomogeneities is a good example of such non-trivial phenomenon \[18\]. Although in that previous work the problem was discussed for the sG model, it can be generalized in principle for any nonlinear Klein Gordon system. Therefore, aiming at that general viewpoint, for our analysis we formulate the model in a general way as follows:

\[
\phi_{tt} + \beta \phi_t - \phi_{xx} + \frac{\partial U}{\partial \phi}[1 + V(x)] = A \sin(\omega t + \delta_0),
\]

where \(U(\phi)\) is the potential for the nonlinear Klein-Gordon equations and \(A \sin(\omega t + \delta_0) \equiv f(t)\) is an external ac force whose parameters \(A, \omega\) and \(\delta_0\) represent the amplitude, frequency and phase of the periodic force, respectively. In particular, we will focus on the \(\phi^4\) and sG models as specific examples; the corresponding nonlinear potentials are \(\tilde{U}(\phi) = \frac{1}{4}(\phi^2 - 1)^2\) and \(\tilde{U}(\phi) = [1 - \cos(\phi)]\) respectively.

For our potential to exhibit ratchet-like phenomenon, we choose \(V(x)\) to be given by a periodically repeated unit cell, formed by an asymmetric array of delta functions (inhomogeneities). The unit cell configuration, of length \(L\), is defined by three inhomogeneities, the first one located at the beginning of the cell, the second at distance \(a\) from the first, and the third at distance \(b\) from the second. The corresponding mathematical expression is

\[
V(x) = \epsilon \sum_r \left[ \delta(x - x_1 - nL) + \delta(x - x_2 - nL) \\
+ \delta(x - x_3 - nL) \right]
\]

where the parameters satisfy the following constraints \(a, b, c \sim l_0\) (static kink width in absence of inhomogeneities); \(a, b < c\) with \(a \neq b\), where \(L = a + b + c\), \(a = x_2 - x_1\), \(b = x_3 - x_2\) and \(c = L + x_1 - x_3\), with \(x_1 < x_2 < x_3\). For our study we have taken \(\epsilon > 0\), where in the case of sG, specifically for LJJ the point-like inhomogeneities represent microshorts \[24, 25\]. However, the same scheme of arrays of point like inhomogeneities can be implemented for \(\epsilon < 0\), where particularly for the sG model many works have been devoted \[26\]. The choice of three inhomogeneities is inspired by biological polymers like DNA where the existence of three bases per codon seems to be the ideal configuration for the occurrence of net transport \[27\]. In principle it is possible to obtain unidirectional motion by using an array whose configuration presents more than three inhomogeneities per unit cell if the distances between the delta functions are in the same length scale as the kink width (otherwise, different behaviors could arise like obtained e.g. in \[28\]). However, the inclusion of more inhomogeneities diminishes the efficiency of the transport as we will see below.

B. Simulations of the model

Contrary to the case of point particles, where motion through point-like inhomogeneities (delta functions) is physically meaningless, in our case we deal with kinks (extended objects) with a determined width. This is an intrinsic feature of these nonlinear excitations, and consequently the competition between their width and the distances among the inhomogeneities is crucial for the kink motion. The interference effects among the inhomogeneities \[22\] create an effective potential for the motion of the kink center, the location of the inhomogeneities determining the direction of motion. For the particular configuration of three inhomogeneities per unit cell, directional motion takes place only under the condition \(a \neq b\). In the upper panel of Fig. I results of simulations of Eq. \(\text{I}\) for the sG case with different values of \(a\) and \(b\) are depicted. Such a picture shows that our ratchet device is an authentic rectifier. In addition, as in standard ratchet systems, the directional motion of the kink center takes place only for certain values of the amplitude of the ac force (see lower panel of Fig. \(\text{I}\), a behavior that
is dependent on the ac force frequency. A more detailed picture of the dynamics of the mean velocity for the sG kink center as a function of the ac force amplitude for different frequencies can be found in [18].

We have restricted ourselves to the overdamped case by taking $\beta = 1$, where the inertial effects are small, reducing the generation and propagation of phonons, and for which the kink center moves on a tilted effective potential due to the external ac force. This regime prevents also the dependence on the initial conditions for the dynamics [30]. For the integration of Eq. (1) we have used a Strauss-Vázquez numerical scheme [30] with free boundary conditions and spatial and temporal steps $\Delta x = 0.1$ and $\Delta t = 0.01$, respectively. We have checked our results with different spatial steps $\Delta x = 0.05$ and $\Delta x = 0.02$. The simulations were done for the spatial interval $[-30,150]$ with inhomogeneities arranged periodically according to our period in $[0,120]$. We have used the numerical representation for delta functions given by

$$
\delta(x - x_c) \rightarrow \begin{cases} 
1/\Delta x, & |x - x_c| < \Delta x/2 \\
0, & \text{otherwise}.
\end{cases}
$$

Such representation is not unique but is one of the simplest forms for the numerical implementation [22, 28].

C. Collective coordinate approach

In order to understand the dynamics of the kink center different CC approaches have been implemented [18]. In this previous work, it was shown that a 1-CC approach is not enough for the correct quantitative description of the results of the simulations even considering possible relativistic effects for high values of ac the force. However, this approach allows us to understand the underlying physics of this ratchet system in the simplest way. On the other hand, satisfactory agreement with the simulations was found by an improved, 2-CC approach, which takes into account the kink width dynamics [18]. At this point we will proceed directly with the discussion of the improved theory. The corresponding collective variable equations of two degrees of freedom for the Eq. (1) (see Appendix B, Eqs. (B21)-(B22) for $D = 0$) can be expressed as

$$
M_0 l_0 \ddot{\bar{X}} + \beta M_0 \dot{\bar{X}} - M_0 \dot{\bar{X}}^2 = -\frac{\partial U}{\partial \bar{X}} - qf(t),
$$

$$
\alpha M_0 \ddot{\bar{l}} + \beta \alpha M_0 \dot{\bar{l}} + \frac{1}{2} \alpha M_0 \dot{\bar{X}}^2 - \frac{1}{2} \alpha M_0 \dot{\bar{l}}^2 = -\frac{\partial U^{int}}{\partial \bar{l}} - \frac{\partial U}{\partial \bar{l}},
$$

where $\bar{X}$ stands for the position of the kink center, $\bar{l}$ represents the kink width, the internal potential energy of the kink is

$$
U^{int} = \frac{1}{2} M_0 \left( \frac{l_0}{\bar{X}} + \frac{l_0}{\bar{X}} \right),
$$

and $U(X,l)$ is an effective potential depending on the specific equation one is dealing with. In particular, for the sG case $M_0 = 8$, $l_0 = 1$, $\alpha = \pi^2/12$, $q = 2\pi$ and the effective potential is given by

$$
U(X,l) = 2e \sum_n \left[ \frac{1}{\cosh^2[(X - x_1 - nL)/l]} \right]
+ \frac{1}{\cosh^2[(X - x_2 - nL)/l]} + \frac{1}{\cosh^2[(X - x_3 - nL)/l]}.
$$

As we can see from the previous equations the kink width dynamics is coupled to the motion of the center of the kink. Therefore, changes in the kink width directly
affect the translational motion. It is possible to observe, for instance, that decreasing the kink width decreases the effective ac force, making necessary to increase the amplitude of the ac force in order to compensate for such effect. This is an important factor that explains in part the shift observed in the locations of the windows of motion of the simulations with respect to those obtained from the 1-CC approach (see Fig. 1b in [18]). Another relevant conclusion is the feedback between the effective potential landscape and the kink width, determined in turn by the potential. In this fashion, the 2-CC approach reflects the non-trivial interaction of the kink with the inhomogeneities, which is otherwise known to exhibit many counterintuitive phenomena [28].

To deepen our understanding of the dynamics, let us look into the oscillations of the kink width. As in the case of simulations we restrict ourselves to the overdamped case (taking \( \beta = 1 \)). A picture of the kink width oscillations versus kink center position is shown in Fig. 2. As we can see, the agreement with the CC approach is excellent, confirming the validity of our predictions. It is particularly interesting the existence of loops, which arises as a consequence of the kink center motion back and forth into the wells of the effective potential (see Fig. 3), i.e., describing half an oscillation before overcoming the barrier.

Interestingly, another feature that stands out clearly is that the oscillations are around a value different from \( l_0 = 1 \), the width of the unperturbed kink. Figure 2 shows that they take place around \( l \approx 0.8 \) and, furthermore, that \( l_0 \) is not even included in the range of oscillations. This phenomenon is the result of the balance between two opposite forces. On the one hand, the inclusion of inhomogeneities increases the potential energy of the system. This fact is reflected in the effective potential energy landscape Fig. 3. Such picture shows that when the kink width decreases, the potential energy decreases as well. Taking two points with the same value for \( X \) but with different kink widths \( l \), for example \( M \) and \( O \) in Fig. 3b), we see this difference in potential energy, i.e., \( E_M > E_O \) where \( l_M > l_O \). Therefore, as the tendency of the system is to go to the minimum of the potential energy, the kink width would decrease. On the other hand, the kink internal potential energy, Eq. 5, has a minimum in \( l_0 \), and hence the energy increases when the kink width decreases (see Fig. 4 for \( l < l_0 \)); notice that the first term of this equation accounts for a repulsive interaction and the second is given by an attractive one. As a result of this balance, a new minimum will appear for the oscillations of the kink width. It is important to note that the difference \( \Delta U^{\text{int}} \) of the internal potential energy for the kink width \( l = 0.7 \) with respect to the value \( l_0 = 1 \) (inset of Fig. 4) is of the same order as the energy difference \( E_M - E_O \) between the points mentioned before for the effective potential introduced by the inhomogeneities, in agreement with this discussion.
FIG. 4: Internal potential energy vs normalized kink width, Eq. (6) (sG case). The inset shows the part of curve where the oscillations of the kink width take place.

D. Related point particle models.

A problem closely related to our 2-CC approach, given by a point particle ratchet with two degrees of freedom, has been studied in [20]. This model was designed for describing molecular motor dynamics consisting of two particles joined by a spring moving in a ratchet potential. The corresponding equations of motion are given by

\[
\begin{align*}
\dot{u}_1 &= - \frac{\partial V(u_1, l)}{\partial u_1} - \frac{\partial W(u_2 - u_1)}{\partial u_1} + A \sin(\omega t) + \xi_1(t), \\
\dot{u}_2 &= - \frac{\partial V(u_2, l)}{\partial u_2} - \frac{\partial W(u_2 - u_1)}{\partial u_2} + A \sin(\omega t) + \xi_2(t),
\end{align*}
\]

where \( u_1, u_2 \) represent the coordinates of the particles, \( V \) is a sawtooth potential and \( W \) is the internal potential energy. Here \( \xi_i \) with \( i = 1, 2 \) are Gaussian white noises. Ignoring the noise terms and their influence on the net motion, we see that the change of variables \( X = \frac{1}{2}(u_1 + u_2) \) and \( l = u_2 - u_1 \) casts the system in a similar shape as Eqs. (8-9) in the overdamped case, for which in good approximation the inertial terms could be neglected. In such a new context the variables \( X, l \) can be interpreted as the mass center and elongation (distance between the particles) respectively, and obviously they resemble to the variables mass center and width of the kink in our system.

Notice that in both models we have an asymmetric potential. In our case it is given by Eq. (7), which is asymmetric at the CC level if the already mentioned conditions for the distances between the inhomogeneities are satisfied. In both systems, there are internal potential energies that characterize their elastic properties. In the model in [20], the internal potential is expressed through a harmonic function (in the original variables):

\[
W(u_1, u_2) = \frac{1}{2} k[(u_2 - u_1) - l_0]^2, \tag{10}
\]

which in our collective coordinates can be written as

\[
W(l) = \frac{1}{2} k(l(t) - l_0)^2.
\]

where \( k \) is the elasticity constant.

The links between the two models can be made more explicit by using a value for \( l_0 \) close to the minimum around which the kink width oscillates in our simulations (cf. the discussion in the preceding subsection). It is important to point out that we have defined \( l \) as a kink width variable as given in the expression (11) of the appendix. However, what the quantity \( l \) actually means is the distance at which the kink shape approaches its asymptotic values, measured from the center. This means that \( l \) in our notation is half the “real kink width”. Consequently the ratio (real kink width)/(period of the effective potential) becomes \( 2l_0/L \approx 0.4 \) for which a very interesting dynamics for point particles dynamics has been reported in related 2-particle model [31]. This comparison between our model and that in [20] allows to point out their main differences as well. It is particularly important that in our framework, the internal energy can describe satisfactorily the repulsive interaction between real molecules where a van-der-Waals like-force prevents their overlap. This is very close to what occurs in molecular motors: if we take again the motion of kinesin as an example, this molecule has two dimer heads that act as “feet”, allowing the molecule to “walk” along a microtubule [32]. The repulsion would then appear when the two dimer heads are too close. Such a repulsive interaction can not be naturally accounted for within the model of two particles. For solving this problem the authors of [20] resort to fix arbitrary values for \( l_0 \) which in our case is not necessary. Note, however, that in spite of the technical differences between both models, phenomenologically they are very similar: both of them try to understand how the motion of molecular motors, which proceeds in steps accompanied by deformations (in the case of kinesin, when one step advances in front of the other) can arise. The common conclusion is that a point particle ratchet would not be a good model because the second degree of freedom is needed to capture the whole mechanism of the motion. The advantage in our approach is that this second degree of freedom arises on its own, without a priori constructions, as an emergent property of the nonlinear excitation. Recent studies [31, 33] show similar phenomena for the two degrees of freedom point particle ratchet of [20] when the ratchet is of flashing type. The close relationship of the model of [20] to ours suggests that nonlinear Klein-Gordon models can also exhibit rectification working as flashing ratchets, an issue we will address in future work.

E. Length scales and quantization of transport

It should be clear, from the results discussed so far, that in order to obtain a ratchet device for extended nonlinear systems with topological nonlinear excitations, the
configuration of the inhomogeneities should be designed in such a way that the distance between the inhomogeneities is of the order of the kink width. However, this picture is somewhat too simple, and as we will see below, another important factor to take into account is the existence of interference effects. Naively, one may try to design a similar ratchet system for the \( \phi^4 \) equation. Considering only the kink width factor, it would seem that enlarging the sG array by a factor of \( \sqrt{2} \) (the ratio between the kink widths in both models) similar phenomena would be observed.

Let us make a more specific comparison between both models. To this end, we use the 1-CC framework in the nonrelativistic approach, where the equation of motion can be written as

\[
\ddot{X} + \beta X = -\frac{du}{dX} - \frac{qA}{M_0} \sin(\omega t + \delta_0),
\]

where \( u = U/M_0 \) is the normalized effective potential.

For the sG case we have the following expression

\[
u(X) = \frac{2\epsilon}{M_0} \sum_{n=1}^{3} \frac{1}{\cosh^2[(X - x_i - nL)/l_0]}
\]

with \( l_0 = 1 \), and \( M_0 = 8 \), whereas for the case of \( \phi^4 \) we have

\[
u(X) = \frac{\epsilon}{4M_0} \sum_{n=1}^{3} \frac{1}{\cosh^4[(X - x_i - nL)/l_0]}
\]

with \( l_0 = \sqrt{2} \), and \( M_0 = 2\sqrt{2}/3 \). The parameter \( q \) is the topological charge and it is given by \( q = 2\pi \) and \( q = 2 \) for the systems sG and \( \phi^4 \), respectively. The normalized effective potentials for two different arrays are depicted in Fig. 5. Panel a) shows standard asymmetric potentials for ratchet systems obtained with an array that satisfies the conditions mentioned above for the location of the inhomogeneities in the sG case. However, in case b) the effective potentials obtained for an array approximately given by the multiplication of the factor \( \sqrt{2} \) of the first one, shows a local minimum similar to an array of asymmetric double-well traps. This last one has been used as a device for generating motion of vortices in superconductor materials.

According to the our previous arguments based on the kink width role, a similar picture is expected for the normalized effective potential of \( \phi^4 \) and sG if the arrays verify the same length ratio as the full systems. Strikingly, Fig. 5 shows that the normalized effective potentials are almost the same but for the same array length. This apparent discrepancy can be explained if we take a detailed look at the potential given by Eqs. 13 and 14 for both cases (sG and \( \phi^4 \)). It is clear from those expressions that, while in the case of \( \phi^4 \) we have a \( \cosh^4 \) factor in the denominator, sG has a \( \cosh^2 \) factor. Therefore, the peaks and valleys in the effective potential for the \( \phi^4 \) system are much narrower than for sG, thus compensating for the increment in length. In addition, as in the sG model we will have dynamical changes of the effective potential due to the kink width variations, making more complicated the dynamics of motion. In any event, these effective potentials obtained in the simple approach highlight the importance of interference effects (see also [23, 28]) and make it clear that the kink width is not the unique quantity to take into account.

The consequences of choosing either the first or the second array for the kink dynamics are revealed in Fig. 6. We have taken for the analysis the \( \phi^4 \) model with a relative low frequency for the ac force, for which the mean velocity as a function of the ac force amplitude shows a staircase structure. The range for the amplitude values was taken from the following rescaling expression: \( q^{\phi^4} A^{\phi^4}/M_0^{\phi^4} = q^{sG} A^{sG}/M_0^{sG} \). This rule is deduced from the comparison between the 1-CC approaches for sG and \( \phi^4 \) models, considering the similitude of the normalized potentials discussed above. Fig. 6 shows the dependence of the kink mean velocity as a function of

![FIG. 5: Normalized effective potential for the kink center within the CC approach, Eq. (13-14), for two different arrays with \( \epsilon = 0.8 \). (a): \( x_1 = 0.5, x_2 = 1, x_3 = 2.3 \) and \( L = 4 \). (b): \( x_1 = 0.7, x_2 = 1.4, x_3 = 3.2, L = 5.6 \). In both panels sG (solid line); \( \phi^4 \) (dashed line).](image)
FIG. 6: Simulation results for $\phi^4$: Mean velocity vs driving amplitude $A$ for the frequency $\omega = 0.015$. (a) $\epsilon = 0.8$, $x_1 = 0.5$, $x_2 = 1$, $x_3 = 2.3$, $L = 4$. (b) $\epsilon = 0.6$, $x_1 = 0.5$, $x_2 = 1$, $x_3 = 2.3$, $L = 4$. (c) $\epsilon = 0.8$, $x_1 = 0.7$, $x_2 = 1.4$, $x_3 = 3.2$, $L = 5.6$. (d) $\epsilon = 0.6$, $x_1 = 0.7$, $x_2 = 1.4$, $x_3 = 3.2$, $L = 5.6$. The lines connecting the points serve as guides for the eye.

The amplitude for two different arrays and heights of the perturbations introduced by the inhomogeneities. As we can see, the motion is quantized as in standard ratchet systems [5, 7] and is characterized by the existence of gaps for which the net motion is absent (i.e., pure oscillating states). The mean velocity can be expressed as $|\langle dX/dt \rangle| = |\langle V \rangle| = \frac{L \omega m}{2 \pi n}$ as usual [8], where the indices $m, n \in \mathbb{N}$ quantize the motion. Using the expression for $|\langle V \rangle|$ we can characterize the motion for each frequency and period of the array. Comparing the values obtained from the simulations with the results derived from the expression for $|\langle V \rangle|$ with corresponding parameters $L$ and $\omega$, we find that $m$ and $n$ can take the following values: For panel a), $m = 1, 2, 3, 4, 5$ and $n = 1$; for panel b), $m = 1, 2, 3, 4$ and $n = 1$; for panel c), $m = 1, 2$ with $n = 1$ and $n = 2$, and for panel d), $m = 1, 2$ with $n = 1$ and $n = 2$. Although the mean velocity increases with the spatial period, the maximum value of the index $m$ significantly decreases, leading to a global decreasing of the velocity. These results prove that the inclusion of more inhomogeneities per cycle, which obviously enhances the spatial period, is not a good option if we want to reach high velocities. Furthermore, a very low frequency would be required to obtain windows of motion. In the case of the dependence on the inhomogeneities height, the starting point of the stair-steps structure shows a shift towards greater amplitude of the ac force when increases the height, which is natural in order to overcome the barrier. Nevertheless, a higher speed is found, arising from a higher $m$ and observable also as a broadening in the windows of motion.

III. DYNAMICS UNDER NOISE

This far, we have analyzed the ratchet-like behavior of our system in the deterministic case. However, it is clear that for our model to be more realistic, for instance, in the context of LJJ, the effect of the temperature has to be taken into account. The behavior of ratchet systems for nonzero temperature has been extensively studied both for point particles [5, 6, 36, 37, 38] and for nonlinear extended systems [10, 12, 39]. As for the problem we are considering here, the fact that there has not been much effort on soliton ratchet-like phenomena induced by spatial inhomogeneities carries over to the stochastic effects. Therefore, it is important that we address this issue here. For the present work, we will focus on the robustness of our rocking ratchet under thermal fluctuations. Another relevant issue would be the possible activation, resonances or modifications of the transport features induced by noise, but this topic deserves a detailed analysis and will be the subject of future work.
For different intensities of the noise. (a) \( \omega = 0.05 \): circles
\( D = 0 \), filled squares \( D = 0.005 \), squares \( D = 0.05 \); (b)
\( \omega = 0.1 \): circles \( D = 0 \), filled squares \( D = 0.005 \), squares
\( D = 0.05 \). Lines serve as guides for the eye. The inset shows
everal realizations for the motion of the kink center with
\( A = 0.43 \), \( \delta_0 = \pi \) and \( D = 0.05 \).

## A. Full model

For the sake of definiteness, we consider the sG model
under the influence of a Gaussian white noise; the results
for the \( \phi^4 \) equation are similar. Introducing the effect of
the temperature through the fluctuation-dissipation relation-
ship and considering the overdamped case as before,
taking \( \beta = 1 \), we find the following equation:

\[
\phi_{tt} + \phi_t - \phi_{xx} + \sin(\phi)[1 + V(x)] = f(t) + \eta(x,t),
\]

with

\[
\begin{align*}
\langle \eta(x, t) \rangle & = 0, \\
\langle \eta(x, t)\eta(x', t') \rangle & = D\delta(x - x')\delta(t - t').
\end{align*}
\]

where \( f(t) \equiv A \sin(\omega t + \delta_0) \) and the intensity of the noise
\( D = 2k_BT \).

For the numerical simulations of the full partial differ-
ential equation as well as for the numerical solution of
the collective variables (to be discussed in the next sub-
section), we have used the Heun method with the Box-
Muller-Wiener algorithm for generating Gaussian ran-
dom numbers of mean zero and variance one \( 40 \). In Fig. 7 we show the behavior of the kink center

tics under thermal fluctuations. Hereafter, we have set
the array parameters to be \( x_1 = 0.5 \), \( x_2 = 1 \), \( x_3 = 2.3 \),
\( L = 4 \) and \( \epsilon = 0.8 \) for our study. The mean velocity was
calculated using the expression in \( 8 \), namely

\[
\langle V \rangle = \langle X \rangle = \lim_{t \to \infty} \frac{\langle X(t) - X(0) \rangle}{t},
\]

where the average is to be understood over many real-
izations of the noise. From this figure we see that the
steps of the deterministic case are now smoothed, a typi-
feature for the dynamics under noise. It is important
to realize that this smoothing affects the regions between
the windows, which become minima of the mean velocity
modulus \( \langle |V| \rangle \) instead of gaps with null mean velocity
(see Fig. 7a). This phenomenon is directly related to
the strength of the noise, i.e., when the noise increases,
the absolute value for the mean velocity decreases but
simultaneously the connection between the windows be-
comes more evident and the windows of motion become
less pronounced.

As in most other ratchet systems, in our model the
stochastic fluctuations due to temperature assist the
jumps of the kink center from one well to the next one,
allowing in some cases jumps in the opposite direction of
the rectification (see the inset graphic in Fig. 7b) which
is not possible in the absence of noise. Accordingly, the
thermal fluctuations affect the mechanism of rectifica-
tion whereas, on the other hand, they yield the dynamics
of the pure oscillating states of the kink center unstable (i.e.,
destabilizing the regions with locked directional motion
for zero temperature). The joint action of both effects
leads to the smoothing of the windows and the connec-
tion of the deterministic gaps. For relative high temper-
atures the thermal kink energy is sufficient for overcoming
the barrier of the effective potential, and the kink mo-
tion is in practice diffusive, the influence of the barrier
becoming negligible. For this reason the rectification of
motion takes place only for not so large values of the
noise intensity (see discussion in \( 11 \)).

A remarkable feature we have observed in the simula-
tions is shown in Fig. 7 for frequency \( \omega = 0.1 \), where
new windows (absent in the deterministic case) appear.
This scenario is very similar to the one reported in \( 12 \)
where a similar surprising and intriguing phenomenon
was noted. There, the authors discussed that these new
windows arose due to jumps of the fluxons between sta-
bale and unstable pinned fixed points of the determinis-
tic dynamics. Considering the interest for this stochastic
phenomenon, we carried out a careful analysis of the cor-
responding zone. To summarize this work, in Fig. 8 we plot
the mean velocity as a function of the noise intensity
for different values of the frequency, showing the ex-
istence of an effective value for the intensity of the noise

![Fig. 7: Mean kink velocity \((dX/dt)\) vs driving amplitude \(A\) for different intensities of the noise. (a) \( \omega = 0.05 \): circles \( D = 0 \), filled squares \( D = 0.005 \), squares \( D = 0.05 \); (b) \( \omega = 0.1 \): circles \( D = 0 \), filled squares \( D = 0.005 \), squares \( D = 0.05 \). Lines serve as guides for the eye. The inset shows several realizations for the motion of the kink center with \( A = 0.43 \), \( \delta_0 = \pi \) and \( D = 0.05 \).](image-url)
for which a maximum absolute value of the mean velocity is obtained. The inset in Fig. 8 makes it clear that, as expected and suggested in [12], the mechanism of activation occurs through jumps between multistable states (states of the kink center which in absence of noise are purely oscillating). Therefore, a higher velocity is obtained when the residence time in these multistates is reduced or, in other words, when the intervals between consecutive jumps decrease. Once again, this process of activation becomes more effective when the noise intensity increases, but above a certain value of the noise intensity the kink center starts to jump in the direction opposite to that of the rectification, leading to a global loss in efficiency. This explains the existence of an effective value for the noise intensity for which the velocity reaches a maximum value.

Another interesting characteristic observed in Fig. 8 is the dependence of the maximum mean velocity on the frequency. Specifically, for a frequency value slightly larger than \( \omega = 0.1 \), the maximum velocity decreases, the peak moving towards greater values of the noise and the corresponding window of motion moving towards greater values of the ac force. Accordingly, for a relatively large value of the frequency, above \( \omega = 0.11 \), the window of motion induced by noise disappears. On the other hand, for frequencies slightly smaller than \( \omega = 0.1 \), a new window in absence of noise is obtained. With all these results, it is clearly established that the unidirectional motion induced by noise occurs only for a narrow window of frequency values.

We will show in the next subsection that this phenomenon seems to be a general feature, since at the CC level the system behaves very much like the dynamics of point particles.

**FIG. 8:** Mean kink velocity \( \langle dX/dt \rangle \) vs intensity of noise \( D \). Circles: \( \omega = 0.1 \) and \( A = 0.70 \); squares: \( \omega = 0.11 \) and \( A = 0.75 \). Inset shows one realization for the motion of the kink center for \( \omega = 0.1, A = 0.70, \delta_0 = 0 \) and \( D = 0.005 \).

**FIG. 9:** CC approach: Mean kink velocity \( \langle dX/dt \rangle \) vs driving amplitude \( A \) for different intensities of the noise and frequency \( \omega = 0.1 \). Continuous line: \( D = 0 \), dotted line: \( D = 0.005 \), dashed line: \( D = 0.05 \). Inset: Mean kink velocity \( \langle dX/dt \rangle \) vs intensity of noise \( D \) for \( A = 0.7625 \).

### B. Collective Coordinates in presence of noise

In order to understand the behavior observed in the previous section we resort again to the CC approach. As a first step, we take only into account one degree of freedom. Although, as discussed above, this framework is inaccurate for describing quantitatively the kink motion on a lattice of inhomogeneities, it does help understand qualitatively most of the features observed in the simulations, without unnecessary analytical complications. After some algebra (see Appendix A for details), with \( \beta = 1 \), we find the following expression for the kink center coordinate with noise:

\[
M_0 \dot{X} + M_0 \ddot{X} = -\frac{dU}{dX} - qf(t) + \sqrt{DM_0} \xi(t) \tag{18}
\]

with \( \langle \xi(t) \rangle = 0 \), \( \langle \xi(t)\xi(t') \rangle = \delta(t - t') \). For the sake of simplicity we have taken the nonrelativistic approach \( X^2 \ll 1 \), for which the noise turns out to be simply additive.

Figure 9 presents the results of the numerical integration of Eq. (18). Much as we did in the simulations, we calculate the mean velocity using Eq. (17), taking up to 500 realizations. From this plot two main features also observed in the simulations can be seen. First, smooth curves are obtained for the mean velocity as a function of the amplitude of the ac force, with values that decrease when the noise is increased. Second, new windows appear, and inside them there is a value of the noise intensity for which the velocity reaches a maximum value (inset in Fig. 9). It is thus evident that, in spite of the quantitative differences with the simulations, this simple approach does predict correctly the qualitative behavior of the full system.
In order to improve the results presented so far, we have extended the framework to two collective variables. By doing so (see Appendix B) we arrive at Eqs. (B21)-(B22) with two uncorrelated multiplicative white noises, meaning that the noises depend on the kink width dynamics. The results for this improved approach are collected in Fig. 10. Comparing with the simulations (Fig. 7), we can observe the excellent agreement, with the locations of the windows correctly predicted. As expected the curves are again smooth, a feature correctly accounted for already in the 1-CC framework. For the frequency \( \omega = 0.1 \), a new window is predicted, whose location is also in very good agreement with its corresponding window in the simulations. These results confirm the importance of considering the kink width dynamics in the framework of the collective coordinates in order to achieve correct quantitative results as compared to the simulations.

IV. CONCLUSIONS

We have studied the dynamics of solitons in a lattice of point-like inhomogeneities in two different nonlinear systems, the sG and the \( \phi^4 \) models, as good representatives of an entire class of nonlinear models. We have designed a periodic lattice made of an asymmetric unit cell, where, depending on the lattice parameters, ratchet-like motion of solitons (rectification) is observed. This is one of the few examples proposed so far for soliton ratchets based on spatial inhomogeneity. Building on a preliminary work reported in [18], we have analyzed in full detail all the characteristics and features of interest of our model. In order to understand the observed phenomenology, we have developed two CC approaches: one that takes into account only the motion of the kink center, and another one that includes the kink width as a second degree of freedom. We have seen that whereas both techniques give good qualitative results and allow for a general understanding the phenomenon, only when the kink width enters in the CC description the results are quantitatively correct. Interestingly, the CC approach allows to show that rectification takes place only when the unit cell gives rise to an effective potential of the same length scale as the kink width. This fact, along with the relevant role played by the width dynamical behavior, makes us conclude that one essential ingredient for observing ratchet-like behavior in this system is the existence of length scale competition [15].

As a necessary complement of the deterministic study, we have considered the influence of thermal noise on the behavior of our model systems. As in the deterministic case, the CC technique yields very good results. Of particular relevance is the appearance, at the 2-CC level, of multiplicative noise in the CC equations, coupled to the kink width. This is yet another hint to the crucial role played by this degree of freedom in the dynamics of the system. Another important feature is the motion activation induced by noise, that was observed in the simulations and later corroborated in the CC framework.

In a wider context, we believe that the CC approach presented here, and the conclusions about the role of the kink width, are of a much more general applicability. This is the case, for instance, with the anomalous resonances observed in nonlinear Klein-Gordon models [42], which can only be explained by considering the width degree of freedom. Specifically within the context of rectification, we have previously shown that the existence of ratchet behavior induced by pure asymmetric temporal driving in a homogeneous system, recently demonstrated in experiments in LJJ [13], is due to the coupling between the translation and the width oscillations [14]. Based on all these experiences, we believe that the implementation of the 2-CC approach can be very useful in the case of spatially correlated noise [33, 12], where the 1-CC approach...
proach can not explain the length scale competition between the correlation length and the size of the kink, first suggested in [13]. The new formulation would be also necessary in using the CC framework for describing the transport of proteins assisted by a thermal bath provoked by ATP molecules hydrolization, where the width is an important quantity to take into account. On the other hand, it is becoming more and more evident the crucial contribution of internal degrees of freedom in the functioning of molecular motors [32]. In this respect, our results suggests that models including in a natural way this degree of freedom, like in our case, can be the proper descriptions of those phenomena. Size dependent rectification has been also reported in colloids [45] and rectification through clustering has been observed in granular gases [46], which further reinforce our conclusion that the deformation or internal degrees of freedom must be an ingredient of good theoretical description of ratchet phenomena beyond the point particle scenario.

Finally, we want to stress that our design of a soliton system with ratchet behavior is a very simple one, that can be implemented in actual experiments and devices such as LJJ, for instance. Another field where the current state-of-the-art allows to apply this result is that of engineered molecular motors, demonstrated, e.g., in [47]. In this case, our proposal may apply to the design of biomolecular devices with medical applications. Generally speaking, this type of approach to rectification can be of interest for applications in which it is needed to have a tunable rectifier tailored for a specific regime. Of course, experimental verification of our predictions is needed to ascertain the accuracy of our results. We hope that this work stimulates experiments in this direction. Indeed the research reported here, opens new perspectives in the design of ratchet devices for more complicated extended nonlinear systems, such as general coupled chains [48]. Of particular interest in this class are stacked LJJ [49], although there are many other systems with potential applications in different areas. Work along this line is in progress.

APPENDIX A: COLLECTIVE COORDINATES. FIRST APPROACH

In order to apply the GTWA first proposed in [50], we rewrite Eq. (11) adding Gaussian white noise

\[ \dot{\phi} = \frac{\delta H}{\delta \psi}, \]

\[ \dot{\psi} = -\frac{\delta H}{\delta \phi} - \beta \dot{\phi} - \frac{\partial U}{\partial \phi} V(x) + f(t) + \eta(x,t) \]  

with

\[ \langle \eta(x,t) \rangle = 0, \]

\[ \langle \eta(x,t)\eta(x',t') \rangle = D \delta(x-x') \delta(t-t'), \]  

where \( \psi = \dot{\phi}, \ f(t) = A \sin(\omega t + \delta_0), \) \( D = 2\beta k_B T \) and \( H \) is the Hamiltonian corresponding to the unperturbed form of Eq. (11) given by

\[ H = \int_{-\infty}^{+\infty} dx \left\{ \frac{1}{2} \dot{\psi}^2 + \frac{1}{2} \dot{\phi}^2 + U(\phi) \right\}. \]  

As starting point we assume that the solution has the form

\[ \phi(x,t) = \phi_K [x - X(t), \dot{X}], \]  

and therefore by definition of \( \psi \) we have that

\[ \psi(x,t) = \psi_K [x - X(t), \dot{X}(t), \dot{X}]. \]  

The index \( K \) refers to the kink shape, but in the following we will omit it for simplicity.

Following the procedure in [50], inserting \( \dot{\phi}, \dot{\psi} \) into Eqs. (A1)-(A2) we get the expressions

\[ \frac{\partial \phi}{\partial X} \ddot{X} + \frac{\partial \phi}{\partial X} \dddot{X} = \frac{\delta H}{\delta \psi}, \]  

\[ \frac{\partial \psi}{\partial X} \ddot{X} + \frac{\partial \psi}{\partial X} \dddot{X} = -\frac{\delta H}{\delta \phi} - \beta \left( \frac{\partial \phi}{\partial X} \ddot{X} + \frac{\partial \phi}{\partial X} \dddot{X} \right) - \frac{\partial U}{\partial \phi} V(x) + f(t) + \eta(x,t). \]  

Multiplying Eq. (A4) by \( \frac{\partial \psi}{\partial X} \) and Eq. (A8) by \( \frac{\partial \phi}{\partial X} \), and then subtracting both expressions and integrating we arrive at the following equation

\[ A \dddot{X} + M \ddot{X} = -\beta C_1 \dot{X} - \beta C_2 \ddot{X} + F^\text{ac} + F^\text{stat} + F^\text{inh} + F^\text{st}, \]  

\[ (A9) \]
whose values for the coefficients and forces are given by

\[ A = \int_{-\infty}^{\infty} dx \frac{\partial \phi}{\partial X} \frac{\partial \psi}{\partial X}, \quad F^{ac} = \int_{-\infty}^{\infty} dx f(t) \frac{\partial \phi}{\partial X}, \]

\[ C_1 = \int_{-\infty}^{\infty} dx \left( \frac{\partial \phi}{\partial X} \right)^2, \quad F^{inh} = -\int_{-\infty}^{\infty} \frac{\partial U}{\partial \phi} V(x) \frac{\partial \phi}{\partial X}, \]

\[ C_2 = \int_{-\infty}^{\infty} dx \frac{\partial \phi}{\partial X} \frac{\partial \phi}{\partial X}, \quad F^{st} = \int_{-\infty}^{\infty} dx \eta(x,t) \frac{\partial \phi}{\partial X}, \]

\[ M = \int_{-\infty}^{\infty} dx \left( \frac{\partial \psi}{\partial X} \frac{\partial \phi}{\partial X} - \frac{\partial \phi}{\partial X} \frac{\partial \psi}{\partial X} \right), \]

\[ F^{stat} = -\int_{-\infty}^{\infty} dx \left\{ \frac{\delta H}{\delta \phi} \frac{\partial \phi}{\partial X} + \frac{\delta H}{\delta \psi} \frac{\partial \psi}{\partial X} \right\} \]

\[ = -\int_{-\infty}^{\infty} dx \frac{\partial H}{\partial X} = -\frac{\partial E}{\partial X}, \]

where \( E \) represents the energy of the system, \( H \) is the Hamiltonian density of Eq. (A1) and \( F^{stat} \) is the static force due to the external field, equal to zero for the above Hamiltonian.

Next we consider the sG potential for the system Eqs. (A1)-A2 for which we assume as solution the ansatz

\[ \phi(x,t) = \phi^{(0)}[\gamma(x-X(t))] = 4 \arctan(\exp[\gamma(x-X(t))]), \quad (A10) \]

where \( \phi^{(0)} = 4 \arctan(\exp[(x-X_0)/l_0]) \) is the static kink solution of the sG system, centered in \( X_0 \) and of width \( l_0 \). Here \( \gamma = 1/\sqrt{1-X^2} \) where we have put \( l_0 = 1 \) for the sG case.

Considering the previous statement for the static force and taking into account \( V(x) \) from Eq. (2), we obtain

\[ A = 0, \quad F^{ac} = -q f(t), \quad M = \gamma^3 M_0, \quad F^{stat} = 0, \]

\[ C_1 = \gamma M_0, \quad F^{inh} = -\frac{\partial U}{\partial X}, \quad C_2 = 0, \]

where \( M_0 = 8 \) is the kink mass, \( q = 2\pi \) is the topological charge and \( U(X,X) \) given by

\[ U(X,X) = 2\epsilon \sum n \sum_{i=1}^{3} \frac{1}{\cosh^2[\gamma(X-x_i-nL)]} \quad (A11) \]

is the effective potential. In the non-relativistic limit \( X^2 \ll 1, U(X,X) \approx U(X) \).

A representation for the stochastic force \( F^{st} \) can be obtained from the calculation of the variance. In the case of additive noise it is allowed to make the following assumption

\[ \left\langle \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} \eta(x,t) \eta(x',t') \right\rangle \]

\[ = \left\langle \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} \right\rangle \left\langle \eta(x,t) \eta(x',t') \right\rangle. \quad (A12) \]

Hence the correlation function for \( F^{st} \) can be written as

\[ \left\langle F^{st}(t) F^{st}(t') \right\rangle \]

\[ = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} dx dx' \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} \eta(x,t) \eta(x',t'), \quad (A13) \]

for which, taking into account the expression (A2), after some algebra we get

\[ \left\langle F^{st}(t) F^{st}(t') \right\rangle = 2\beta k_B T \gamma M_0 \delta(t-t'), \quad (A14) \]

i.e., \( F^{st}(t) \) is a white noise with kink diffusion constant

\[ D_K = \gamma M_0 D. \]

As a consequence we obtain a non-additive noise due to the factor \( \gamma(X) \), i.e., we have a problem with multiplicative noise.

Then the equation of motion (A9) can be rewritten as

\[ \gamma^3 M_0 \ddot{X} + \beta \gamma M_0 \dot{X} = -q f(t) - \frac{\partial U}{\partial X} + \sqrt{D_K} \xi(t) \quad (A15) \]

with \( \langle \xi(t) \rangle = 0, \langle \xi(t) \xi(t') \rangle = \delta(t-t') \). The Eq. (A15) in absence of inhomogeneities and noise agrees with the results presented in [23, 52]. The other r.h.s. terms that appear in (A15) are in correspondence with those already obtained in [23, 52] in the presence of impurities (non-relativistic approach) and Gaussian white noise, respectively. The procedure used here is equivalent to the so-called adiabatic approach by using modified conservation laws [23].

**APPENDIX B: COLLECTIVE COORDINATES. SECOND APPROACH**

In order to get the CC equations we follow a similar procedure as in the previous section but this time we propose a solution with the form

\[ \phi(x,t) = \phi[x - X(t), l(t)], \quad (B1) \]

\[ \psi(x,t) = \psi[x - X(t), l(t), \dot{X}(t), \dot{l}] \quad (B2) \]

with \( \psi = \dot{\phi} \), which considers the kink width as a new collective variable (see e.g. [12]).

Inserting Eqs. (B1) and (B2) in our system Eqs. (A1)-(A2) and then multiplying the first equation by \( \frac{\partial \psi}{\partial X} \) and the second one by \( \frac{\partial \phi}{\partial X} \); subtracting both expression and integrating we arrive at the following equation
\[
\begin{align*}
\int_{-\infty}^{+\infty} dx \frac{\partial \phi}{\partial X} \frac{\partial \psi}{\partial X} + \int_{-\infty}^{+\infty} dx \int_{-\infty}^{+\infty} \{ \delta \partial H \frac{\partial \phi}{\partial \psi} + \frac{\partial H}{\partial X} \frac{\partial \psi}{\partial X} \} = - \int_{-\infty}^{+\infty} dx \frac{\partial H}{\partial X},
\end{align*}
\]

with \(F(x,t,\phi,\psi,...) = -\beta \dot{\phi} - \frac{\partial U}{\partial \phi}(x(t)) + f(t) + \eta(x,t),\) and
\[
\begin{align*}
[\phi, \psi] &= \frac{\partial \phi}{\partial X} \frac{\partial \psi}{\partial X} - \frac{\partial \phi}{\partial \psi} \frac{\partial \psi}{\partial X},
\end{align*}
\]

\[
F_{stat} = - \int_{-\infty}^{+\infty} dx \left\{ \frac{\partial H}{\partial \phi} \frac{\partial \phi}{\partial X} + \frac{\partial H}{\partial \psi} \frac{\partial \psi}{\partial X} \right\}
\]

\[
= - \int_{-\infty}^{+\infty} dx \frac{\partial H}{\partial X},
\]

where \(H\) is the Hamiltonian density of Eq. [A1] for which, as was seen before, a null value for \(F_{stat}\) is obtained.

Repeating the same procedure, but now with \(\frac{\partial \psi}{\partial l}\) and \(\frac{\partial \phi}{\partial l}\), we get the expression

\[
\begin{align*}
\int_{-\infty}^{+\infty} dx[\psi, \phi] X + \int_{-\infty}^{+\infty} dx \frac{\partial \phi}{\partial l} \frac{\partial \psi}{\partial l} X + \int_{-\infty}^{+\infty} dx \frac{\partial \phi}{\partial l} \frac{\partial \psi}{\partial l}
\end{align*}
\]

\[
-K_{int} = \int_{-\infty}^{+\infty} dx F(x,t,\phi,\psi,...) \frac{\partial \phi}{\partial l}.
\]

Following Rice [53] for the particular case of sG

\[
\phi(x,t) = \phi^{(0)}|x-X(t),t(t)| = 4 \arctan \left( \exp \left[ \frac{x-X(t)}{l(t)} \right] \right),
\]

Eq. [B3] becomes

\[
M_0 \dot{X} + \beta M_0 \dot{X} - M_0 \dot{X} = F_{\alpha c} + F_{\alpha in h} + F_{\alpha st}
\]

with

\[
F_{\alpha c} = \int_{-\infty}^{+\infty} dx f(t) \frac{\partial \phi^{(0)}}{\partial X} = -2\pi f(t) = -q(t),
\]

\[
F_{\alpha in h} = \int_{-\infty}^{+\infty} dx \sin(\phi^{(0)}(x)) \frac{\partial \phi^{(0)}}{\partial X} = -\frac{\partial U}{\partial X},
\]

\[
F_{\alpha st} = \int_{-\infty}^{+\infty} dx \eta(x,t) \frac{\partial \phi^{(0)}}{\partial X},
\]

and

\[
U(X,l) = 2\varepsilon \sum_{n} \sum_{i=1}^{3} \frac{1}{\cosh^{2}[|X-x_i-nL|/l]}.
\]

On the other hand, Eq. [B6] is transformed into

\[
\alpha M_0 \dot{X} + \beta \alpha M_0 \dot{X} + M_0 \dot{X} = K_{int}(l,\dot{X}) + K_{\alpha in h} + K_{\alpha st}
\]

with

\[
K_{\alpha in h} = -\int_{-\infty}^{+\infty} dx \sin(\phi^{(0)}(x)) \frac{\partial \phi^{(0)}}{\partial l} = -\frac{\partial U}{\partial l},
\]

\[
K_{\alpha st} = \int_{-\infty}^{+\infty} dx \eta(x,t) \frac{\partial \phi^{(0)}}{\partial l},
\]

\[
K_{\alpha int}(l,\dot{X}) = -\int_{-\infty}^{+\infty} dx \frac{\partial H}{\partial l} = -\frac{\partial E}{\partial l},
\]

where \(\alpha = \pi^2/12, M_0 = 8, l_0 = 1\)

\[
E = \frac{1}{2} l_0 \alpha M_0 \dot{X}^2 + \frac{1}{2} l_0 \alpha M_0 l^2 + \frac{1}{2} M_0 \left( \frac{l_0}{l} + \frac{l}{l_0} \right).
\]

As in the previous section we use the variances of the stochastic forces in order to obtain approximate expressions for it. Taking the assumption given by the expression [A12] we find for [B11] the correlation function

\[
\langle F_{\alpha st}(t)F_{\alpha st}(t') \rangle
\]

\[
= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dx' \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} (\eta(x,t)\eta(x',t'))
\]

\[
= D\delta(t-t') \int_{-\infty}^{+\infty} dx \left( \frac{\partial \phi^{(0)}}{\partial X} \right)^2 = D\delta(t-t') l_0 M_0,\]

In what follows similar expressions to the Eq. [A12] valid for additive noise are used in order to calculate other correlation functions like

\[
\langle K_{\alpha st}(t)K_{\alpha st}(t') \rangle
\]

\[
= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dx' \frac{\partial \phi^{(0)}(x,t)}{\partial l} \frac{\partial \phi^{(0)}(x',t')}{\partial l} (\eta(x,t)\eta(x',t'))
\]

\[
= D\delta(t-t') \int_{-\infty}^{+\infty} dx \left( \frac{\partial \phi^{(0)}}{\partial l} \right)^2 = D\delta(t-t') l_0 M_0,\]

and

\[
\langle F_{\alpha st}(t)K_{\alpha st}(t') \rangle
\]

\[
= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dx' \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} (\eta(x,t)\eta(x',t'))
\]

\[
= D\delta(t-t') \int_{-\infty}^{+\infty} dx \left( \frac{\partial \phi^{(0)}}{\partial X} \right)^2 = D\delta(t-t') l_0 M_0,\]

and

\[
\langle F_{\alpha st}(t)K_{\alpha st}(t') \rangle
\]

\[
= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dx' \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} (\eta(x,t)\eta(x',t'))
\]

\[
= D\delta(t-t') \int_{-\infty}^{+\infty} dx \left( \frac{\partial \phi^{(0)}}{\partial X} \right)^2 = D\delta(t-t') l_0 M_0,\]

and

\[
\langle F_{\alpha st}(t)K_{\alpha st}(t') \rangle
\]

\[
= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dx' \frac{\partial \phi^{(0)}(x,t)}{\partial X} \frac{\partial \phi^{(0)}(x',t')}{\partial X} (\eta(x,t)\eta(x',t'))
\]

\[
= D\delta(t-t') \int_{-\infty}^{+\infty} dx \left( \frac{\partial \phi^{(0)}}{\partial X} \right)^2 = D\delta(t-t') l_0 M_0,\]
From the latter correlation for the stochastic forces we see that these are not cross-correlated.

Finally, collecting all the previous results we can rewrite Eqs. (B1) and (B2) as follows

\[ M_0 l \ddot{X} + \beta M_0 l \dot{X} - M_0 l \ddot{X} \frac{l}{l^2} = - \frac{\partial U}{\partial X} - qf(t) \]
\[ + \sqrt{\frac{D M_0 l}{l}} \xi_1(t), \quad (B21) \]
\[ \alpha M_0 l \ddot{l} + \beta \alpha M_0 l \dot{l} + M_0 l \ddot{l} \frac{l^2}{l^2} = - \frac{\partial U}{\partial l} + K^{\text{int}}(l, \dot{l}, \dot{X}) \]
\[ + \sqrt{\frac{D \alpha M_0 l}{l}} \xi_2(t), \quad (B22) \]

with \( \langle \xi_i(t) \rangle = 0, \langle \xi_i(t) \xi_j(t') \rangle = \delta_{ij} \delta(t - t'), \) for \( i, j = 1, 2. \)

A feature of particular interest in these new equations is the presence of stochastic forces which are multiplicative white noises dependent on the kink width variable.

The method described here using the technique of projection is equivalent to the variational calculations of the momentum and the energy of the system for perturbed nonlinear Klein-Gordon systems of the form of Eqs. (A1) and (A2) and with a Hamiltonian of the form of Eq. (A4) (see [19] for details). Another procedure and derivation has been recently presented in [19].
