Microhydration of protonated biomolecular building blocks: protonated pyrimidine†

Kuntal Chatterjee and Otto Dopfer†*

Protonation and hydration of biomolecules govern their structure, conformation, and function. Herein, we explore the microhydration structure in mass-selected protonated pyrimidine–water clusters (H\(^+\)Pym–W\(_n\), \(n = 1–4\)) by a combination of infrared photodissociation spectroscopy (IRPD) between 2450 and 3900 cm\(^{-1}\) and density functional theory (DFT) calculations at the dispersion-corrected B3LYP-D3/aug-cc-pVTZ level. We further present the IR spectrum of H\(^+\)Pym–N\(_2\) to evaluate the effect of solvent polarity on the intrinsic molecular parameters of H\(^+\)Pym. Our combined spectroscopic and computational approach unequivocally shows that protonation of Pym occurs at one of the two equivalent basic ring N atoms and that the ligands in H\(^+\)Pym–L (L = N\(_2\) or W) preferentially form linear H-bonds to the resulting acidic NH group. Successive addition of water ligands results in the formation of a H-bonded solvent network which increasingly weakens the NH group. Despite substantial activation of the N–H bond upon microhydration, no intracluster proton transfer occurs up to \(n = 4\) because of the balance of relative proton affinities of Pym and W and the involved solvation energies. Comparison to neutral Pym–W\(_n\) clusters reveals the drastic effects of protonation on microhydration with respect to both structure and interaction strength.

1. Introduction

Nucleobases, the building blocks of the genetic materials RNA and DNA, are derived from two different aromatic N-heterocycles, pyrimidine (Pym, \(\text{C}_4\text{H}_5\text{N}_2\), 1,3-diazine, 1,3-diazabenzene) and purine.\(^{1,2}\) Pyrimidine bases include uracil, thymine, and cytosine, whereas adenine and guanine belong to purines. The protonated form of these nucleobases plays a key role in physiological media,\(^{3–16}\) for example in RNA catalysis.\(^{17}\) The site of protonation as well as the base pairing involving the additional proton leads to structural motifs, which are crucial for the stability of DNA structures.\(^{18–20}\) For example, the interaction between cytosine and protonated cytosine stabilizes the d(CCCAAT) tetraplex.\(^{21}\) Protonated cytosine further participates in Hoogsteen base pairing, which is sensitive to the pH value.\(^{22}\) Such pairing involving a proton is critical because it can alter structure and function of DNA, often resulting in mutagenesis.\(^{23,24}\)

The stability and reactivity of biomolecules in vivo are generally controlled by their (micro-)hydration environment.\(^{25}\) Thus, water (W, \(\text{H}_2\text{O}\)) is considered as an integral part of these bioactive compounds (biological or interfacial water).\(^{26–35}\) For example, a combined X-ray crystallographic and NMR study on a model dodecamer B-DNA complex shows that the minor groove is more extensively hydrated than the major groove.\(^{36,37}\) The surface water molecules are strikingly influential for DNA structure and the recognition of proteins and drugs by balancing enthalpic and entropic contributions to the overall free energy.\(^{38–41}\) Furthermore, water acts as a transport medium in interbase proton transfer reactions.\(^{26,27,30,42–45}\)

The molecular picture of the hydration network around small building blocks provides information about their macroscopic function. Mass spectrometry coupled with vibrational spectroscopy and quantum chemical calculations has shown to be a powerful strategic approach for yielding such microscopic insight at the molecular level.\(^{16,46–53}\) Despite several mass spectrometric studies\(^{54–57}\) and very limited spectroscopic data on more complex pyrimidine molecules,\(^{46}\) the spectroscopic knowledge on the structure of even simple protonated building blocks of nucleobases within their microhydration environment remains elusive.\(^{14,15,58,59}\) In addition to biochemical topics, the Pym–W interaction is also relevant for astrochemical applications related to prebiotic synthesis of DNA/RNA bases. For example, it has been reported that UV irradiation of pyrimidines: \(\text{H}_2\text{O}\) ices leads to the formation of uracil,\(^{60–62}\) which has been found in carbonaceous chondrites\(^{63–65}\) and thus provides hints about the enigmatic prebiotic chemistry of the nucleobase–water interaction.

Knowledge of protonated pyrimidine–water clusters (H\(^+\)Pym–W\(_n\)) offers the opportunity to understand their role in more complex biomolecular architectures as well as the

mechanistic chemical route toward uracil. Previous mass spectrometric (ion mobility, thermochemical equilibrium measurements, multiphoton ionization of neutral clusters) and computational studies of H‘Pym and H‘Pym–Wn clusters suggest that protonation occurs at one of the two heterocyclic basic N atoms and that the water clusters form anionic hydrogen-bonded (H-bonded) network attached to the resulting NH group.66–68 In addition, mass spectrometric experiments suggest that bimolecular dissociative proton transfer according to

\[
{\text{H'}}\text{Pym} - \text{W}_{n-1} + \text{W} \rightarrow \text{Pym} + \text{W}_n\text{H}'
\]  

(1)

becomes exothermic for clusters larger than the critical size \( n \geq 4 \),66,67 because at this cluster size the proton affinity of \( \text{W}_n \) clusters (PA = 691, 808, 900, 904, 908 kJ mol\(^{-1}\) for \( n = 1–6 \)) exceeds that of Pym (PA = 886 kJ mol\(^{-1}\)).69–73 However, all structures calculated so far for \([\text{Pym} - \text{W}_n]_n\)\(^+\) are of the type \( \text{H'}\text{Pym} - \text{W}_n \),66,67 i.e. no intracluster proton transfer (ICPT) from \( \text{H'}\text{Pym} \) to \( \text{W}_n \) occurs in the size range \( n \leq 4 \) due to favourable solvation energies compared to \( \text{Pym} - \text{H'}\text{W}_n \) which compensate the difference in proton affinity. In general, no spectroscopic information is available to support these structures and binding motifs in \([\text{Pym} - \text{W}_n]_n\)\(^+\). Such spectroscopic data provide much more reliable structural information than the bare combination of mass spectrometry and quantum chemistry, which often leads to wrong conclusions, as recently demonstrated for the example of the microhydrated naphthalene cation.74,75 To this end, we report herein the IR signatures of mass selected \([\text{Pym} - \text{W}_n]_n\)\(^+\) clusters and interpret them with the aid of reliable density functional theory (DFT) calculations. This approach has recently been applied in our laboratory to a variety of microhydrated protonated aromatic ions and radical cations.49–51,53,76–87 A particular question to be addressed is the degree of N–H bond activation and propensity for ICPT to solvent as a function of the degree of hydration, which has been observed for a number of protonated aromatic molecules and cations above a critical hydration size \( n \geq 7 \).50,85,88–91 Furthermore, the study of \( \text{H'}\text{Pym} - \text{N}_n \) elucidates the impact of solvent polarity on the physical properties of \( \text{H'}\text{Pym} \) and its solvation pattern. Comparison with neutral \( \text{Pym} - \text{W}_n \) clusters92,93 reveals the drastic effects of protonation on the microhydration process, with respect to both structure and interaction strength.

2. Experimental and computational methods

IRPD spectra of mass selected \( \text{H'}\text{Pym} - \text{L}_n \) clusters with \( L = \text{W} \) \(( n = 1–4) \) and \( L = \text{N}_n \) \(( n = 1) \) are obtained in a tandem quadrupole mass spectrometer coupled to an electron ionization (EI) source and an octopole ion guide.52,94 In short, the clusters are produced in a pulsed supersonic plasma expansion by electron or chemical ionization and subsequent clustering reactions in the high-pressure region of the expansion. A mixture of \( N_2 \) and 5% H\(_2\)/He in a 1:1 ratio is guided as a carrier gas (8–10 bar) through a sample reservoir containing liquid Pym (Sigma-Aldrich, ≥98%, used without further purification, heated to 60 °C). Distilled water is added to the gas line to produce hydrated clusters. The desired \( \text{H'}\text{Pym} - \text{L}_n \) parent clusters are mass-selected in the first quadrupole and irradiated in the adjacent octopole with a tunable IR laser pulse (\( \nu_{IR} \), 10 Hz, 2–5 mJ, bandwidth 2 cm\(^{-1}\)) of an optical parametric oscillator pumped by a Q-switched Nd:YAG laser. Calibration of \( \nu_{IR} \) is achieved by a wavemeter. Resonant vibrational excitation followed by intracluster vibrational redistribution leads to the loss of a single water or \( \text{N}_2 \) ligand. Loss of Pym is not observed. Resulting \( \text{H'}\text{Pym} - \text{L}_{n-1} \) fragment ions are mass-selected by the second quadrupole and recorded with a Daly detector as a function of \( \nu_{IR} \) to derive the IRPD spectrum of the parent cluster. The IRPD yield is linearly normalized for laser intensity variations measured with a pyroelectric detector. The separation of the laser-induced dissociation signal from the signal generated by metastable decay is achieved by triggering the ion source at twice the laser repetition rate and subtracting signals from alternating triggers. The observed peak widths of vibrational transitions are mainly due to unresolved rotational structure, lifetime broadening, sequence hot bands involving inter- and intramolecular modes, and possibly contributions from different structural isomers.

To analyze the IRPD spectra, conceivable \( \text{H'}\text{Pym} - \text{L}_n \) clusters are characterized at the B3LYP-D3/aug-cc-pVTZ level.95 This dispersion-corrected functional accounts well for the electrostatic, induction, and dispersion forces and IR spectra of the investigated clusters.49–51,74,77–80,83,86 For instance, there is quantitative agreement between the binding energies computed for \( \text{W}_2 \) and \( \text{H'}\text{Pym} - \text{W} \) \(( D_0 = 1103 \text{ and } 5854 \text{ cm}^{-1}) \) and their experimental values \(( D_n = 1105 \pm 10 \text{ cm}^{-1}) \) and \( -\Delta H^0 = 5840 \pm 350 \text{ cm}^{-1}) \),67,96 indicating that effects of self-interaction errors present in several density functional theory approximations do not play a major role in the evaluation of binding energies using our approach.97 For comparison, neutral Pym, W, and Pym–W are also computed to understand the effect of protonation on their molecular properties. All coordinates are allowed to relax during the search for stationary points, and their nature as minima or transition states are verified by harmonic frequency analysis. Harmonic intramolecular vibrational frequencies are subjected to a linear scaling factor of 0.96221, derived from a comparison of computed CH and OH stretch frequencies of neutral Pym and W with their measured values.98–101 Scaled harmonic IR stick spectra are convoluted with a Gaussian line shape (fwhm = 10 cm\(^{-1}\)) for convenient comparison with the experimental spectra. All relative energies \(( E_n \) and equilibrium dissociation energies \(( D_n \) are corrected for harmonic zero-point vibrational energy to derive \( E_0 \) and \( D_0 \) values. Gibbs free energies \(( G \) are reported for \( T = 298.15 \text{ K} \). If not stated otherwise, the total intermolecular dissociation energies \(( D_n \) are determined with respect to the molecular \( \text{H'}\text{Pym} \) and W monomer fragments. Previous experience with the employed DFT level demonstrates that basis set superposition errors are less than 1%,49,80 and thus they are not considered further here. Cartesian coordinates of all relevant structures and their energies are available in the ESL.1 The atomic charge distribution and second-order perturbation energies \(( \beta^{(2)} \) of the
donor–acceptor orbital interactions involved in the H-bonds are evaluated using the natural bond orbital (NBO) approach. To further estimate the strength of these H-bonds, noncovalent interaction (NCI) calculations are performed by analyzing the reduced gradient of the electron density, \( s(\rho) \sim |\text{grad}(\rho)|/\rho^{6/3} \), as a function of electron density \( \rho \) oriented by the sign of second eigenvalue \( \lambda_2 \) of the Hessian, \( \rho^* = \rho \text{sign}(\lambda_2) \). The strength of the intermolecular bonds can be estimated by comparing the magnitude of the \(-\rho^* \) value.

### 3. Results and discussion

Fig. 1 displays the experimental IRPD spectra of \( \text{H}^+\text{Pym–L}_n \) recorded between 2450 and 3900 cm\(^{-1} \) in the \( \text{H}^+\text{Pym–L}_{n-1} \) fragment channel. The positions and widths of the bands observed are listed in Table 1, along with the vibrational and isomer assignments based on scaled harmonic frequencies. The spectral range covers the OH (\( \nu_{\text{OH}} \)), NH (\( \nu_{\text{NH}} \)), and CH (\( \nu_{\text{CH}} \)) stretch fundamentals, providing detailed information about the protonation site and the solvation network. Peaks A–C between 3600 and 3800 cm\(^{-1} \) correspond to free OH stretch modes (\( \nu_{\text{OH}} \)), peaks D in the 3200–3500 range are due to H-bonded OH stretch modes (\( \nu_{\text{OH}} \)), bands E near 3200 cm\(^{-1} \) arise from aromatic CH stretch modes (\( \nu_{\text{CH}} \)), and bands F are associated with free and bound NH stretch fundamentals (\( \nu_{\text{NH}} \)). To assign the spectra to structures, we explore possible isomers of H-Pym and H-Pym-L\(_n\) by DFT calculations and compare their predicted IR spectra to the experimental ones.

#### 3.1 Pym, H’Pym, and W

Pym has a planar equilibrium structure with \( C_{2v} \) symmetry in its \( ^1A_1 \) ground electronic state (Fig. 2), as revealed from microwave, IR, and Raman spectroscopy, X-ray crystallography, and quantum chemical calculations.\(^98,99,105–109\) Our calculated geometric and vibrational parameters compare favourably with experimental values (Table S1 in the ESI†). Furthermore, the measured proton affinity is comparable to the computed one assuming N-protonation (PA = 886 vs. 890 kJ mol\(^{-1} \), confirming the reliability of the current computational approach.

Protonation of Pym reduces its symmetry from \( C_{2v} \) to \( C_s \) in its ground electronic state (\( ^1A_1 \)). Protonation can occur either at one of the two equivalent ring N atoms or at the ring C atoms (carbenium ions) (Fig. S1 in the ESI†). C-protonation results in an aliphatic CH\(_2\) group, and the corresponding \( \nu_{\text{CH}} \) modes are calculated below 2850 cm\(^{-1} \) with high IR activity for all isomers (> 100 km mol\(^{-1} \), Fig. S2 in the ESI†). All three nonequivalent carbenium isomers are very high in relative energy. Because C-protonation strongly perturbs the aromatic ring, they are less stable than the N-protonated isomer by at least \( E_0 \geq 200 \text{ kJ mol}^{-1} \), consistent with previous mass spectrometric and computational findings.\(^67,68\) Thus, we mainly focus herein on the N-protonated isomer denoted H’Pym and do not consider carbenium isomers in detail further. The effect of N-protonation is rather large on the ring skeleton (up to \( \Delta_{\text{CC CN}} \ll 25 \text{ m\AA} \)), while the peripheral C–H bonds are less affected (\( \Delta_{\text{CH}} \ll 5 \text{ m\AA} \)). Nearly half of the positive charge resides on the additional proton (0.45 e), while the remaining partial charge is delocalized over the aromatic ring (mostly on the peripheral hydrogen atoms, Fig. S3 in the ESI†). Protonation increases the average \( \nu_{\text{CH}} \) frequency with a concomitant decrease in total IR oscillator strength (\( \Delta \nu_{\text{CH}} = 41 \text{ cm}^{-1} \), \( \Delta_{\text{total}} = -20 \text{ km mol}^{-1} \)), and the free NH stretch mode of H’Pym calculated at \( \nu_{\text{NH}} = 3396 \text{ cm}^{-1} \) is the dominant IR transition in the 3 \( \mu \)m range (\( I_{\text{NH}} = 159 \text{ km mol}^{-1} \), Fig. 3).

The O–H bond parameters of neutral W in its \( ^1A_1 \) ground state (\( \nu_{\text{OH}} = 0.9619 \text{ Å}, \nu_{\nu_{\text{OH}}} = 3653/3752 \text{ cm}^{-1} \)) are close to the corresponding experimental values (0.9578 Å, 3657/3776 cm\(^{-1} \)).\(^100,110\) The minor discrepancy in the \( \nu_{\text{OH}} \) modes (\( \Delta \nu_{\text{OH}} \approx -4 \text{ cm}^{-1} \)) arises because of the simultaneous consideration of the \( \nu_{\text{CH}} \) modes of Pym and the \( \nu_{\text{OH}} \) modes of W determining the single scaling factor.

#### 3.2 H’Pym–N\(_2\)

We consider in Fig. 2 all relevant binding motifs for N\(_2\) in H’Pym–N\(_2\) with N-protonated Pym. In the most stable H’Pym–N\(_2\)(H) global minimum (\( D_0 = 1530 \text{ cm}^{-1} \), N\(_2\) is H-bonded to the acidic NH group (\( R_{\text{NH}–N_2} = 2.061 \text{ Å} \)), whereas in the much less stable H’Pym–N\(_2\)(π) local minimum a π-bonded N\(_2\) ligand is located above the aromatic ring (\( D_0 = 858 \text{ cm}^{-1} \)).

|             | 3063 (42) |      |        |
In both cases, \( N_2 \) is pointing toward the positive charge, because the anisotropy of the charge-quadrupole and charge-induced dipole interactions favour a linear to a T-shaped approach for cation–\( N_2 \) clusters.\(^{111,112}\) The \( p \) attachment of \( N_2 \) occurs without significant perturbation of the structural and vibrational parameters of the \( NH \) group (\( D_{r\text{NH}} = 0.4 \text{ mÅ}, D_{n\text{NH}} = 1.8 \text{ cm}^{-1}, D_{I\text{NH}} = 694 \text{ km mol}^{-1} \)), and the same is true for the \( CH \) groups (Fig. 2, 3 and Table 1). In contrast, the \( N-H \) bond in the planar \( H^+\text{Pym}–N_2(H) \) isomer is substantially modified by the linearly \( H \)-bonded \( N_2 \) ligand. The \( N-H \) bond elongates with a concomitant decrease in the \( \nu_{\text{NH}} \) frequency and a nearly fivefold increase in IR oscillator strength (\( D_{r\text{NH}} = 6.4 \text{ mÅ}, D_{n\text{NH}} = 119 \text{ cm}^{-1}, D_{I\text{NH}} = 594 \text{ km mol}^{-1} \)). The NBO analysis of the \( NH \)/\( N_2 \) ionic H-bond results in an orbital interaction energy of \( E^{(2)} = 36 \text{ kJ mol}^{-1} \) between the \( \sigma^* \) orbital of the \( N-H \) bond and the lone pair of \( N_2 \), which further supports its relatively high binding energy (Fig. S4 in the ESI\(^*\)). The NCI calculation also confirms the strong bonding (\( \rho^* = 0.21 \text{ a.u.}, \) Fig. S5 in the ESI\(^*\)). Formation of the \( NH \cdot \cdot \cdot N_2 \) H-bond has almost no effect on the \( \nu_{\text{CH}} \) frequencies, because of the almost uncharged C–H bond lengths (\( \Delta \nu_{\text{CH}} \leq 1 \text{ cm}^{-1}, \Delta r_{\text{CH}} \leq 0.2 \text{ mÅ}, \) Fig. 2 and 3). In addition to the NH-bonded global and doubly degenerate \( \pi \)-bonded local minimum, we also explore the possibility of \( N_2 \) binding to the weakly acidic \( CH \) groups. All attempts to locate such \( CH \)-bonded minima with linear \( CH \)/\( N_2 \) bonds fail. In the case of \( C_2H \) and \( C_6H \), the structures converge to the NH-bonded global minimum. For \( C_4H \) and \( C_5H \), optimization leads to a bifurcated \( H^+\text{Pym}–N_2(C_4/C_5) \) dimer with \( D_0 = 703 \text{ cm}^{-1} \) (Fig. 2). This isomer is thus less stable than \( H^+\text{Pym}–N_2(H) \) but the IR spectra predicted for both local minima are quite similar in the investigated spectral range (Fig. 3). The corresponding \( C_5/C_6 \) structure converges to \( H^+\text{Pym}–N_2(H) \). We further consider two \( N_2 \)-bound isomers of a single C-protonated carbenium isomer, \( H^+\text{Pym}(C_5)–N_2 \)

### Table 1 (continued)

| Mode | Isomer          |
|------|----------------|
| \( \nu_{\text{NH}} \) | \( H^+\text{Pym}–W_4[b2] \) |
| \( \nu_{\text{NH}} \) | \( H^+\text{Pym}–W_4[r] \) |

\(^{a}\) Ref. 101. \(^{b}\) Ref. 118–120. \(^{c}\) Ref. 98–100.
In general, the H⁺Pym–W interaction is much stronger than the H⁺Pym–N₂ interaction because of the additional dominating charge-dipole forces operating in the monohydrate. As a result, the structures optimized for all H⁺Pym–W isomers displayed in Fig. 4 have a cation–dipole orientation with the O atom of W pointing toward the positive charge of N-protonated H⁺Pym. The binding energy of W in the linearly NH-bonded structure (θ_{CH/NH} = 179°), H⁺Pym–W(H), is almost twice that of π-bonded H⁺Pym–W(π), Δ0 = 5854 vs. 3081 cm⁻¹, consistent with the shorter intermolecular bonds (R_{NH–O} = 1.688 Å, R_{O–N} = 2.9–3.0 Å). In the H⁺Pym–W(π) local minimum, the C–H and N–H bond stretching parameters remain mostly unchanged upon monohydration (Δν_{CH}\ and \ Δν_{NH} < 1.3 mÅ), and the corresponding ν_{NH/CH}\_O\_H\_mom\ frequencies are little affected (e.g. Δr_{NH} = +14 cm⁻¹, Fig. 5). Similar to the N₂ case, W strongly perturbs the NH group in the H⁺Pym–W(H) global minimum through the formation of the linear NH–Oionic H-bond, which is reflected in the elongated N–H bond, along with a significant decrease in ν_{NH} and a roughly tenfold enhancement in the IR oscillator strength (Δν_{NH} = 13 mÅ), and the corresponding ν_{NH/CH} frequencies are more pronounced than for ν_{N₂} (factor 11 and 2). The large Δν_{OH} (94 km mol⁻¹) favours the formation of a strong NH–O ionic H-bond by attracting a substantial amount of positive charge (q = 55 me) from H⁺Pym (Fig. S3 in the ESI†). This charge transfer to W induces an elongation of the O–H bond (Δν_{OH} = 1.9 mÅ), along with frequency redshifts of −Δν_{OH} = 16/30 cm⁻¹ for the symmetric/asymmetric OH stretch modes (Fig. 5). In addition, the polarization induced by the nearby positive charge leads to a substantial increase in the IR oscillator strength, which is more pronounced for ν_{1} than for ν_{2} (factor 11 and 2). The large ΔE(2) energy (94 km mol⁻¹ and high ρ° value (−0.047 a.u.) obtained from the NBO and NCI analyses further indicate the strength of this NH–O ionic H-bond (Fig. S4 and S5 in the ESI†). Monohydration does not significantly affect the C–H bond parameters of H⁺Pym–W(H) (Δν_{CH} ≤ 2 cm⁻¹, Δr_{CH} ≤ 6 km mol⁻¹). In addition to the NH-bonded global and doubly degenerate π-bonded local minimum, we find two local CH-bonded minima with W binding to the CH groups via bifurcated CH–O H-bonds (Fig. 4). These C4/C5 and C5/C6 local minima have similarly low binding energies as the π isomer, Δ0 = 3027 and 3346 cm⁻¹, and are characterized by intense free NH stretch modes at 3403 and 3402 cm⁻¹ (Fig. 5).

The IRPD spectrum recorded for H⁺Pym–W is compared in Fig. 5 to the IR spectra computed for the all considered H⁺Pym–W dimers and the H⁺Pym and W monomers. At first glance, the IRPD spectrum lacks any signal for a free ν_{NH} band near 3400 cm⁻¹, implying that only the NH-bonded H⁺Pym–W(H) global minimum contributes to the experimental spectrum, consistent with its much larger binding energy. From the integrated band intensities and the achieved signal-to-noise ratio, the abundance of the π-bonded and CH-bonded isomers is estimated to be well below 10%. In general, the
overall appearance of the IRPD spectrum agrees well with that predicted for H\textsuperscript{+}Pym–W(H). Specifically, the two relatively sharp bands A and B at 3717 and 3633 cm\textsuperscript{-1} are readily assigned to the free OH stretch modes predicted at \(\nu_{3} = 3722\) and \(\nu_{1} = 3637\) cm\textsuperscript{-1}, respectively. The observed redshifts from bare W are consistent with the computed ones (\(D_{0} = 5854\) cm\textsuperscript{-1}) and bond lengths are given in Å, respectively. Numbers in parentheses correspond to relative energies and free energies in cm\textsuperscript{-1} (\(E_{0}, G\)). For comparison, the structures of W and W\textsubscript{2} are also given.

3.4 H\textsuperscript{+}Pym–W\textsubscript{2}

The IRMPD spectra of H\textsuperscript{+}Pym–W\textsubscript{n} in Fig. 1 reveal substantial incremental redshifts of band F assigned to \(\nu_{b\text{NH}}\) as \(n\) increases from (near) resonant anharmonic interaction between the strongly IR active \(\nu_{\text{NH}}\) fundamental and the essentially dark \(2\nu_{\text{NH}}\) overtone (and possibly \(2\nu_{\text{OH}}\) of W) along with weakly IR active overlapping aromatic \(\nu_{\text{CH}}\) fundamentals. It is difficult to identify the predicted \(\nu_{\text{CH}}\) modes near 3100 cm\textsuperscript{-1} experimentally, because they fall within the blue wing of band F. The transition X at 3233 cm\textsuperscript{-1} is currently attributed to the water bend overtone predicted at \(2\nu_{\text{OH}} = 3220\) cm\textsuperscript{-1} or to \(2\nu_{\text{NH}} = 3248\) cm\textsuperscript{-1} (using a scaling factor of 0.98). In conclusion, the IRPD spectrum is assigned to a single isomer, namely the most stable H-bonded H\textsuperscript{+}Pym–W(H) global minimum. This single-photon IRPD spectrum is obtained in the W loss channel, although its computed binding energy is much higher than the IR photon energy (\(D_{0} = 5954\) cm\textsuperscript{-1}, \(\nu_{\text{IR}} < 3800\) cm\textsuperscript{-1}). Hence, we do not observe IRPD from the ground vibrational state but of ions with substantial internal energy (\(E_{\text{int}} > 2000–3000\) cm\textsuperscript{-1}), explaining the observed larger width of the transitions as compared to the H\textsuperscript{+}Pym–N\textsubscript{2} spectrum for which no internal energy is required for IRPD to be observed (\(D_{0} = 1530\) cm\textsuperscript{-1} is actually an upper limit for \(E_{\text{int}}\)).
from 1 to 4, demonstrating that the W ligands successively attach to the NH binding site of H’Pym by forming a Wn solvent network. Indeed, in the most stable structure of H’Pym–W2(l1) shown in Fig. 4, a linear H-bonded W3 dimer is attached to H’Pym via a NH···O ionic H-bond, with a total binding energy of \( D_0 = 9945 \text{ cm}^{-1} \). The formation of such a H-bonded solvent network is strongly cooperative because of nonadditive induction forces, so that both the NH···O and OH···O H-bonds in H’Pym–W2 are much stronger and shorter than in the respective H’Pym–W and W2 dimer subunits \( (R_{\text{NH}} = 1.588 \text{ vs. } 1.688 \text{ Å}, R_{\text{OH}} = 1.720 \text{ vs. } 1.947 \text{ Å}) \). This effect is also visible in the binding energies, because the total binding energy of \( D_0 = 9945 \text{ cm}^{-1} \) is 43% larger than the sum of the two dimer units (\( D_0 = 6957 \text{ cm}^{-1} \)). Similarly, the \( K^2 \) and \( -\rho^* \) values for the two H-bonds in the trimer (141 and 74 kJ mol\(^{-1}\), 0.061 and 0.042 a.u.) are larger than those in the dimers (94 and 32 kJ mol\(^{-1}\), 0.047 and 0.026 a.u., Fig. S4 and S5 in the ESI†). The stronger NH···O bond in the \( n = 2 \) cluster is also rationalized by the higher proton affinity of W3 as compared to W (808 vs. 691 kJ mol\(^{-1}\), \( ^{b,70} \)) leading to a larger charge transfer from H’Pym to the solvent (79 vs. 55 me, Fig. S3 in the ESI†). Due to the stronger NH···O H-bond in the \( n = 2 \) cluster, the N–H bond is more strongly activated by dihydration than by monohydration \( (\Delta D_{\text{NH}} = 44 \text{ vs. } 27 \text{ mA}) \), leading to a larger redshift in \( v_{\text{NH}}^b \) \( (-\Delta v_{\text{NH}}^b = 738 \text{ vs. } 463 \text{ cm}^{-1}) \) and IR enhancement \( (I_{\text{NH}} = 2701 \text{ vs. } 1712 \text{ km} \text{ mol}^{-1}) \) as shown in Fig. 6. The O–H bonds of the terminal W in H’Pym–W2 are less elongated than in H’Pym–W \( (\Delta D_{\text{OH}} = 1.2 \text{ vs. } 1.9 \text{ mA}) \), because they are farther away from the positive charge, thus producing smaller redshifts in \( v_{\text{OH}}^b \) \( (-\Delta v_{\text{OH}} = 8/18 \text{ vs. } 16/30 \text{ cm}^{-1}) \). The free O–H bond of the proton donor W ligand is much shorter than the bonded one \( (23 \text{ mA}) \), leading to a much higher frequency for the free OH stretch \( (v_f = 3766 \text{ cm}^{-1}) \), occurring between \( \nu_1 \) and \( \nu_2 \) than the bonded OH stretch \( (v_{\text{OH}}^b = 3275 \text{ cm}^{-1}) \). The latter one is largely redshifted from that of bare W3 \( (v_{\text{OH}}^b = 3601 \text{ cm}^{-1}) \) due to the massive threebody effects induced by the nearby H’Pym cation (Fig. 6). Similar to \( n = 1 \), the parameters of the C–H bonds including \( \nu_{\text{CH}}^b \) are hardly affected for \( n = 2 \) upon hydration of the NH group of H’Pym (Fig. 4 and Table 1).

We consider in Fig. 4 two further less stable local minima. Like in the l1 global minimum, in the l2 isomer a H-bonded W3 dimer is attached to the NH group of H’Pym. This isomer is further stabilized by a weak CH···O contact of the terminal W ligand to the C2H group in ortho position of the NH group. However, to make this contact, the first W ligand has to rotate into the H’Pym plane leading to a weaker and longer NH···O H-bond. In addition, the W···W bond is less linear and weaker due to this additional steric constraint. The weaker OH···O and NH···O H-bond strengths are also indicated by the NBO and NCI indices (Fig. S4 and S5 in the ESI†). Both of these modifications cost energy so that the l2 isomer is in total \( \Delta E_0 = 199 \text{ cm}^{-1} \) less stable than the global minimum despite its additional CH···O H-bond. As a result, the spectral signatures of the l2 isomer are less redshifted \( v_{\text{NH}}^b \) and \( v_{\text{OH}}^b \) transitions than for l1, a weakly appearing \( v_{\text{CH}}^b \) band, and merging of \( \nu_1 \) and \( \nu_3 \) into a single band (Fig. 6). The third and much less stable H’Pym–W2 isomer denoted H–C5/C6 has two W ligands separately attached to the NH group (linear) and C5H/C6H groups (bifurcated). The H-bonds are slightly weaker than those in the respective H’Pym–W dimers, because of the small noncooperative threebody induction forces typical for interior ion solvation. These effects are also visible in the NBO and NCI indices of these H-bonds (Fig. S4 and S5 in the ESI†). As a result, the total binding energy of this isomer, \( D_0 = 8789 \text{ cm}^{-1} \), is 4.5% smaller than the sum of the two dimer binding energies \( (D_0 = 9200 \text{ cm}^{-1}) \), and thus much smaller than that of the l1 global minimum (by \( \Delta E_0 = 1156 \text{ cm}^{-1} \)). The spectral signatures of this isomer are \( v_{\text{NH}}^b \) band slightly blueshifted from that of H’Pym–W(H), a weakly appearing \( v_{\text{CH}}^b \) band, and the lack of any \( v_{\text{OH}}^b \) transitions (Fig. 6).

Addition of the second W ligand to H’Pym–W leads to several new features occurring in the IRPD spectrum (Fig. 1), such as bands C and D. In addition, band F exhibits a large redshift. Both observations are consistent with the formation of the H’Pym–W2(l1) global minimum shown in Fig. 4. Its predicted IR spectrum is compared in Fig. 6 to the observed IRPD spectrum, along with the spectra computed for the two less stable H’Pym–W2 isomers and bare W2. At first glance, the IRPD spectrum of H’Pym–W2 shows very good agreement with the spectrum computed for the l1 isomer, suggesting the presence of a single isomer, namely the most stable global
minimum. The broad blueshaded band F peaking at 2605 cm\(^{-1}\) is assigned to the \(v_{\text{NH}}^b\) proton donor stretch predicted at 2658 cm\(^{-1}\), implying good agreement between observed and computed redshifts (\(-v_{\text{NH}}^b = 786\) vs. 738 cm\(^{-1}\)). Bands A and B are assigned to \(v_1\) (3734 cm\(^{-1}\)) and \(v_1\) (3645 cm\(^{-1}\)) of the terminal W acceptor ligand. The observed blueshifts with respect to the \(n = 1\) cluster agree well with the prediction (\(\Delta R_{3/1} = 13/12\) vs. 12/8 cm\(^{-1}\)). The two new bands C and D at 3698 and 3340 cm\(^{-1}\) are attributed to \(v_1\) and \(v_{\text{OH}}^b\) of the H-bonded W donor ligand computed as 3706 and 3275 cm\(^{-1}\), respectively. Similar to \(n = 1\), the remaining band X at 3250 cm\(^{-1}\) is tentatively attributed to the water bending overtone (\(2\delta_{\text{OH}}\)) or to \(2\delta_{\text{ONH}}\), which are not included in the harmonic simulations (Table 1).

We may exclude a significant population of the two less stable \(\text{H}^+\text{Pym–W}_2\) isomers, because their predicted intense \(v_{\text{NH}}^b\) and \(v_{\text{OH}}^b\) bands do not show up as pronounced separate peaks (with sharp P-branch heads and blueshaded shoulders) in the IRPD spectrum. The binding energy of the terminal W ligand in \(\text{H}^+\text{Pym–W}_2\) (11) is calculated as 4091 cm\(^{-1}\), implying that single-photon IRPD for W loss should be possible for ions with little vibrational excitation. Thus, the IRPD spectrum of the \(n = 2\) cluster is obtained from ions with lower effective temperature, leading to narrower transitions than for \(n = 1\) (Fig. 1 and Table 1).

### 3.5 \(\text{H}^+\text{Pym–W}_3\)

We consider in Fig. 7 four conceivable low-energy isomers of \(\text{H}^+\text{Pym–W}_3\), which are derived from the \(\text{H}^+\text{Pym–W}_2\) (11/2) isomers by addition of W to either the bridging or terminal W ligand. This procedure yields two branched and two linear isomers within \(\Delta E_0 = 275\) cm\(^{-1}\), with \(D_0 = 13454\) (b1) > 13296 (b2) > 13213 (11) > 13179 cm\(^{-1}\) (l2), respectively. Based on their small energy difference at \(T = 0\) K, all four may be populated in the supersonic expansion. However, the b1 and l1 isomers are entropically strongly favoured at elevated temperature, because they are more flexible due to the lack of the \(\text{CH} \cdot \cdot \cdot \text{O}\) contact.

The \(\text{H}^+\text{Pym–W}_3\) (b1) global minimum with \(C_3\) symmetry has two equivalent terminal W ligands. The increased proton affinity of \(W_3\) (\(PA = 862\) kJ mol\(^{-1}\)) improves the binding of the solvent cluster to the acidic NH group of \(\text{H}^+\text{Pym}\), which further activates its N–H bond (\(\Delta E_\text{NH} = 68\) mA, \(\Delta v_{\text{NH}}^b = -1084\) cm\(^{-1}\), \(\lambda_{\text{ONH}} = 3640\) km mol\(^{-1}\), Fig. 8). The stronger H-bond (\(R_{\text{NH} \cdot \cdot \cdot \text{O}} = 1.500\) Å) implies an increasing charge transfer from \(\text{H}^+\text{Pym}\) to \(W_3\) (111 me), a larger \(D(2)\) energy (201 kJ mol\(^{-1}\)) and a higher \(\mu^*\) value (\(-0.077\) a.u.) (Fig. S3–S5 in the ESI†). The intermolecular OH···O–H bonds within the \(W_3\) network are slightly weaker than in \(\text{H}^+\text{Pym–W}_2\) (1.767 vs. 1.720 Å) because of increased charge delocalization in the larger hydrate. As a result, all O–H bonds become slightly shorter (\(\Delta R_{\text{OH}} = -6.2\) and \(-0.3\) mA for bonded and free O–H bonds), resulting in blueshifts of both the bound and the free OH stretch modes (\(\Delta v_{\text{OH}}^b = 122/84\) cm\(^{-1}\), \(\Delta v_{\text{OH}}^b = 4/5\) cm\(^{-1}\)).

In the \(\text{H}^+\text{Pym–W}_3\) (11) local minimum, a linear \(W_3\) chain is attached to the acidic NH group of \(\text{H}^+\text{Pym}\). The NH···O H-bond is slightly weaker than in \(\text{H}^+\text{Pym–W}_3\) (b1), as evidenced from longer values for \(R_{\text{NH} \cdot \cdot \cdot \text{O}} = 1.545\) Å, and smaller \(B(2)\) (169 kJ mol\(^{-1}\)), \(\Delta q_{\text{NH}} = 96\) me, \(\mu^* = -0.069\) a.u.), \(\Delta E_{\text{NH}} = 55\) mA), \(\Delta v_{\text{NH}}^b = -899\) cm\(^{-1}\), and \(\lambda_{\text{ONH}} = 3286\) km mol\(^{-1}\). The two

---

**Fig. 7** Stable structures of various \(\text{H}^+\text{Pym–W}_3\) isomers calculated at the B3LYP-D3/aug-cc–pVTZ level. Binding energies (\(D_0\)) and bond lengths are given in cm\(^{-1}\) and Å, respectively. Numbers in parentheses correspond to relative energies and free energies in cm\(^{-1}\) (\(E_0, G\)).

**Fig. 8** Comparison of experimental IRPD spectrum of \(\text{H}^+\text{Pym–W}_3\) with linear IR spectra of \(W_3\) and various \(\text{H}^+\text{Pym–W}_3\) clusters calculated at the B3LYP-D3/aug-cc–pVTZ level (Table 1).
non-equivalent OH···O H-bonds ($R_{\text{OH}···\text{O}} = 1.636$ and 1.772 Å) give rise to rather different $\nu_{\text{OH}}$ frequencies of 3068 and 3373 cm$^{-1}$, while their corresponding $\nu_1$ modes are rather similar (3712 and 3710 cm$^{-1}$). The terminal W ligand is far away from the positive charge, and thus its perturbation from bare W is small ($\Delta r_{\text{OH}} = 0.8$ mÅ, $\Delta r_{1/3} = -4/-12$ cm$^{-1}$).

The b2 and l2 isomers of H$^+$ Pym–W$_3$ are characterized by a weak CH···O contact. However, like for the l2 isomer of the $n = 2$ clusters, this additional H-bond is accompanied by steric strain in the other H-bonds leading as a net effect to only slightly higher relative energies ($E_0 = 159$ and 275 cm$^{-1}$) but substantially larger relative free energies at room temperature ($G = 653$ and 1035 cm$^{-1}$).

The IRPD spectrum of H$^+$ Pym–W$_3$ is compared in Fig. 8 to the IR spectra predicted for the linear and branched isomers, along with the spectrum computed for cyclic W$_3$. At first glance, it is obvious that the IRPD spectrum mostly arises from the branched H$^+$ Pym–W$_3$(b1) global minimum. The bands A and B at 3736 and 3647 cm$^{-1}$ are attributed to the free $\nu_3$ and $\nu_1$ modes predicted at 3739 and 3649 cm$^{-1}$. The observed incremental blueshifts from the $n = 2$ cluster agree well with the prediction ($\Delta \nu_{3/1} = 6/2$ vs. 5/4 cm$^{-1}$). The corresponding symmetric and antisymmetric bound $\nu_{\text{OH}}$ modes predicted at 3359 and 3397 cm$^{-1}$ occur as a single blueshifted band D1 peaking at 3399 cm$^{-1}$. The b2 and l2 isomers can be excluded as major carriers of the experimental spectrum, in line with their high free energies. The spectrum predicted for b2 has two roughly equally intense $\nu_{\text{OH}}$ modes at 3507 and 3359 cm$^{-1}$ (with a large splitting of 148 cm$^{-1}$), and such a pattern is not observed experimentally. A similar argument applies to isomer l2. Band C at 3709 cm$^{-1}$ cannot be explained by b1 and is thus considered as a unique spectroscopic signature of the l1 local minimum, because it is the only remaining structure with uncoupled free OH stretch oscillators (predicted at 3710 and 3712 cm$^{-1}$). Its corresponding bound OH stretch modes predicted at 3068 and 3373 cm$^{-1}$ appear as band D2 centred at 3152 cm$^{-1}$ and overlap with band D1 at 3399 cm$^{-1}$, respectively. Similarly, its predicted $\nu_{3/1}$ bands coincide with those of the b1 isomer resulting in bands A and B. The signal near ~3100 cm$^{-1}$ (E) and 3228 cm$^{-1}$ (X) is attributed to $\nu_{\text{CH}}$ and $2\nu_{\text{OH}}$ modes of both the linear and branched isomers. At the red end of the experimental spectrum, the signal rises more or less monotonically toward 2450 cm$^{-1}$ (band F), which is the end of the scanning range of the IR laser. Signal in this spectral range is attributed to the blue wing of the $\nu_{3/1}$ modes of H$^+$ Pym–W$_3$(b1) and H$^+$ Pym–W$_3$(l1) predicted at 2312 and 2497 cm$^{-1}$, respectively. Considering the relative intensities of bands D2 and D1, as well as bands A–C, along with the calculated oscillator strengths, we can clearly conclude a much higher abundance of the b1 global minimum compared to the l1 local minimum, with a crudely estimated population ratio of ~5:1.

### 3.6 H$^+$ Pym–W$_4$

Four low-energy computed minima of H$^+$ Pym–W$_4$ are considered in Fig. 9 (structures) and Fig. 10 (IR spectra), all of which are within $E_0 < 205$ cm$^{-1}$. In contrast to the $n = 1$–3 isomers,
a new structure with a cyclic H-bonded W4 ring attached to the NH group of H·Pym (C1) is calculated to be the most stable isomer at T = 0 K, with D0 = 16675 cm−1. Its additional stability arises from the extra OH····O H-bond produced by closing the solvation ring. The enhanced strength of the NH····O ionic H-bond in this H·Pym-W4(r) isomer as compared to the most stable n = 3 structure is rationalized by the higher PA of W4 as compared to W3 (PA = 862 vs. 900 kJ mol−1). As a result, ΔNH⋅··O becomes shorter (1.46 vs. 1.50 Å), and the N–H bond gets longer (ΔN–H = 16 mA) which lowers δCH further from 2312 to 2088 cm−1. The enhanced strength of the NH····O ionic H-bond is further supported by the increased charge transfer to the solvent cluster (Δq = 129 vs. 111 me) and the larger E(2) and ρ∗ values (E(2) = 241 vs. 201 kJ mol−1; −ρ∗ = 0.086 vs. 0.077 a.u.) documented in Fig. S3–S5 in the ESI.† The characteristic δCH modes associated with the two single-donor single-acceptor W ligands are calculated at significantly higher frequencies (νCH = 3529 and 3510 cm−1) than those of the other isomers (νCH < 3500 cm−1), because their H-bonds to the bridging double-acceptor W ligand are rather weak and long, as also indicated by their NBO and NCI indices. As a result, also the ν3 and ν1 frequencies of the latter ligand are slightly higher than those of the other isomers (3715/3630 cm−1).

Attaching a further W ligand to the b1 and b2 isomers of the n = 3 clusters leads to the corresponding isomers of n = 4, with a reversed energy order (D0 = 16471 and 16537 cm−1, E0 = 204 and 138 cm−1). The stability of b2 exhibiting the CH····O H-bond is higher than that of b1 (without such a contact) because of the additional cooperative effects induced by the terminal W ligand, leading to a shorter H-bond (RCH–O = 2.386 vs. 2.491 Å) and higher E(2) and ρ∗ values compared to its n = 3 analogue (E(2) = 8.6 vs. 5.9 kJ mol−1; −ρ∗ = 0.011 vs. −0.008 a.u.) (Fig. S4 and S5 in the ESI†). The δCH mode at 3063 cm−1 becomes slightly more intense (ΔCH = 42 km mol−1) by this enhanced interaction, which is however still smaller than the additional OH····O interaction in the most stable ring (r) isomer, as reflected from its E(2) and ρ∗ parameters (30 kJ mol−1, −0.025 a.u.). For cooperativity reasons, also the NH····O H-bonds are stronger in the b1/b2 isomers of n = 4 as compared to n = 3. Computationally, b2 is the most favoured isomer n = 4 at T = 298 K (G = 0) due to its larger structural flexibility which enhances the entropic contribution.

Unlike the branched isomers, simple linear addition of a W ligand to the linear l1 and l2 isomers of n = 3 converges to the single n = 4 structure at E0 = 163 cm−1. The resulting linear (l) isomer of n = 4 features a CH····O H-bond that renders this isomer more stable than b1. Despite its shorter RCH–O distance (2.213 vs. 2.386 Å), isomer l is slightly less stable than b2, which is rationalized by its partially solvated W ligand adjacent to the H·Pym moiety.

For all n = 4 isomers, we fail to optimize Pym–H·W4 structures with the additional proton located at the solvent site, because of barrierless proton transfer leading to formation of the corresponding more stable H·Pym–W4 structures. This result is similar to previous computational efforts66,67 and at first glance surprising because the proton affinity reported for W4 is substantially higher than that of Pym (PA = 900 vs. 886 kJ mol−1), in line with the mass spectrometric observation of exothermic bimolecular proton transfer in ion–molecule reaction (1).66,67 The lack of intracluster proton transfer (ICPT) is rationalized by the difference in solvation energies in Pym–H·W4 and H·Pym–W4, which compensates for the difference in the PA of Pym and W4. One has also to keep in mind that the minimum geometries of both cyclic W4 and H·W4 are not conserved during the formation of conceivable Pym–H·W4 and H·Pym–W4 clusters, which also influences the effective PA values of Pym and W4 via solvation and reorganization effects.

The IRPD spectrum of H·Pym–W4 is compared in Fig. 10 to the IR spectra predicted for the cyclic, linear, and branched isomers, along with the spectrum computed for cyclic W4. Compared to the IRPD spectra recorded for n = 1–3, the signal-to-noise ratio of the n = 4 spectrum is quite low due to the reduced parent ion signal (Fig. 1), making the assignments less certain for the larger hydrate. Three sharp bands A (3740 cm−1), C (3716 cm−1), and B (3648 cm−1) are observed in the free OH stretch range above 3600 cm−1, and assigned to ν3, ν1, and ν1, respectively. These are accompanied by a relatively broad and weakly resolved feature between 3000 and 3500 cm−1 in the bound OH stretch range, which may be divided into transitions D1 (3464 cm−1), D2 (3393 cm−1),
D3 (3200 cm$^{-1}$), and E (3087 cm$^{-1}$). The bending overtones of the W ligands (2f$_{\text{IR}}$, band X) may also contribute to some extent to the signal in the spectral range in the vicinity of band D3. Although the quality of the IRPD spectrum is not sufficient to single out the dominating contributing structures, we attempt to tentatively explain the spectrum in terms of the two most stable isomers (which however does not imply the absence of other isomers). Unlike the $n = 1$–3 clusters, discernible intensity occurs in the spectral range near 3460 cm$^{-1}$ (D1), which is characteristic of weakly-bonded $v_{\text{OH}}$ modes of single-donor single-acceptor W ligands, and thus a unique signature of the most stable ring isomer, with calculated frequencies of 3529 and 3510 cm$^{-1}$. The two $v_{\text{CH}}$ modes of the W ligand attached to H$^+$Pym (3310 and 3304 cm$^{-1}$) may explain the broad band D3, while the overlapping $v_{\text{NH}}$ and $v_{\text{C}=\text{O}}$ modes of the ring isomer at 3715 and 3712 cm$^{-1}$ are attributed to band C at 3716 cm$^{-1}$ and its $v_{\text{NH}}$ mode (3630 cm$^{-1}$) to the weak feature B at 3648 cm$^{-1}$ ($\Delta$). The free OH stretch bands A–C, and the free OH stretch bands A–C of the NH group, the interaction potential with quadrupolar d modes of the ring isomer at 3423, 3380, and 3348 cm$^{-1}$, is proven for the first time by spectroscopic analysis of the IRPD spectra of H$^+$Pym–L.

3.7 Effect of solvent environment and cluster growth

The analysis of the IRPD spectra of H$^+$Pym–L$_n$ with L = W ($n = 1$–4) and L = N$_2$ ($n = 1$) with the aid of DFT calculations provides detailed insight into the preferred protonation site, the acidity of the NH group, the interaction potential with quadrupolar dipolar ligands and the evolution of the microhydration network of this fundamental biomolecular building block. Significantly, these IRPD spectra provide the first spectroscopic information about isolated H$^+$Pym and its clusters. From the H$^+$Pym–L$_n$ spectra it is proven for the first time by spectroscopic means that isolated H$^+$Pym indeed protonates at the N atom, as suggested from mass spectrometric and quantum chemical studies, and as condensed phase data. From the H$^+$Pym–N$_2$($\pi$) spectrum, we derive an accurate value for the NH stretch frequency as $v_{\text{NH}} = 3391 \pm 3$ cm$^{-1}$. This value may be compared to $v_{\text{NH}}$ frequencies of related aromatic (heterocyclic) ions, such as protonated imidazole (3470 cm$^{-1}$), oxazole (3470 cm$^{-1}$), 5-hydroxyindole (3405, 3478, 3503 cm$^{-1}$ for C3/C4/O-protonation), and benzoxazole (3555 ± 3 cm$^{-1}$), illustrating that the NH group of H$^+$Pym has a relatively high acidity leading to low $v_{\text{NH}}$. As a result, the NH···L ionic H-bonds are relatively strong, and the preferred binding motif for both hydrophobic nonpolar ligands (N$_2$) and hydrophilic polar ligands (W). Due to the higher PA of W as compared to N$_2$ (494 vs. 691 kJ mol$^{-1}$), the H-bond in H$^+$Pym–W(H) is much stronger than in H$^+$Pym–N$_2$(H), as evident from the larger $D_0$ value (5854 vs. 1530 cm$^{-3})$, the shorter $R_{\text{NH···L}}$ bond (1.688 vs. 2.061 Å), larger values for $\varepsilon_2^p$, $\rho^*$, and $\Delta\varepsilon$ (94 vs. 36 kJ mol$^{-1}$, 0.047 vs. 0.021 a.u., 55 vs. 24 me), and the larger perturbation of the NH group ($\Delta_{\text{NH}} = 27$ vs. 6 mÅ, $\Delta_{\text{NH}} = 463$ vs. 119 cm$^{-1}$, $\Delta_{\text{NH}} = 1553$ vs. 594 km mol$^{-1}$). N-protonation of Pym decreases the acidity of the C–H bonds, as illustrated by the increase in the $v_{\text{CH}}$ values. Neutral Pym–Ar/N$_2$ dimers prefer $\pi$-stacking to the aromatic ring because of the dominant dispersion forces between these nonpolar ligands and the aromatic $\pi$-electron system of Pym, and the binding energy of Pym–N$_2$(n) has been estimated as $D_0 = 384 \pm 33$ cm$^{-1}$ from fluorescence spectroscopy. Despite the exess charge, ionization of Pym–N$_2$(n) induces only a minor increase in bond strength ($D_0 = 479 \pm 33$ cm$^{-1}$ derived from $\Delta D_0 = 95$ cm$^{-1}$), because N$_2$ rotates by 90° upon ionization to optimize the charge-quadrupole and charge-induced dipole forces. On the other hand, our calculations yield $D_0 = 858$ cm$^{-1}$ for H$^+$Pym–N$_2$(n), suggesting that protonation changes the preference from $\pi$-stacking to H-bonding ($D_0 = 1530$ cm$^{-1}$) because of the high acidity of the newly formed NH group, so that H$^+$Pym–N$_2$(n) is much less abundant than H$^+$Pym–N$_2$(H) in our plasma expansion (~20%). For the polar W ligand, this effect is more dramatic because the energy gap between $\pi$-stacking and H-bonding increases from 672 to 2773 cm$^{-1}$, so that only the H$^+$Pym–W(H) global minimum is detected. The strength of the NH···O ionic H-bond in H$^+$Pym–W may be compared to that in related aromatic clusters with an ionic NH···W bond, such as protonated benzonitrile ($D_0 = 6924$ cm$^{-1}$), oxazole ($D_0 = 6904$ cm$^{-1}$), imidazole ($D_0 = 5836$ cm$^{-1}$), and 5-hydroxyindole ($D_0 = 5040/3301/4071$ cm$^{-1}$ for C3/O/C4-protonation), and the radical cations of aminobenzonitrile ($D_0 = 6924$ cm$^{-1}$), pyrrole ($D_0 = 5442$ cm$^{-1}$), 5-hydroxyindole ($D_0 = 4422$ cm$^{-1}$), acetonilide ($D_0 = 4513$ cm$^{-1}$) and trans/cis-formanilide ($D_0 = 4897/4878$ cm$^{-1}$).

The evolution of the IRPD spectra of H$^+$Pym–W$_n$ with $n = 1$–4 show drastic effects upon sequential hydration. Significantly, the IRPD spectra provide for the first time an experimental impression for the microhydration structure of this fundamental protonated biomolecule. The spectra are assigned to the single dominating isomers H$^+$Pym–W(H), H$^+$Pym–W$_2$(H), and H$^+$Pym–W$_3$(b1) for $n \leq 3$ and predominantly H$^+$Pym–W$_n$(r) for $n = 4$, in which a bonded W$_n$ solvent network is attached to the acidic NH proton. For $n = 3$, we also identify a less stable linear H$^+$Pym–W$_3$(l) isomer and for $n = 4$ there may be more contributing isomers. The computed structures agree well with previous predictions. Our computed sequential hydration energies decrease as $D_0 = 5854 > 4091 > 3509 > 3221$ cm$^{-1}$ for the global minima of $n = 1$–4, a trend that is well reproduced by the bond enthalpies measured by mass spectrometry for $n = 1$–3 ($\Delta H^0 = 16.7 \pm 1 > 12.7 \pm 1 > 11.0 \pm 1$ kcal mol$^{-1}$ or $5840 \pm 350 > 4440 \pm 350 > 3850 \pm 350$ cm$^{-1}$). In general, the proton affinity of W$_n$ increases with cluster size (PA = 691 < 808 < 862 < 900 kJ mol$^{-1}$ for $n = 1$–4), and thus the strength of the NH···W$_n$ H-bond increases with $n$ ($R_{\text{NH···W}} = 1.688 > 1.588 > 1.500 > 1.464$ Å for $n = 1$–4), $D_0 = 5849 < 8842 < 9534 < 9220$ kJ mol$^{-1}$). This drastic cooperative effect is also visible in the increasing charge transfer from H$^+$Pym to W$_n$.
(Δq = 55 < 79 < 111 < 129 me), and the E(2) and −ρ∗ values of the NH−O ionic H-bond [94 < 141 < 201 < 241 kJ mol−1; 0.047 < 0.061 < 0.077 < 0.086 a.u.]. The progressive activation of the acidic NH group by sequential microhydration is documented by the elongation of the N−H bond (ΔSNH = 27 < 44 < 68 < 84 mÅ), which goes along with increasing computed νNH redshifts (−ΔνNH = 463 < 738 < 1084 < 1308 cm−1) that are consistent with the measured ones for n = 1–3 [516 < 786 < at least 950 cm−1]. In general, there is a monotonic trend for the reduction of νNH with the proton affinity of the solvent (Fig. 11). While the νNH band (F) shifts to the red upon hydration, the bound and free OH stretch frequencies (A−D) tend to increase by hydration, because of increasing delocalization of the positive partial charge on the solvent cluster. For example, band A (νA) moves from 3717 to 3740 cm−1, band B (νB) from 3633 to 3648 cm−1, band C (νC) from 3698 to 3716, and band D(1) from 3340 to 3464 cm−1. These experimental trends are fully in line with the predictions.

Up to n = 3, we do not have any evidence for intracluster proton transfer (ICPT) in H+Pym−Wn both experimentally and computationally. This may be expected from the PA values of W1−3 (PA = 691−862 kJ mol−1),69−72 which are well below that of Pym (886 kJ mol−1). However, from n = 4 onwards, the PA of Wn clusters are larger (PA = 900 kJ mol−1 for W4) than for Pym so that one may expect ICPT in H+Pym−Wn for n larger than a critical size n∗ = 4. However, one has to bear in mind that apart from relative PA values also the solvation energies are important for the determination of n∗.74,90,91,116 Indeed, there is indirect evidence from mass spectrometry that proton transfer from H+Pym to W4 is exothermic in bimolecular reactions, leading to the observation of H+PymW4 fragment clusters with n < m,66 which is explained by ionization of the Wn moiety and subsequent elimination of OH (and further W ligands). Calculations performed in that work66 illustrate that the excess proton in [Pym−Wn]H+ with n = 1−4 moves from the H+Wn solvent to Pym via barrierless ICPT leading to H+Pym−Wn structures. These results are consistent with our calculations for [Pym−Wn]H+ and suggest that for this cluster size the excess proton should be attached to Pym and not to Wn, in disagreement with the expectation from the bare PA values. One might argue that the experimental PA of Wn clusters is not a well-defined quantity, because the structures of Wn and H+H+Wn are quite different in the bare clusters and also different from the hydration structure within the [Pym−Wn]H+ heteroclusters. On the other hand, the mass spectrometric evidence from reaction (1) is consistent with an exothermic reaction for n ≥ 4, indicating that indeed PA(Wn) > PA(Pym).66,67 Hence, the lack of ICPT in H+Pym−W4 is attributed to the higher solvation energy compared to Pym−H+W4, which overcomes the difference in PA of W4 and Pym. Thus, the critical size for ICPT in [Pym−Wn]H+ must be n∗ > 4. For comparison, for related closed-shell protonated aromatic ions, such ICPT has been observed for benzene (n∗ = 1, PA = 746 kJ mol−1),90,91 naphthalene (n∗ = 2, PA = 803 kJ mol−1),86,88 benzonitrile (n∗ = 2, PA = 812 kJ mol−1),50 benzaldehyde (n∗ = 3, PA = 834 kJ mol−1),85 and phenol (n∗ = 3, PA = 817 kJ mol−1),89 but not for aniline up to n = 6 (PA = 883 kJ mol−1).117

It is instructive to compare H+Pym−Wn with neutral Pym−Wn to evaluate the drastic effects of protonation on microhydration with respect to both the interaction energy and the structure of the H-bonded solvent network. The geometry and bonding of neutral Pym−Wn clusters have been characterized by microwave (n = 1),92 matrix isolation IR (n = 1–2),93 and multiphoton ionization spectroscopy (n = 1–6),66 along with quantum chemical calculations (n = 1–2). Pym−W adopts a coplanar structure with a OH···N H-bond between the OH donor of W and the basic N atom of Pym as acceptor. This neutral OH···N H-bond is much weaker and longer (D0 = 1790 cm−1, ROHN = 1.946 Å, Fig. S8 in the ESI†) than the NH···O ionic H-bond in H+Pym−W(H) between the highly acidic NH proton donor and W, which is stabilized by strong cation−dipole forces (D0 = 5854 cm−1, RONH− = 1.688 Å). Furthermore, the structures computed for Pym−Wn have an H-bonded hydration network incorporating the neighboring CH group as weak proton donor or forming a second H-bond to the highly basic second N atom of Pym as proton acceptor.66,93 Thus, the additional acidic proton in H+Pym strongly increases the interaction with Wn and forms hydration motifs in which the Wn solvent cluster grows away from the aromatic molecule because of the strong anisotropy of the dominant cation−dipole interaction absent the neutral cluster.

4. Concluding remarks

In summary, we combine IRPD spectroscopy of mass-selected H+Pym−Ln clusters with L = W (n = 1–4) and L = N2 (n = 1) in the sensitive CH, NH, and OH stretch range with DFT calculations at the B3LYP-D3/aug-cc-pVTZ level to unravel the solvation structure around this protonated biomolecular building block.
Significantly, these spectra provide the first spectroscopic information about isolated H′Pym and its clusters with non-polar and polar ligands. As such, they serve as benchmark for the interaction of protonated nucleobases with a polar hydrophilic protic solvent (W) and a nonpolar hydrophobic aprotic solvent (N2). The salient results may be summarized as follows. In agreement with previous indirect mass spectrometric data and quantum chemical calculations,\textsuperscript{66–68} as well as condensed phase measurements,\textsuperscript{111} the analysis of the H′Pym–L\textsubscript{n} spectra provide the first unambiguous spectroscopic evidence that isolated H′Pym has a strong energetic preference (\(>200\) kJ mol\(^{-1}\)) for protonation at one of the two equivalent basic N atoms rather than at the C atoms. This is expected because C-protonation strongly perturbs the stability of the aromatic π-electron system. The H′Pym–N\textsubscript{2} spectrum is interpreted with the more stable n-electron system.

The H′Pym–W spectrum is interpreted with the more stable H-bonded H′Pym–N\textsubscript{2}(H) global minimum and a minor contribution of the less stable stacked H′Pym–N\textsubscript{2}(π) isomer (\(\sim20\%\)). From the latter spectrum, the \(\nu\textsubscript{NH}\) frequency of bare H′Pym is extracted as 3391 \(\pm\) 3 cm\(^{-1}\). Moreover, the \(\nu\textsubscript{CH}\) frequencies of H′Pym are higher than those in neutral Pym, indicating that N-protonation strengthens the aromatic C–H bonds. The H′Pym–W spectrum is interpreted with a single H-bonded H′Pym–W(H) isomer, and its linear NH – W ionic H-bond is much stronger than the NH – N\textsubscript{2} H-bond in H′Pym–N\textsubscript{2}(H) because of the higher PA of the ligand. In the larger H′Pym–W\textsubscript{n} clusters, a H-bonded W\textsubscript{n} cluster is attached to the acidic NH group. Thus, the formation of a H-bonded hydration network (external solvation) supported by large cooperative threebody effects arising from induction forces is strongly preferred to interior ion solvation suffering from small noncooperative threebody effects arising from charge delocalization. Furthermore, the n, PA of W\textsubscript{n} increases, and as a result the NH group is progressively activated upon sequential microhydration. However, no intracluster proton transfer from H′Pym to W\textsubscript{n} is observed in H′Pym–W\textsubscript{n} for the size range \(n \leq 4\), although the PA of W\textsubscript{n} exceeds the one of Pym by 14 kJ mol\(^{-1}\). This result demonstrates that the PA values are not the only criterion for determining the threshold size for ICPT, and differences in solvation energies must be taken into account as well. Thus, the critical size for ICPT in [Pym–W\textsubscript{n}]H′ must be \(n\textsubscript{c} \geq 5\), and the determination of its exact value remains as a challenging topic of future computational and experimental work. Although the IRPD spectra (at least for \(n \leq 3\)) are well assigned by the most stable static structures at \(T = 0\) K (\(E_0\)) as well as \(T = 289.15\) K (\(G\)) including at least part of entropic effects at elevated temperatures, it would be interesting to perform molecular dynamics simulations to unravel dynamical effects in more detail. Comparison of the properties of H′Pym–W\textsubscript{n} with those of neutral Pym–W\textsubscript{n} clusters reveals the drastic effects of protonation on microhydration, with respect to both their H-bonded structures and their interaction strength.
