Abstract

We study the longitudinal polarization of the $\bar{\Sigma}^-$, $\bar{\Sigma}^+$, $\bar{\Xi}^0$ and $\bar{\Xi}^+$ anti-hyperons in polarized high energy $pp$ collisions at large transverse momenta, extending a recent study for the $\bar{\Lambda}$ anti-hyperon. We make predictions by using different parameterizations of the polarized parton densities and models for the polarized fragmentation functions. Similar to the $\bar{\Lambda}$ polarization, the $\bar{\Xi}^0$ and $\bar{\Xi}^+$ polarizations are found to be sensitive to the polarized anti-strange sea, $\Delta\bar{s}(x)$, in the nucleon. The $\bar{\Sigma}^-$ and $\bar{\Sigma}^+$ polarizations show sensitivity to the light sea quark polarizations, $\Delta\bar{u}(x)$ and $\Delta\bar{d}(x)$, and their asymmetry.

I. INTRODUCTION

The self spin-analyzing parity violating decay of hyperons and anti-hyperons provides a practical way to determine the hyperon and anti-hyperon polarization by measuring the angular distributions of the decay products. The polarizations have been used widely in studying various aspects of spin physics in high energy reactions. The discovery of transverse hyperon polarization in unpolarized hadron-hadron and hadron-nucleus collisions in the 1970s led to many subsequent studies, both experimentally and theoretically. Phenomenological studies of longitudinal hyperon polarization may be found in Refs. 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26. The main themes of these studies can be categorized as follows. On the one hand, one aims to study spin transfer in the fragmentation process. On the other, one aims to get insight in the spin structure of the initial hadrons. Experimental data are available from $e^+e^-$-annihilation at the Z-pole, deep-inelastic scattering with polarized beams and targets, and proton-proton ($pp$) collisions.

The study of anti-hyperon polarization remains topical. Recent COMPASS data seem to indicate a difference between Lambda and anti-Lambda polarization. The proton spin physics program at the Relativistic Heavy Ion Collider (RHIC) has come online. A recent study for anti-Lambda polarization in polarized pp collisions shows sensitivity to the anti-strange quark spin contribution to the proton spin, which is only poorly constrained by existing data. In this paper, we evaluate the longitudinal polarization of the $\bar{\Sigma}^-$, $\bar{\Sigma}^+$, $\Xi^0$ and $\Xi^+$ anti-hyperons in $pp$ collisions at large transverse momenta $p_T$. Section II contains the phenomenological framework and discusses the current knowledge of the parton distribution and fragmentation functions. The contributions to the anti-hyperon production cross sections are discussed in Section III, followed by results for the polarizations in Section IV and a short summary in Section V.

II. PHENOMENOLOGICAL FRAMEWORK

The method to calculate the longitudinal polarization of high $p_T$ hyperons and anti-hyperons in high energy $pp$ collisions is based on the factorization theorem and perturbative QCD and has been described in earlier works. For self-containment
we briefly summarize the key elements and emphasize the aspects that are specific to anti-hyperons in the following of this section.

A. Formalism

We consider the inclusive production of high $p_T$ anti-hyperons ($\bar{H}$) in $pp$ collisions with one of the beams longitudinally polarized. The longitudinal polarization of $\bar{H}$ is defined as,

$$
P_{\bar{H}}(\eta) \equiv \frac{d\sigma(p_+p \rightarrow \bar{H}_+X) - d\sigma(p_+p \rightarrow \bar{H}_-X)}{d\sigma(p_+p \rightarrow \bar{H}_+X) + d\sigma(p_+p \rightarrow \bar{H}_-X)} = \frac{d\Delta\sigma}{d\eta}(\bar{p}p \rightarrow \bar{H}X)/\frac{d\sigma}{d\eta}(pp \rightarrow \bar{H}X),$$

where $\eta$ is the pseudo-rapidity of the $\bar{H}$, the subscripts + and − denote positive and negative helicity, and $\Delta\sigma$ and $\sigma$ are the polarized and unpolarized inclusive production cross sections.

We assume that transverse momentum $p_T$ of the produced $\bar{H}$ is high enough so that the cross section can be factorized in a collinear way. In this case, the $\bar{H}$’s come merely from the fragmentations of high $p_T$ partons from $2 \rightarrow 2$ hard scattering ($ab \rightarrow cd$) with one initial parton polarized, and the polarized inclusive production cross section is given by,

$$
\frac{d\Delta\sigma}{d\eta}(\bar{p}p \rightarrow \bar{H}X) = \int_{p_T^{min}} dp_T \sum_{abcd} \int dx_a dx_b \Delta f_a(x_a)f_b(x_b) D^{\bar{a}b\rightarrow \bar{c}d}_L(y) \frac{d\hat{\sigma}}{d\hat{t}}(ab \rightarrow cd) \Delta D^{\bar{H}}_c(z),
$$

where the transverse momentum $p_T$ of $\bar{H}$ is integrated above a threshold $p_T^{min}$; the sum concerns all sub-processes; $\Delta f_a(x_a)$ and $f_b(x_b)$ are the polarized and unpolarized parton distribution functions in the proton, $x_a$ and $x_b$ are the momentum fractions carried by partons $a$ and $b$, $D^{\bar{a}b\rightarrow \bar{c}d}_L(y) \equiv d\hat{\sigma}/d\hat{t}$ is the partonic spin transfer factor in the elementary hard process $\bar{a}b \rightarrow \bar{c}d$ with cross section $\hat{\sigma}$, $y \equiv p_b \cdot (p_a - p_c)/p_a \cdot p_b$ is defined in terms of the four momenta $p$ of the partons $a$–$d$, and $\Delta D^{\bar{H}}_c(z)$ is the polarized fragmentation function. It is defined by,

$$
\Delta D^{\bar{H}}_c(z) \equiv D^{\bar{H}}_c(z,+) - D^{\bar{H}}_c(z,-),
$$

in which the argument $z$ is the momentum carried by $\bar{H}$ relative to the momentum of the fragmenting parton $c$, and the arguments + and − denote that the produced $\bar{H}$ has equal or opposite helicity as parton $c$. The scale dependencies of the parton distribution and fragmentation functions have been omitted for notational clarity. Intrinsic transverse momenta in the proton and in the fragmentation process are small compared to $p_T$ and are not considered above.
The unpolarized inclusive production cross section, \(d\sigma/d\eta\), is given by an analogous expression with unpolarized parton distribution and fragmentation functions.

### B. Inputs

The differential cross section is a convolution of three factors, the parton distribution functions, the cross section of the elementary hard process, and the fragmentation functions. We discuss them separately in the following.

1. **The partonic spin transfer factors** \(D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y)\) in the hard scattering

   The partonic spin transfer factor \(D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y)\) is determined by the spin dependent hard scattering cross sections, many of which are known at leading and next to leading order \([29, 30, 31]\). The leading order results for \(D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y)\) are functions only of \(y\), defined above, and are tabulated in Ref. \([18]\) for quarks. Here, we are particularly interested in anti-quarks. By using charge conjugation, a symmetry which is strictly valid in QCD, one obtains

   \[D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y) = D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y),\]  
   \[D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y) = D_{\vec{a} \vec{b} \rightarrow \vec{c} \vec{d}}^L(y),\]  

   etc. Consistency demands that the partonic spin transfer be used with the polarized parton distributions and fragmentation functions of the same order. In view of the current knowledge of the polarized fragmentation functions, we consider only the leading order.

2. **The parton distribution functions**

   The unpolarized parton distribution functions \(f(x)\) are determined from unpolarized deep inelastic scattering and other related data from unpolarized experiments. Many parametrizations exist also for the polarized parton distribution functions \(\Delta f(x)\), e.g. GRSV2000, BB, LSS, GS, ACC, DS2000, and DNS2005 \([32, 33, 34, 35, 36, 37, 38]\). However, they are much less well constrained by data and large differences exist in particular for the parameterizations of the polarized anti-sea distributions. This is illustrated in Fig. \([1]\) where the anti-sea distributions from the GRSV2000 \([32]\) and DNS2005 \([38]\) parametrizations are shown.
FIG. 1: Polarized anti-sea quark distributions from the leading order GRSV2000 (upper) and DNS2005 (lower) parameterizations evaluated at a scale $Q = 10 \text{GeV}$.

3. The polarized fragmentation functions $\Delta D^H_c(z)$

The polarized fragmentation functions $\Delta D^H_c(z)$ are defined in Eq. (3) and represent the difference of the probability densities for finding an anti-hyperon $\bar{H}$ in a parton $c$ with equal and opposite helicity as parton $c$. They have been studied experimentally in $e^+e^-$-annihilation, polarized deep-inelastic scattering, and high $p_T$ hadron production in polarized $pp$ collisions, but present data [2, 3, 4, 5, 6, 7, 27] do not provide satisfactory constraints. It is thus necessary to make an Ansatz or model.

Several Ansätze have been adopted in the literature [13, 14, 15, 23]. One possibility is to relate $\Delta D^H_c(z)$ to the unpolarized fragmentation functions $D^H_c(z)$ by means of spin transfer coefficients. Alternatively, one could use the Gribov relation [39], a proportionality relating $D^H_c(z) \propto q^H_c(z)$ and $\Delta D^H_c(z) \propto \Delta q^H_c(z)$ in which $q^H_c(z)$ and $\Delta q^H_c(z)$ are the parton distributions in the (anti-)hyperon. Other approaches to $\Delta D^H_c(z)$ are in essence often different combinations or approximations of the aforementioned approaches. Although this paper is focused on the leading order, it should be noted that in general the distributions depend also on the scale $Q^2$. The $Q^2$-evolutions of the distributions are generally different and Ansätze
of this type are thus necessarily made at specific values of $Q^2$. The $\bar{H}$ sample produced in experiment consists of the QCD contributions and of contributions from electromagnetic or electroweak decays of heavier resonances. The latter are not formally part of the cross sections in the factorized framework, but do need to be considered in comparisons between theory and experiment.

In this paper, we use the Lund string fragmentation model [40] to describe the hadronization process and hence to evaluate the probability densities expressed by the fragmentation functions. This model enables us to distinguish between directly produced $\bar{H}$ and $H$ which are decay products of heavier resonances and, furthermore, to distinguish between $\bar{H}$ that contain the initial parton $c$ and those that do not. It should be noted that Lund string fragmentation is in general not equivalent to the independent fragmentation in the factorized framework, and the fragmentation probability densities are not necessarily universal. We expect that such effects are numerically unimportant for the $\bar{H}$ considered in this paper, $\bar{H}$ produced at central rapidities with large $p_T$ in polarized $pp$ collisions at RHIC, and have verified explicitly for the $\bar{\Lambda}$ in these conditions that indeed the same (anti-)quark fragmentation probabilities are found as in a kinematically equivalent colliding $e^+e^-$ system.

Keeping the notation, we thus express polarized fragmentation function as the sum of contributions from directly produced and from decay $\bar{H}$,

$$\Delta D^\bar{H}_c(z) = \Delta D^\bar{H}_c(z; \text{direct}) + \Delta D^\bar{H}_c(z; \text{decay}),$$

and evaluate the decay contribution $\Delta D^\bar{H}_c(z; \text{decay})$ by a sum over parent anti-hyperons $\bar{H}_j$ and kinematic convolutions,

$$\Delta D^\bar{H}_c(z; \text{decay}) = \sum_j \int dz' t_{\bar{H},\bar{H}_j}^{D} K_{\bar{H},\bar{H}_j}(z, z') \Delta D^\bar{H}_j(z'),$$

in which the kernel function $K_{\bar{H},\bar{H}_j}(z, z')$ is the probability for the decay of the parent $\bar{H}_j$ with a fractional momentum $z'$ to produce $\bar{H}$ with fractional momentum $z$, and $t_{\bar{H},\bar{H}_j}^{D}$ is the spin transfer factor in the decay process.

Most of the decay processes involved here are two body decay $\bar{H}_j \rightarrow \bar{H}M$. For an unpolarized two body decay, the kernel function $K_{\bar{H},\bar{H}_j}(z, z')$ can easily be calculated and is the same as that for $H_j \rightarrow H M$. In this case, the magnitude of the momentum of $H$ is fixed and the direction is isotropically distributed in the rest frame of the parent $H_j$. A Lorentz
transformation to the moving frame of $H_j$ gives,

$$K_{H,H_j}(z, \bar{p}_T'; z', \bar{p}_T') = \frac{N}{E_j} Br(H_j \rightarrow HM) \delta(p \cdot p_j - m_j E^*),$$  

(8)

where $Br(H_j \rightarrow HM)$ is the decay branching ratio, $N$ is a normalization constant, and $E^*$ is the energy of $H$ in the rest frame of $H_j$, which depends on the parent mass $m_j$ and on the masses of the decay products. The corresponding calculation of $K_{H,H_j}(z, z')$ for a polarized $H_j$ is more involved since the angular decay distribution can be anisotropic in the case of a weak decay and each decay process needs to be dealt with separately. However, since the $E^*$ is usually small compared to the momentum of $H_j$ in the $pp$ center of mass frame, the anisotropy can be neglected and Eq. (8) forms a good approximation.

The decay spin transfer factors for hyperons $H_j \rightarrow H + X$ are discussed and given e.g. in Refs. ([11, 17]). Charge conjugation is a good symmetry for these decays, and hence $t^{D}_{H,H_j} = t^{D}_{H,H_j}$. Furthermore, $\Delta D^H_f(z; \text{direct}) = \Delta D^H_f(z; \text{direct})$, so that only $\Delta D^H_f(z; \text{direct})$ need to be modeled. The main strong decay contributions are those from $J^P = (3/2)^+$ hyperons, such as $\Sigma^* \rightarrow \Sigma \pi$, and $\Xi^* \rightarrow \Xi \pi$. The electromagnetic and weak decay contributions, for example $\Sigma^0 \rightarrow \Lambda \gamma$ and $\Xi \rightarrow \Lambda \pi$, can be evaluated analogously and we will include these contributions in our results.

Our aforementioned classification follows Refs. ([11, 12, 16, 17, 18, 19] and distinguishes (A) directly produced hyperons that contain the initial quark $q$ of flavor $f$; (B) decay products of heavier polarized hyperons; (C) directly produced hyperons that do not contain the initial $q$; (D) decay products of heavier unpolarized hyperons. Therefore,

$$D^H_f(z; \text{direct}) = D^H_f(z; \text{direct}) + D^H_f(z; \text{direct}).$$  

(9)

for the unpolarized fragmentation functions and, similarly, for the polarized fragmentation functions,

$$\Delta D^H_f(z; \text{direct}) = \Delta D^H_f(z; \text{direct}) + \Delta D^H_f(z; \text{direct}).$$  

(10)

We assume that directly produced hyperons which do not contain the initial quark are unpolarized, so that

$$\Delta D^H_f(z; \text{direct}) = 0.$$  

(11)

The polarization of directly produced hyperons then originates only from category (A) and is given by,

$$\Delta D^H_f(z; \text{direct}) = t^F_{H,f} D^H_f(z; \text{direct}),$$  

(12)
in which $t^F_{H,f}$ is known as the fragmentation spin transfer factor. If the quarks and anti-quarks produced in the fragmentation process are unpolarized, consistent with Eq. (11), then $t^F_{H,f}$ is a constant given by,

$$t^F_{H,f} = \Delta Q_f / n_f,$$

(13)

where $\Delta Q_f$ is the fractional spin contribution of a quark with flavor $f$ to the spin of the hyperon, and $n_f$ is the number of valence quarks of flavor $f$ in $H$. In recursive cascade hadronization models, such as Feynman-Field type fragmentation models [41] where a simple elementary process takes place recursively, $D^H_f(A_f)(z)$ and $D^H_{C_f}(z)$ are well defined and determined. In such hadronization models, $D^H_f(A_f)$ is the probability to produce a first rank $H$ with fractional momentum $z$. This probability is usually denoted by $f^H_q(z)$ in these models, so that $D^H_{C_f}(z) = D^H_f(z)$; direct $- f^H_q(z)$, and $f^H_q(z)$ is well determined by unpolarized fragmentation data. Hence, in such models the $z$-dependence of the polarized fragmentation functions $\Delta D$ is obtained from the unpolarized fragmentation functions, which are empirically known. The only unknown is the spin transfer constant $t^F_{H,q} = \Delta Q_f / n_f$.

By using either the SU(6) wave function or polarized deep-inelastic lepton-nucleon scattering data, two distinct expectations have been made for $\Delta Q_f$, the so-called SU(6) and DIS expectations [16].

The approach described above has been applied to the polarizations of different hyperons in $e^+e^-$, semi-inclusive DIS and $pp$ collisions, anti-hyperons in semi-inclusive DIS and anti-Lambda in $pp$ [11, 12, 16, 17, 18, 19, 20, 21, 26]. The results can be compared with data [2, 3, 4, 5, 6, 7, 27]. The current experimental accuracy does not allow one to distinguish between the expectations for $t^F_{H,f}$ based on the SU(6) and DIS pictures. The $z$-dependence of the available data on $\Lambda$ polarization is well described [16]. The approach is thus justified by existing data. We will use both the SU(6) and DIS pictures for our present predictions.

**C. Implementation**

The expression for the polarization of anti-hyperons, $P_{\bar{H}}$, follows from the definition in Eq. (11) and the factorized cross sections (c.f. Eq. (2)), and is given by

$$P_{\bar{H}}(\eta) = \frac{\int_{p_T^{min}} dp_T \sum_{abcd} \int dx_a dx_b f_a(x_a) f_b(x_b) \frac{d\sigma}{dt}(ab \rightarrow cd) P_{c/ab \rightarrow cd(x_a, y)} \Delta D^\bar{H}_c(z)}{\int_{p_T^{min}} dp_T \sum_{abcd} \int dx_a dx_b f_a(x_a) f_b(x_b) \frac{d\sigma}{dt}(ab \rightarrow cd) D^H_c(z)},$$

(14)
where, \( P_{c/ab \rightarrow cd}(x, y) = D_L^{\bar{a}b \rightarrow \bar{c}d}(y) \Delta f_a(x_a)/f_a(x_a) \) is the polarization of parton \( c \) before it fragments. This can be rewritten using the model to calculate \( \Delta D_{c}^\bar{H}(z) \) according to the origin of \( \bar{H} \) (c.f. section II B 3),

\[
P_{\bar{H}}(\eta) = \frac{\int_{p_{T_{\text{min}}}} d^2 p_T \sum_{abcd} \sum_\alpha \int dx_a dx_b f_a(x_a) f_b(x_b) \frac{d\mathcal{A}}{dt}(ab \rightarrow cd) D_{c}^{\bar{H}(\alpha)}(z) P_{c/ab \rightarrow cd}(x_a, y) S_{c}^{\bar{H}(\alpha)}(z)}{\int_{p_{T_{\text{min}}}} d^2 p_T \sum_{abcd} \sum_\alpha \int dx_a dx_b f_a(x_a) f_b(x_b) \frac{d\mathcal{A}}{dt}(ab \rightarrow cd) D_{c}^\bar{H}(z)},
\]

where the summation over \( \alpha \) concerns the four process classes from which the \( \bar{H} \) originate, and \( S_{c}^{\bar{H}(\alpha)}(z) = \Delta D_{c}^{\bar{H}(\alpha)}(z)/D_{c}^{\bar{H}(\alpha)}(z) \) denotes the spin transfer factor in the fragmentation for each of these classes (c.f. section II B 3).

The anti-hyperon polarization \( P_{\bar{H}} \) can be in principle be evaluated numerically from Eq. (14). In practice, it is feasible and actually advantageous to use a Monte-Carlo event generator that incorporates all hard scattering processes and uses a recursive hadronization model to evaluate \( P_{\bar{H}} \) from Eq. (15). In particular, this ensures in a natural way that all sub-processes, including feed-down contributions, are taken into account. Furthermore, it facilitates comparisons of the predictions with experiment data since event generator output can be propagated through detailed detector simulations so that, for example, the experiment kinematic acceptance for the observed \( \bar{H} \) decay products can be taken into account without relying on extrapolation over unmeasured regions.

We have used the PYTHIA event generator, which incorporates the hard scattering processes and uses the Lund string fragmentation model \([40]\), in our calculations. PYTHIA is commonly used for hadron-hadron collisions and its output has been tested and tuned to describe a vast body of data. In particular, reasonable agreement is found for \( \Lambda + \bar{\Lambda} \) production that was recently measured for transverse momenta up to 5 GeV in \( pp \) collisions at RHIC \([42]\) when a \( K \)-factor of \( \sim 3 \) is used. For the results presented here we have used PYTHIA version 6.4 with all hard scattering processes selected and initial and final state radiation switched off. We have verified that the aforementioned \( K \)-factor does not affect the polarization results.

III. ANTI-HYPERON PRODUCTION

The longitudinal polarization of high \( p_T \) anti-hyperons produced in \( pp \) collisions is determined by the polarization of the initial partons taking part in the hard scattering, the
partonic spin transfer factor, and the spin transfer in the fragmentation process. Since the up, down, and strange quark and anti-quark polarizations in the polarized proton are different and the spin transfer in the fragmentation process for a given type of anti-hyperon is flavor dependent as well, the contributions to $\bar{H}$ production from the fragmentation of different quark flavors and gluons need to be studied. These contributions are independent of polarization and have been determined in multi-particle production data in high energy reactions. An impressive body of data has been collected over the past decades and the contributions can thus be considered to be known accurately and to be well-modeled in Monte-Carlo event generators.

As described in Section II C, we have used the \textsc{pythia} generator [40] to evaluate the contributions to the production of the $\bar{\Sigma}^-$, $\bar{\Sigma}^+$, $\bar{\Xi}^0$ and $\bar{\Xi}^+$ anti-hyperons. The flavor compositions of these anti-hyperons lead us to expect a large contribution to the production of $\bar{\Sigma}^+ (\bar{d}\bar{d}\bar{s})$ from $\bar{d}$-fragmentation, a large contribution to $\bar{\Sigma}^- (\bar{u}\bar{u}\bar{s})$ production from $\bar{u}$-fragmentation, and a large contribution to $\bar{\Xi}$-production from $\bar{s}$-fragmentation.

![FIG. 2: Contributions to $\bar{\Sigma}^- (\bar{u}\bar{u}\bar{s})$ production with $p_T \geq 8$ GeV/c in $pp$ collisions at $\sqrt{s} = 200$ GeV. The continuous and dashed lines are respectively the directly produced and decay contributions.](image-url)
Fig. 3 shows the results for the fractional contributions to \( \bar{\Sigma}^- \) production from the fragmentation of anti-quarks/quarks of different flavors and of gluons in \( pp \) collisions at \( \sqrt{s} = 200 \) GeV for hyperon transverse momenta \( p_T > 8 \) GeV versus pseudo-rapidity \( \eta \). The decay contribution to \( \bar{\Sigma}^- \) production is seen to be negligibly small. This is different than for \( \bar{\Lambda} \) production and implies that its polarization measurement will reflect more directly the spin structure of the nucleon and the polarized fragmentation function. The results are symmetric in \( \eta \leftrightarrow -\eta \) since \( pp \) collisions are considered. The \( \bar{d} \)-quark and \( s \)-quark fragmentation contributions originate from second or higher rank particles in the fragmentation and have similar shapes since both are sea quarks (anti-quarks). The increasingly large \( u \)-quark contribution with increasing \( |\eta| \) originates from valence quarks. Only the \( \bar{u} \)-quark and \( \bar{s} \)-quark give first rank fragmentation contributions. These contributions are sizable. Most important for the production of \( \bar{\Sigma}^- \) with \( p_T > 8 \) GeV and \( |\eta| < 1 \) are \( \bar{u} \) and gluon fragmentation. Since the \( \bar{\Sigma}^- \) spin is carried mostly by the \( \bar{u} \)-quark spins, this implies that the \( \bar{\Sigma}^- \) polarization in singly polarized \( pp \) collisions should be sensitive to \( \Delta \bar{u}(x) \), the \( \bar{u} \)-quark
polarization distribution in the polarized proton.

The results for $\Sigma^+$, shown in Fig. 3, are similar to those for $\Sigma^-$ when $\bar{u}$ and $\bar{d}$ are interchanged. The small difference between the fractional contribution of the $\bar{u}$-quark to $\Sigma^-$ production and of the $\bar{d}$-quark to $\Sigma^+$ production reflects the asymmetry of the light sea density in the proton, $\bar{d}(x) > \bar{u}(x)$, which is built into the parton distribution functions. The large $\bar{d}$-quark fragmentation contribution to $\Sigma^+$ production and the large $\bar{d}$-quark spin contribution to the $\Sigma^+$ spin lead us to expect that $\Sigma^+$ polarization measurements in $pp$ collisions are sensitive to $\Delta \bar{d}(x)$.

![Graph showing contributions to $\Xi^0(\bar{u}\bar{s}\bar{s})$ production with $p_T \geq 8$ GeV/c in $pp$ collisions at $\sqrt{s} = 200$ GeV.](image)

**FIG. 4**: Contributions to $\Xi^0(\bar{u}\bar{s}\bar{s})$ production with $p_T \geq 8$ GeV/c in $pp$ collisions at $\sqrt{s} = 200$ GeV. The continuous and dashed lines are respectively the directly produced and decay contributions.

Figs. 4 and 5 show the fractional contributions for $\Xi^0$ and $\Xi^+$ production, respectively. The dominant contribution originates from $\bar{s}$-quark fragmentation. It amounts to almost half the $\Xi$ production, and is larger than the $\bar{d}$-quark fragmentation contribution to $\Sigma^+$ production and the $\bar{u}$-quark fragmentation contribution to $\Sigma^-$ production. This results from strange suppression, which reduces the relative contributions from $\bar{u}$ and $\bar{d}$-quark fragmentation to $\Xi$ production. We thus expect that $\Xi$ polarization measurements are sensitive to
FIG. 5: Contributions to $\Xi^+(d\bar{s}\bar{s})$ production with $p_T \geq 8$ GeV/c in $pp$ collisions at $\sqrt{s} = 200$ GeV. The continuous and dashed lines are respectively the directly produced and decay contributions.

FIG. 6: Contributions to $\Sigma^-(\bar{u}\bar{s}\bar{s})$, $\Sigma^+(d\bar{d}\bar{s})$, $\Xi^0(\bar{u}\bar{s}\bar{s})$ and $\Xi^+(d\bar{s}\bar{s})$ production for $|\eta| < 1$ in $pp$ collisions at $\sqrt{s} = 200$ GeV versus transverse momentum $p_T$. 
\( \Delta s(x) \) in the nucleon. They are thus complementary to polarization measurements of the \( \Lambda \) \[20\], which has a larger production cross section but also larger decay contributions.

In Fig. 6 we show the \( p_T \) dependence of the fractional fragmentation contributions for the mid-rapidity region, \(|\eta| < 1\), for the \( \Sigma^-\), \( \Sigma^+\), \( \Xi^0\), \( \Xi^+\), as well as the \( \Lambda \). The anti-quark contributions generally increase with increasing \( p_T \), and the gluon contributions decrease.

### IV. RESULTS AND DISCUSSION

We have evaluated \( P_H \) for the \( \Sigma^-\), \( \Sigma^+\), \( \Xi^0\), and \( \Xi^+\) anti-hyperons as a function of \( \eta \) for \( p_T \geq 8\text{GeV} \) and \( \sqrt{s} = 200\text{ GeV} \) using different parametrizations for the polarized parton distributions and using the SU(6) and DIS pictures for the spin transfer factors \( t_{H,q}^F \) in the fragmentation. In all cases, the unpolarized parton distributions of Ref. \[43\] were used. The results using the polarized parton distributions of Ref. \[32\] are shown in Fig. 7 together with our previous results for \( P_\Lambda \) \[26\]. The main characteristics are:

- the size of the polarization increases in the forward direction with respect to the polarized proton beam and can be as large as \( 10\% \) (\( \Xi^0\), \( \Xi^+ \)) at \( \eta = 2 \),
- the differences between the \( H \) polarizations obtained for different parametrizations of the polarized parton distribution functions are generally larger than the differences between the results for different models for the spin transfer in fragmentation,
- the size of the polarizations for the \( \Sigma^-\) and \( \Sigma^+\) hyperons is smaller than for the \( \Lambda \) and \( \Xi \) hyperons because of the lower fractional contributions from \( \bar{u} \) and \( \bar{d} \) fragmentation to \( \Sigma^-\) and \( \Sigma^+\) production than from \( \bar{s} \) fragmentation to the \( \Lambda \) and \( \Xi \) production,
- the results for \( \Sigma^-\) and \( \Sigma^+\) for the GRSV2000 valence distributions differ in sign because of the sign difference in \( \Delta \bar{u}(x) \) and \( \Delta \bar{d}(x) \), and in size and shape because of flavor-symmetry breaking in the unpolarized and this polarized parton distribution scenario,
- the \( \Xi^0\) and \( \Xi^+\) polarizations are similar to each other because of the dominance of \( \bar{s} \)-fragmentation; they are somewhat larger than the \( \Lambda \) polarization because of the smaller decay contributions and their sensitivity to \( \Delta \bar{s} \) is thus more direct.

Fig. 8 shows the polarizations in the pseudo-rapidity range \( 0 < \eta < 1 \) versus transverse momentum \( p_T \). The polarizations are sensitive mostly to the polarized anti-quark distributions for momentum fractions \( 0.05 < x < 0.25 \) and the \( p_T \)-dependences are consequently
FIG. 7: Longitudinal polarization for anti-hyperons with transverse momentum $p_T \geq 8$ GeV/c in $pp$ collisions at $\sqrt{s} = 200$ GeV with one longitudinally polarized beam versus pseudo-rapidity $\eta$. Positive $\eta$ is taken along the direction of the polarized beam.

not very strong. Only a modest variation is expected also with center-of-mass energy. To illustrate this, we have repeated the calculations for $\sqrt{s} = 500$ GeV. Fig. 9 shows the $\eta$-dependence for $p_T > 10$ GeV. Apart from differences expected from phase-space, the results are seen to be very similar to those in Fig. 7.

Gluon fragmentation is seen to contribute sizably to the production of anti-hyperons in the central rapidity range in Figs.(2-6). The fragmentation of gluons is less well known than that of quarks even in the unpolarized case and also the polarization of gluons in the colliding polarized protons cannot be determined precisely from current data. In the estimates, as in earlier calculations [11, 12, 16, 17, 18, 19, 20, 21, 26], we have taken into account the spin transfer in the hard scattering of gluons, and have neglected the spin transfer in the fragmentation of gluons into anti-hyperons. This assumption is consistent with the model used for the polarized fragmentation functions. Data with improved precision on the production cross sections and on gluon polarization would provide important constraints.
FIG. 8: Longitudinal polarization for anti-hyperons with pseudo-rapidity $0 < \eta < 1$ in $pp$ collisions at $\sqrt{s} = 200$ GeV with one longitudinally polarized beam versus transverse momentum $p_T$. Positive $\eta$ is taken along the direction of the polarized beam.

In particular, we expect that our results are largely unaffected if the gluon spin contribution to the proton spin is found to be small. Current data \cite{44} excludes the large values that were proposed originally to explain the quark spin contribution to the proton spin \cite{45}.

Last, we have estimated the precision with which $\vec{H}$ polarization measurements could be made at RHIC \cite{28}. For an analyzed integrated luminosity of $\mathcal{L} \simeq 300$ pb$^{-1}$ and a proton beam polarization of $P \simeq 70\%$, we anticipate that e.g. $P_\Xi$ could be measured to within $\sim 0.02$ uncertainty. Measurements of $\vec{H}$ polarization at RHIC are thus worthwhile in view of the presently limited knowledge of $\Delta \bar{q}(x)$ in the nucleon, as evidenced in particular by the large differences between the parametrization sets of Ref. \cite{32}.

V. SUMMARY

In summary, we have evaluated the longitudinal polarizations of the $\bar{\Sigma}^-, \bar{\Sigma}^+, \bar{\Xi}^0$, and $\bar{\Xi}^+$ anti-hyperons in highly energetic collisions of longitudinally polarized proton beams. The
FIG. 9: Longitudinal polarization for anti-hyperons with $p_T > 10$ GeV as a function of the pseudo-rapidity $\eta$ in $pp$ collisions at $\sqrt{s} = 500$ GeV with one longitudinally polarized beam. Positive $\eta$ is taken along the direction of the polarized beam.

results show sensitivity to the anti-quark polarizations in the nucleon sea. In particular, the $\bar{\Sigma}^-$ and $\bar{\Sigma}^+$ polarizations are sensitive to the light sea quark polarizations, $\Delta \bar{u}(x)$ and $\Delta \bar{d}(x)$. The $\bar{\Xi}^0$ and $\bar{\Xi}^+$ polarizations are sensitive to strange anti-quark polarization $\Delta \bar{s}(x)$. Precision measurements at the RHIC polarized $pp$-collider should be able to provide new insights in the sea quark polarizations in the nucleon.
