ABSTRACT
We analyse the dark matter (DM) distribution in an ≈ 10^{12} M_{⊙} halo extracted from a simulation consistent with the concordance cosmology, where the physics regulating the transformation of gas into stars was allowed to change producing galaxies with different morphologies. Although the DM profiles get more concentrated as baryons are collected at the centre of the haloes compared to a pure dynamical run, the total baryonic mass alone is not enough to fully predict the reaction of the DM profile. We also note that baryons affect the DM distribution even outside the central regions. Those systems where the transformation of gas into stars is regulated by supernova (SN) feedback, so that significant disc structures are able to form, are found to have more concentrated DM profiles than a galaxy which has efficiently transformed most of its baryons into stars at early times. The accretion of satellites is found to be associated with an expansion of the DM profiles, triggered by angular momentum transfer from the incoming satellites. As the impact of SN feedback increases, the satellites get less massive and are even strongly disrupted before getting close to the main structure causing less angular momentum transfer. Our findings suggest that the response of the DM halo is driven by the history of assembly of baryons into a galaxy along their merger tree.

Key words: galaxies: haloes – galaxies: structure – dark matter.

1 INTRODUCTION
Dark matter (DM) haloes in cold dark matter (CDM) scenarios have been extensively studied during the last decades (e.g. Merritt et al. 2006; Prada et al. 2006; Gao et al. 2008; Navarro et al. 2008), since understanding their properties is relevant not only for the study of galaxy formation but also for constraining the nature of DM itself (e.g. Springel et al. 2008a). Several controversies have been issues of thoughtful discussions such as the universality of the DM profiles (Navarro, Frenk & White 1996, hereafter NFW) or the systematic increasing central DM density with increasing numerical resolution (Moore et al. 1999). However, new improvements in the numerical codes and computational power have challenged previous results. Recently, Navarro et al. (2008) found evidence for the non-universality of the DM profiles and non-cuspy inner profiles by using high-resolution N-body simulations.

The assembly of baryons in galaxies is expected to drive changes in the DM distribution as it reacts to gas infall and outflows (e.g. Read & Gilmore 2005) and to the angular momentum redistribution caused by infalling satellites (Barnes & Hernquist 1996; Debattista et al. 2008, hereafter D08). Blumenthal et al. (1986, B86; see also Young 1980 for a different implementation) proposed the adiabatic contraction (AC) model to globally predict the effects of central baryonic accumulation on the DM distribution. Although it is clear that the condensation of baryons increases the DM concentration, it remains to be determined how this would proceed and how the transformation of baryons into stars and supernovae (SN) feedback might affect the DM distribution. Gnedin & Zhao (2002) studied the effects of maximum feedback on the central density of DM haloes of gas-rich dwarfs, finding them to be too weak to explain the observed rotation curves. Interestingly, Read & Gilmore (2005) showed that two impulsive mass-loss phases are needed to significantly change the DM profiles of dwarf galaxies, suggesting the need for bursty star formation histories. Also, several works have studied the change in shape of DM haloes towards rounder configurations induced by the presence of a central baryonic concentration (Kazantzidis et al. 2004). D08 claimed that a larger, irreversible change in the DM distribution can be produced if there is transport of angular momentum from baryons to the DM. In a fully cosmological context, simulations have already shown how the DM haloes concentrate with increasing baryonic condensation, providing hints of a possible dependence on the assembly history of baryons (e.g. Tissera & Dominguez-Tenreiro 1998; Gnedin et al. 2004; O’lohere et al. 2007). However, the high complexity of the problem requires high numerical resolution to describe in more detail the joint evolution of the DM and the baryonic distributions to get more robust results. Also, none of these previous studies

*E-mail: susana.pedrosa@gmail.com
included treatments for SN feedback and a multiphase interstellar medium (ISM) self-consistently. This is of particular relevance since feedback regulates the star formation not only in the main galaxy, but also in the merging substructures and, as a consequence, it might also change the history of angular momentum transfer process which plays a major role in hierarchical scenarios (e.g. Navarro et al. 2004; D08).

We study a set of intermediate-resolution cosmological simulations where different baryonic structures have been formed from the same initial condition (IC), through the modification of the physics of baryons (Scannapieco et al. 2008, hereafter S08). These experiments are taken as toy models to analyse how the DM evolves when baryons are assembled in a different fashion. In this Letter, we focus our discussion on four experiments which better illustrate the main results (for further details see Pedrosa et al. in preparation).

2 SIMULATIONS AND ANALYSIS

We analysed four simulations of an $\approx10^{12} M_\odot$ type galaxy run with an extended version of the code GADGET-2 (Scannapieco et al. 2005, 2006). Although all cosmological numerical simulations to date suffer from a number of limitations such as coarse-resolved star formation and ISM physics, this extended GADGET-2 code has been designed to improve the representation of the ISM and SN feedback (S08). Our simulations are fully cosmological and include a multiphase model for the gas component, metal-dependent cooling, chemical enrichment and energy feedback by Type II and Ia SN. The IC corresponds to an $\approx10^{12} M_\odot$ halo extracted from a cosmological simulation and re-simulated with higher resolution. This halo was required to have no major mergers since $z = 1$. The simulations are consistent with a ΛCDM universe with $\Omega_m = 0.7$, $\Omega_b = 0.3$, $\sigma_8 = 0.9$ and $H_0 = 100 h$ km s$^{-1}$ Mpc$^{-1}$, with $h = 0.7$. The particle mass is $1.6 \times 10^7$ and $2.4 \times 10^9 h^{-1} M_\odot$ for the DM and baryonic particles, respectively. The maximum gravitational softening used was $\epsilon_g = 0.8 h^{-1}$ kpc. At $z = 0$, the haloes are relaxed as indicated by a relaxation parameter of $\approx0.002$ (Neto et al. 2007). All analysed DM haloes have more than 120 000 particles within their virial radius (the total number of particles goes from $\approx170 000$ to $\approx320 000$ depending on the star formation histories). We analysed three simulations (NF, E-0.7 and E-3) of the same IC but using different input parameters for the SN feedback model. As a result, DM haloes finally host baryonic structures with different morphologies. In particular, simulation NF has been run without including SN feedback, while E-0.7 and E-3 include feedback assuming an energy per SN of $0.7 \times 10^{51}$ and $3 \times 10^{51}$ erg, respectively. For comparison, we also performed a pure gravitational run (DM-only) of the same IC (particle mass of $1.84 \times 10^7 h^{-1} M_\odot$).

A full discussion of the effects of SN feedback on the baryonic dynamics and star formation histories can be found in S08. Here, we only summarize the main characteristics of the galaxies which are relevant to our discussion. At $z = 0$, the galaxy formed in NF is dominated by an extended spheroid, with most of its stars formed at $z > 2$. E-0.7 has been able to produce a galaxy with an important disc component as a result of the regulation of star formation by SN feedback. This system has a half-mass radius of $5.72 h^{-1}$ kpc and a mass disc-to-spheroid ratio of 0.82. In E-3, the large amount of energy assumed per SN triggers violent outflows which expel a significant amount of the gas content of the main galaxy, producing a small thick stellar disc. Table 1 lists the final stellar masses of the galaxies formed in these simulations.

We constructed the DM profiles for the simulated galaxies at $z = 0$, after cleaning them from substructures. We fitted the NFW, Jaffe (1983) and Einasto (1965) expressions to the DM profiles, between three times the gravitational softening and the virial radius, finding that the Einasto model provides the best fit in all cases. The Einasto formula has three free parameters, $n$, $r_{\text{in}}$ and $r_{\text{in}}$, which indicate the sharpness of the profiles, and the radius and density where their logarithmic slope takes the isothermal value. The fitting values obtained for the different simulations are shown in Table 1. We estimated bootstrap errors for $n$ and $r_{\text{in}}$ by fitting the Einasto’s formula to 100 randomly generated realizations of the DM profiles and by estimating the standard dispersion over the generated set of parameters.

When baryons are considered, the shape of the DM profiles in the central regions changes significantly in comparison to the DM-only case, as it is shown in Fig. 1. The profile of the DM-only run is sharper (i.e. smaller $n$ value) than those of haloes with baryons, indicating the increase in the DM concentration in the latter cases. In E-3, where an extreme (and perhaps unrealistic) value of $3 \times 10^{51}$ erg was assumed, we obtained the less concentrated DM profile among the cases with baryons. In fact its DM profile is weakly more concentrated than the DM-only one. As expected, the galaxy in E-3 is also the most DM dominated one in the central region, as indicated by the total to stellar mass ratio $M_s/M_s$ (Table 1). In this simulation,
We compare the residuals of the circular velocities estimated by applying the AC method of B86 to the DM-only run taking into account the baryonic distributions of the corresponding hydrodynamical runs (thick lines) and those obtained directly from the simulations (thick lines) as shown in Fig. 3. All residuals are estimated with respect to the circular velocity of the DM-only run. We found that the B86 model not only overpredicts the level of concentration but also changes the shape of the DM distribution when compared to the DM profiles obtained from the cosmological runs. While in the B86 method, the effects are principally determined by the amount of baryons accumulated at the centre, the simulated profiles are the result of the joint evolution of baryons and DM. More sophisticated AC methods could account for these differences as suggested by the results of Gnedin et al. (2004) and Sellwood & McGaugh (2005). We will explore this possibility in a forthcoming paper.

As can be seen in Fig. 3, while the simulations yield the largest residuals for the E-0.7 run which has the important disc component, the B86 model predicts the strongest effect for the NF run because it has the largest baryonic mass system, almost twice more massive than in E07. In the case of E-3, similar level of residuals is obtained. In the very central regions (within one $\epsilon_g$ and three $\epsilon_g$), our simulations predict an expansion of the DM profiles when baryons are present which can be related to the evolution of the systems as discussed below. We also found this behaviour in the higher numerical resolution haloes of the Aquarius projects (Springel et al. 2008b).

These results suggest a connection between the DM evolution and the history of formation of the baryonic structures. To study this point, we estimated the concentration parameter proposed by Alam, Bullock & Weinberg (2002), $\Delta_{c/2}$. This parameter has the advantage of being independent of a specific density profile and, as it is an integrated quantity, it can be estimated more robustly at any time. In Fig. 4, we show $\Delta_{c/2}$ as a function of redshift for our set of simulations. All haloes increase their central concentration as they grow with time. The solid line shows the expected relation (i.e. hereafter critical relation) due to the expansion of the Universe alone. The DM-only run has the lowest DM concentration, as expected, at all times, although it flattens between $z \approx 1$ and 1.8, coinciding with the close approaching of two satellites. The transfer of angular momentum from the satellites to the DM can explain its

1This parameter measures the mean DM density normalized to the cosmic closure density within the radius at which the circular rotational speed due to the DM alone rises to half its maximum value.
The presence of baryons increases the weak action of SN feedback. An interesting behaviour is determined by the NF and E-0.7 runs. Both haloes have similar concentrations until \( z \approx 1.5 \), and from there on, the E-0.7 halo has systematically higher values of \( \Delta_{\rho/\rho_{\text{vir}}} \) than the NF one. The analysis of the baryonic dynamics of these tests shows that by this redshift the disc component in E-0.7 starts forming. The incoming satellites are less massive and the gas is able to settle on to a disc smoothly. This and the fact that the stellar disc is stable produce a smaller effective transfer of angular momentum to the DM which, at the end, is slightly more concentrated than in the NF.

The shape in the central region of the DM profiles can also be quantified by calculating the logarithm slope \( \gamma(r) = -d \ln \rho/\ln r \) at the innermost resolved radius. We found \( \gamma_{\text{inner}} \approx 1 \) for the DM-only run (Table 1), in agreement with recent estimations of Navarro et al. (2008) for galaxy-sized DM haloes in the Aquarius project. The presence of baryons increases \( \gamma_{\text{inner}} \) to \( \approx 1.25 \) as it can be seen in Table 1.

The shape of the DM profiles in dwarf galaxies is one of the main caveats of the CDM cosmology. And it is also a difficult problem to tackle by numerical codes due to limited numerical resolution and oversimplified modelling of baryonic physics. To shed light on this point, we studied a scaled down version of our galaxy designed to get a system of \( 10^{12} M_{\odot} \) virial mass, for the DNF (solid lines), DE-0.7 (short-dashed lines) and the D-only (long-dashed lines) experiments. The inner bin corresponds to three gravitational softenings. The inset plot shows the corresponding \( \Delta_{\rho/\rho_{\text{vir}}} \) concentration parameters as a function of redshift.

3 CONCLUSIONS

We found that, in all our \( 10^{12} \) haloes, including the baryons resulted in a more concentrated DM density distribution compared to the equivalent pure DM simulation. However, using the total baryonic mass that collects at the centre as input to the AC model of B86, we were not able to reproduce our final DM density distributions. Our results indicate that the way baryons are assembled into a galaxy affects the DM evolution so that its final distribution also depends on the morphology of the baryonic system. An efficient star formation activity produces satellites with larger stellar masses which are able to survive further in the halo. This could cause a larger angular momentum transfer (D08) which, on its turn, might explain the expansion of the DM central concentration. The treatment of SN feedback prevents this early overproduction of stars. Hence, the gas is allowed to get to the centre before being transformed into stars forming a more compact stellar spheroid at early times. At later times, the remnant gas and the disrupted satellites are able to settle on to more important disc structures. When SN feedback is very efficient and blows away significant masses of gas, then the DM profile is less affected because of both the low central baryonic concentration and the easier dissolution of smaller satellites that get into the halo. We found that this behaviour can be linked to a larger DM concentration presumably due to a weaker angular momentum transfer from the satellites to the DM. Our findings confirm previous lower resolution results and suggest new clues for
the understanding of galaxy formation, which will be explored in a forthcoming paper.
