Abstract

In this paper we present the outcome of the first international comparison in the terahertz frequency range among three different kinds of spectrometers. A Fourier-Transform infrared spectrometer, a vector network analyzer and a time-domain spectrometer have been employed for measuring the complex refractive index of three travelling standards made of selected dielectric materials in order to offer a wide enough range of parameters to be measured. The three spectrometers have been compared in terms of measurement capability and uncertainty.

Keywords: time domain spectrometer (TDS), Fourier transform infrared (FTIR) spectrometer, vector network analyzer (VNA), measurement intercomparison, terahertz (THz) radiation

1. Introduction

Terahertz (THz) radiation can pass through dielectric materials and is reflected back by conducting materials. Unlike x-rays, it is non-ionizing and allows for a variety of non-destructive tests giving access to significant material properties. Its potential for imaging is very high compared to microwaves, which offer a lower spatial resolution. On the other hand, it is more and more absorbed by water with increasing frequency [1]. Due to these unique properties, THz radiation has proved to be a valuable non-contact tool to gain insight into material properties [2].

Recently, THz technology has become more mature and ready-to-use: THz time-domain spectrometers (TDS) are now commercially available; Fourier transform infrared (FTIR) spectrometers can also be adapted for measurements in the THz frequency range typically defined from 100 GHz to 10 THz; vector network analyzers (VNA) have been utilized for THz dispersive spectroscopy, too [3, 4]. However, important properties and parameters such as the measurement uncertainty remain difficult to evaluate. Moreover, traceability of the main physical quantities to the international system of units (SI) is hardly available. The lack of measurement capabilities and methodologies for the main system parameters hinders the application of these technologies. Furthermore, missing metrological capabilities hamper the use of THz systems as measurement tools in fields such as security where reliability is crucial [5].

Because of the reasons mentioned above, instrument sellers do not quote the measurement uncertainty of their instruments, and measurements on the same material performed in different labs and with different techniques may not agree.

Given the availability of three different types of instruments, having a significant overlap of their frequency bands, a measurement comparison has been undertaken among three labs in two National Metrology Institutes (Istituto Nazionale di Ricerca Metrologica, INRIM, Torino, Italy, and Physikalisch-Technische Bundesanstalt, PTB, Braunschweig and Berlin, Germany). The aim of this work is to evaluate the performance of these spectrometers for measurements of material properties in the THz gap, in particular for what concerns measurement uncertainty. To the best of the authors'...
knowledge, no other comparison of the results obtained from the same material samples with different types of instruments has been performed apart from two comparisons between a TDS and a VNA [6, 7], the latter giving not fully compatible results. A multi-lab intercomparison among TDS is currently ongoing [8], but final results are not available yet.

2. Measurands and travelling standards

The measurand chosen for this intercomparison was the complex refractive index of the materials under test. In particular, participants had to measure the refractive index and the extinction coefficient, i.e. the real and the imaginary part of the complex refractive index.

Travelling standards have been chosen in order to ensure wide enough ranges in terms of refractive index and extinction coefficient. Selected materials were fused quartz, pyrex and BK7. The travelling standards were optically-polished, thin disks having diameters of 100 mm (quartz) and 76 mm (pyrex and BK7). Their thicknesses were mechanically measured at INRIM. The results are summarized in table 1.

| Material | Thickness (µm) |
|----------|---------------|
| BK7      | 545 ± 1       |
| Pyrex    | 570 ± 1       |
| Quartz   | 549 ± 1       |

3. Employed instrumentation

A THz TDS has been used at INRIM. The spectrometer has been set up in the framework of a Joint Research Project of the European Metrology Research Program (EMRP), entitled Microwave and Terahertz Metrology for Homeland Security (JRP NEW07 THz Security). A picture of the system is shown in figure 1.

The TDS used a standard transmission configuration, with a photo-conductive antenna as THz emitter, a ZnTe crystal as detector, four off-axis parabolic mirrors to focus the THz beam onto the sample and a moving stage acting as delay line. It was capable of measuring from about 250 GHz to about 2 THz. The frequency resolution was about 29 GHz, a value set by the delay line path length, which was limited in order to perform fast measurements. A higher resolution was not needed because no absorption lines were expected. The delay line was characterized by means of a laser interferometer. The contribution to the SNR of the TDS due to the delay line position uncertainty has been addressed in [9]. The maximum bandwidth of our TDS, as set by the delay line position uncertainty, was found to be slightly below 3 THz. However the observed bandwidth was further limited by the emitter we used.

In order to reduce absorbing water vapor the TDS was placed in an almost-sealed box. Dehumidification was performed in a cost-effective and easy way by circulating the air in a closed loop, and condensing the water vapor at a cold point. After about 1 h, dry air was inserted in order to further reduce humidity. After less than 2 h, a relative humidity of 5% was achieved. Humidity was constantly monitored during measurements by means of an hygrometer placed inside the box, close to the measurement point.

It is worth noting that the samples were placed in the system focal plane. It is known that, by positioning the samples in this way, a correction may be necessary to take into account the effect of the Gouy shift [10]. Anyway, after an a priori evaluation on the base of the estimated beam waist, we found this contribution to be negligible in our case with respect to the measurement uncertainty at low frequencies (less than 0.5%) while it vanishes at high frequency.

The measurement principle relies on the Fourier transformation of pulsed THz radiation. To extract the complex refractive index from the measured data, the ratio of the THz pulse spectra taken with \(E_{\text{sam}}(\omega)\) and without \(E_{\text{ref}}(\omega)\) the sample in the THz beam path was used to calculate the transfer function \(H(\omega)\):

\[
H(\omega) = \frac{E_{\text{sam}}(\omega)}{E_{\text{ref}}(\omega)}.
\]

The refractive index \(n(\omega)\) and the extinction coefficient \(k(\omega)\) were calculated from the following equations [9]:

\[
n(\omega) = n_0 - \frac{c}{\omega L} \angle H(\omega)
\]

\[
k(\omega) = \frac{c}{\omega L} \ln \left(\frac{4n(\omega)n_0}{(n(\omega) + n_0)^2}\right) - \ln |H(\omega)|
\]

where \(n_0\) is the refractive index of air, \(c\) is the speed of the light and \(L\) is the sample thickness. The contributions due to the parameters appearing in equation (2) were taken into account in the uncertainty analysis, along with the contribution of other parameters such as Fabry–Pérot reflections inside the sample (ignored by the model used for the optical parameter extraction) and the incidence angle on the sample of the THz beam [11]. It is worth noting that method in [11] ignores the reflections inside the sample in writing the transfer function, therefore they must be explicitly considered as an uncertainty source (see [11], equations (25) and (26)). Moreover, multiple measurements have been performed. Their average and standard deviation have been taken into account according to [11].

The stability of the system during the time scale of the measurement has also been checked by taking a reference measurement before and another after the actual measurements, and by looking for any change. Anyway, no relevant effects have been noted.

For both refractive index and extinction coefficient, the highest contributions to the uncertainty come from the reflections inside the sample and from the thickness of the sample itself, while the contributions due to the approximation of the transfer function needed for obtaining (2) [11], to the sample alignment and to the air refractive index are less influential. An example of uncertainty budget is shown in section 5.

Within the same EMRP project, PTB developed a VNA-based THz spectrometer, which is shown in figure 2. Its
frequency coverage is band-limited by the frequency converters used. It is capable of measuring in the range from 50 GHz to 500 GHz [12]. For this intercomparison it has been used in the frequency range 300–500 GHz with the frequency extension modules for the WR-3 and WR-2.2 waveguide bands setting a frequency resolution of approximately 55 MHz. Conventional rectangular horn antennas were mounted to the waveguide ports and two symmetrical parabolic mirrors were used to reduce the free-space transmission path-loss. Their distances to the antennas must be precisely determined in order to satisfy the plane-wave conditions on the material-under-test surface and to guarantee maximum energy passing through for a further improved sensitivity. The horn antennas have to be positioned so that their phase centers coincide with the focal points of the parabolic mirrors. The phase center positions can be estimated as a function of frequency, e.g. according to [13]. The frequency extension modules are positioned based on the distances obtained for the center frequency of the respective waveguide band. As shown in figure 2(a), the parabolic mirrors convert a diverging beam (assumed to originate from the phase center of the antenna) to a collimated beam at the sample position. The horn antennas are symmetrically put at the focal distance $f_0$ of parabolic mirrors which themselves are separated by a distance equal to $2f_0$ providing a plane wave at the middle of the two mirrors where the material-under-test is placed. The distance between the mirrors has to be $2f_0$ in order to obtain minimum phase distortion [14]. The system is calibrated at the flanges of the frequency extension modules as needed for material parameter extraction and tested with regard to stability as part of the uncertainty analysis (see section 5).

For data extraction, a new concept is used [12]. It consists in virtually shifting the calibration plane from the VNA waveguide ports to the material-under-test surface. This represents a complete de-embedding technique for which the overall scattering effect of the propagation path from the actual VNA ports to the material surface is evaluated experimentally. The propagation path loss/diffraction is evaluated by measuring the $S$-parameters of the empty setup, which is supposed to be symmetrical. Then the same process is repeated with the material, in order to extract its parameters.

The permittivity and permeability of the material can be extracted by taking into account multiple-reflection effects.
The complex permittivity \( \varepsilon_r = \varepsilon'_r - j\varepsilon''_r \) can be calculated from the slope \( a \) of the phase of the transmission \( T \) using

\[
\varepsilon'_r = \left( \frac{a}{-j2\pi\sqrt{\varepsilon_0\mu_0}L} \right)^2
\]

and

\[
\varepsilon''_r = -\frac{\varepsilon_0\ln|T|\sqrt{\varepsilon_r}}{\pi f L},
\]

where \( L \) is the slab thickness, \( f \) is the frequency and \( \varepsilon_0 \) and \( \mu_0 \) are the electric and magnetic field constants, respectively. Because of multiple reflection effects inside the material slab, the measured S-parameters are different from the actual transmission values \( T \) and reflection values \( \Gamma \) of the slab. Starting with \( T = S_{21} \), a first estimate of \( \varepsilon_r \) is obtained. This is used to get a better estimate of \( T \) and \( \Gamma \). A new intrinsic material parameter estimate of \( \varepsilon_r \) is then determined from \( T \) and \( \Gamma \), and so on, whereas the result converges after 1 or 2 iterations.

From the complex permittivity \( \varepsilon_r \), the complex refractive index \( n \), consisting of real part \( n \) and imaginary part \( \kappa \), are determined with \( n = \sqrt{\varepsilon_r} \).

The errors relative to the factors \( L \) and \( a \) can affect the deduced permittivity. These effects can be observed as regular oscillations on the resulting curves especially for the imaginary part of a material slab which is not homogenous and has a non-uniform surface thickness. The oscillations appear as the removal of Fabry–Pérot resonances with the iterative method does not work very well if thickness varies or the sample is inhomogeneous. In many cases, the non-uniformity of the material surface and the thickness variation \( \delta L \) are the most important contributions to the \( \varepsilon''_r \) uncertainty. The uncertainty increases if the thickness (electrical length) of the sample gets smaller.

### Table 2. Frequency ranges and resolutions of the three instruments used.

| Instrument | Freq. range (THz) | Resolution |
|------------|-------------------|------------|
| TDS        | 0.25–2.5          | 29 GHz     |
| VNA        | 0.3–0.5           | 55 MHz     |
| FTIR       | 0.2–6             | 15 GHz     |

PTB also used a commercial FTIR spectrometer (Bruker Optics—Vertex 80v) adapted for measuring at THz frequencies. An optimized setup for the far infrared spectral region consisted of a high-pressure mercury discharge lamp as a powerful external THz radiation source. In contrast to its standard mounting directly at an external input port of the spectrometer, this high-power discharge lamp is connected via an off-axis parabolic mirror to a polyethylene (PE) entrance window which is transparent for the far infrared radiation but blocks the unwanted UV radiation of the discharge lamp. The external beam bath between the discharge lamp and PE entrance window is encased enabling a nitrogen purge to avoid water vapor absorption of the THz radiation. In addition, a pyroelectric THz detector at room temperature records the interferogram of the FTIR spectrometer. A room-temperature detector does not suffer from thermal background radiation of the sample at room temperature in contrast to cryogenic bolometers which are often used as sensitive detector for THz radiation [15]. Moreover, the good linear response of pyroelectric detectors prevents the occurrence of artifacts caused by nonlinear signal recording in the spectra after Fourier transformation. These advantages over bolometers at cryogenic temperatures are accompanied by a limited capability of measuring signals at very low powers caused by strong absorbing samples even if the high-pressure mercury discharge lamp is applied as a powerful external THz radiation source.

The samples are mounted on a motorized translation stage at an intermediate focus inside the compartment of the spectrometer. Vacuum inside the spectrometer avoids water vapor absorption similar to the nitrogen purge outside. Therefore, this instrument is capable of measuring in a broad spectral range down to approximately 200 GHz. The measurement principle is based on Fourier transformation of the recorded interferogram generated by the Michelson interferometer inside the FTIR spectrometer. The samples had to be slightly tilted off normal incidence in order to avoid spectral artifacts by specular reflection of the modulated THz radiation back to the interferometer. In order to get low noise spectra an average of 256 scans was recorded.

The frequency accuracy of the FTIR spectrometer with a relative uncertainty less than \( 2 \times 10^{-6} \) is assured by a red He–Ne laser of known absolute wavelength (632.816 nm) which is integrated into the beam path of the interferometer. The He–Ne interference pattern is used to linearize the movement of the mirror of the spectrometer for each interferogram. The spectral resolution is determined by the maximum travel of mirror movement which limits the resolution of this spectrometer to 6 GHz. The resolution was set to 15 GHz in this experiment because there are no sharp spectral features of
Figure 4. Comparison of measurement results for the quartz travelling standard.

Figure 6. Comparison of measurement results for the pyrex travelling standard.
the three samples in the spectral range. The power stability of the optimal setup with temperature stabilization of the whole instrument including the external high-pressure mercury discharge lamp is better than 1% after a warm up time of 1 h.

The transmission spectrum of the sample is calculated as the ratio of two measurements, with and without the sample in the optical path. As an example, the transmission spectrum of quartz is shown in figure 3.

The thin samples allowed the extraction of the refractive index with low uncertainty simply from the frequency position of the Fabry–Pérot fringes of the transmission spectra without applying a complex analytical model as described in [16]. The absolute interference order is easily determined because the free spectral range of a 0.5 mm thin sample is only about one half of the lower frequency limit of the recorded spectra. Just these frequency positions \( \nu(m) \) of both the maxima (integer order: \( m \)) and the minima (half integer order: \( m + 1/2 \)) are used to calculate the frequency dependent refractive index \( n(\nu) \) from the known thickness \( L \), the speed of light \( c \), and the tilt angle \( \delta \) of the beam inside the sample:

\[
n(\nu) = \frac{m \cdot c}{2L \cdot \cos(\delta) \cdot \nu(m)}.
\]

For a given thickness \( L \), the uncertainty of \( n(\nu) \) is simply given by two terms: the uncertainty of maxima/minima frequency position determination in the recorded spectra and a minor contribution by the uncertainty due to cosine of a small tilt angle. The spectral transmission signal is used to extract the spectral absorption. First of all only the maxima \( m \) and the minima \( m + 1/2 \) are used to calculate the frequency dependant refractive index \( n(\nu) \) from the known thickness \( L \), the speed of light \( c \), and the tilt angle \( \delta \) of the beam inside the sample:

\[
n(\nu) = \frac{m \cdot c}{2L \cdot \cos(\delta) \cdot \nu(m)}.
\]

Table 6. INRIM TDS uncertainty contributions of the quartz measurements at 400 GHz. Contributions have been combined as per [11] equation (30).

| Contribution                        | \( n \) | \( k \) | Type |
|-------------------------------------|--------|--------|------|
| Sample thickness                    | 1.8 \times 10^{-3} | 5.21 \times 10^{-4} | A    |
| Sample measurement                  | 3.6 \times 10^{-4} | 1.15 \times 10^{-4} | A    |
| Noise and repeatability             | 6.1 \times 10^{-5} | 3.01 \times 10^{-4} | A    |
| Reference measurement noise and repeatability | 1.5 \times 10^{-4} | 4.95 \times 10^{-6} | B    |
| Sample alignment                    | 1.1 \times 10^{-5} | 2.17 \times 10^{-6} | B    |
| Transfer Function approximation     | 2.5 \times 10^{-2} | 2.45 \times 10^{-2} | B    |
| Fabry–Perot internal reflections    | 2.7 \times 10^{-4} | 2.82 \times 10^{-5} | B    |
| Air refractive index                | —      | —      | —    |

Besides the uncertainty of the absorption \( \ln(T) \) there are relative uncertainty contributions to the uncertainty of the extinction coefficient \( k \) similar to the relative uncertainty of \( n(\nu) \) namely the relative uncertainty of the thickness \( L \), the cosine of the small tilt angle \( \cos(\delta) \) and the frequency \( \nu \).

To better clarify ranges and resolutions of the three instruments, these data are summarized in table 2.

4. Measurement results

In this section, the measurement results are compared in form of graphs. The comparison between TDS, FTIR and VNA spectrometer, in the lower part of the THz frequency range (i.e. below 500 GHz), has been performed on two samples only (quartz and BK7), as pyrex was not measured in the VNA spectrometer. The comparison between TDS and FTIR spectrometer has been made among measurements concerning all the travelling standards, but the FTIR measurement of the refractive index of BK7 has been made at the frequency of 400 GHz only, due to high material absorption at higher frequencies. Here and in the rest of the paper, reported uncertainties are always expanded with coverage factor \( k = 2 \) for a 95% confidence interval [17].

4.1. Quartz

As seen from figure 4, FTIR measurements span over the widest frequency range. The band covered by the VNA spectrometer is the smallest one while TDS is in between. TDS and FTIR spectrometer have roughly comparable refractive index uncertainty while that of the VNA spectrometer is larger. On the other hand, the TDS has the largest extinction coefficient uncertainty and the FTIR
As can be seen from the measurement results shown in section 4, the measurement of the refractive index did not cause particular problems. The TDS showed better performances, in terms of measurement uncertainty, in measuring the refractive index compared to the VNA spectrometer in the band of overlapping and slightly better performance compared to the FTIR spectrometer.

The measurement of the extinction coefficient was more critical. Apart from FTIR, there is a difficulty in measuring the extremely low absorption of quartz and pyrex, almost transparent at lower frequencies i.e. below about 800 GHz. The VNA-based spectrometer performs slightly better than the TDS but the FTIR spectrometer is by far the best choice. However for BK7 with a ten times higher absorption, the TDS exhibits the smallest uncertainty above 500 GHz.

Although the FTIR spectrometer has the widest frequency coverage, this instrument is not capable to determine the BK7 refractive index from transmittance measurements in the complete frequency band due to its high absorption. Only a single point evaluation at 400 GHz could be performed. Moreover, the FTIR measurement of BK7 reveals a high uncertainty of the extinction coefficient due to the low transmitted signal caused by the strong absorption of the sample.

The VNA-based spectrometer turned out to be a good choice for measurements in the lower part of the THz frequency range and below, while FTIR spectrometers are more suitable for measurements of the extinction coefficient in the band of interest and beyond. THz Time-Domain spectrometers turned out to be the best choice for measuring the refractive index in the whole band from about 100 GHz to about 2.5 THz. At lower frequencies VNA-based spectrometers should be preferred while FTIR spectrometers are needed above 2.5 THz.

As an example, detailed uncertainty budgets for the three instruments are reported in tables 6–8. Data refer to the fused quartz measurements at 400 GHz reported in table 3.

6. Conclusions

The first bilateral measurement comparison on material properties in the THz frequency range has been conducted between INRIM and PTB. Travelling standards have been chosen in order to ensure wide enough ranges in terms of refractive index and extinction coefficient. Three different kinds of spectrometers i.e. Time-Domain, Fourier Transform Infrared and vector network analyzer-based systems have been involved. These spectrometers employ different spectroscopic methods, namely Fourier transformation of pulsed radiation, Fourier transformation of broadband radiation and dispersive spectroscopy.

Results show good compatibility among the three measurement systems. The comparison between the performances of the different instruments involved frequency coverage and measurement uncertainty. It highlights the kind of instrument being best suited for every material measured.

Table 7. PTB VNA uncertainty contributions of the quartz measurements at 400 GHz.

| Contribution                        | n   | k   | Type |
|-------------------------------------|-----|-----|------|
