Abstract: The black yeast *Exophiala dermatitidis* is known as a rare etiologic agent of neurotropic infections in humans, occurring particularly in East and Southeast Asia. In search of its natural habitat, a large sampling was undertaken in temperate as well as in tropical climates. Sampling sites were selected on the basis of the origins of previously isolated strains, and on the basis of physiological properties of the species, which also determined a selective isolation protocol. The species was absent from outdoor environments in the temperate climate, but present at low abundance in comparable habitats in the tropics. Positive outdoor sites particularly included faeces of frugivorous birds and bats, in urban as well as in natural areas. Tropical fruits were found *E. dermatitidis* positive at low incidence. Of the human-made environments sampled, railway ties contaminated by human faeces and oily debris in the tropics were massively positive, while the known abundance of the fungus in steam baths was confirmed. On the basis of the species’ oligotrophy, thermotolerance, acidotolerance, moderate osmotolerance, melanization and capsular yeast cells a natural life cycle in association with frugivorous animals in foci in the tropical rain forest, involving passage of living cells through the intestinal tract was hypothesized. The human-dominated environment may have become contaminated by ingestion of wild berries carrying fungal propagules.

Key words: Black yeasts, *Exophiala dermatitidis*, frugivorous animals, human faeces, intestinal colonization, neurotropism.

INTRODUCTION

The black yeast *Exophiala dermatitidis* is an uncommon etiologic agent of fatal infections of the central nervous system in otherwise healthy, mainly adolescent patients in East Asia (Hiruma et al. 1993, Matsumoto et al. 1993, Chang et al. 2000). The species shows neurotropism in animal experiments (Dixon et al. 1989, 1992). In the U.S.A., cases have been reported where inoculation of patients with medical fluids containing contaminated water led to nosocomial common-source outbreaks with sometimes fatal neurological implications (Woollons et al. 1996, Engemann et al. 2002). More frequently than brain infection, asymptomatic colonization is observed in protected body sites, e.g. in the mucus of lungs in 2-8 % of patients with cystic fibrosis (CF) (Haase et al. 1991, Horré et al. 2003), in the intestinal tract in 0.3 % of the European population (de Hoog et al. 2005) and occasionally in the wax of human external ear canals (Kerkmann et al. 1999, G. Haase unpublished data). The fungus is a constitutive producer of melanin (Langfelder et al. 2003), is consistently able to grow at temperatures above 37 °C (Padhye et al. 1978) and produces extracellular polysaccharide capsules (Yurlova et al. 2002), which all are regarded to be virulence factors.

The route of infection is still a mystery. The species is known to occur in the environment, but is not among the commonly encountered saprobes. It is practically absent from dead plant material or soil, and has never been reported from outdoor air (Matos et al. 2002). The somewhat odd spectrum of main sources of isolation of strains presently available in culture collections (fruit surfaces, steam baths, faeces, and human tissue) suggests that a hitherto unknown, quite specific natural niche must be concerned. Particularly the occurrence in steam rooms of public bathing facilities is consistent and with high colony counts (Nishimura et al. 1987, Matos et al. 2002). The artificial environment of the steam bath apparently provides a novel environmental opportunity for this fungus. The transition from the hitherto unknown natural niche to the human-dominated environment may be accompanied by selection and/or adaptation to the new habitat, facilitated by the stress protection provided by melanin. Given the nature of the fungus as an opportunistic agent of potentially fatal infections in humans, this process may have clinically relevant consequences. The present article documents a possible natural habitat of the fungus and on processes taking place during transition from nature to the domestic environment.

MATERIAL AND METHODS

Samples

Varying numbers of replicates each containing 0.1–0.5 g of fresh and dry faeces of wild or semi-wild birds, chickens, bats, flying foxes, jackdaws, rats and elephants were collected from different localities in the Netherlands and/or in Thailand. (Fig. 1) Forty-four bathing facilities, toilets, hot springs and railway ties (Tables 4–9) were sampled, either by using sterile cotton swabs, or by collecting 0.5–1.0 g (wet weight) bottom soil or aliquots of 10 L were filtered over a 0.8 µm pore size, sterile membrane cellulose acetate filter (Göttingen, Germany). In addition, 731 intestinal samples (~1 g)
Identification of accompanying biota

White yeasts were identified physiologically by testing fermentation and carbon and nitrogen assimilation. C-assimilative capabilities were tested using API-ID 32 C strips (bioMérieux, Marcy-l’Etoile, France). Single colonies were grown at 25 °C for 3 d as a maximum. Suspensions were made and the densities were scored by McFarland turbidity standard point 2. Strips were inoculated according to specifications provided by the manufacturer and incubated at 25 °C. For nitrogen assimilation the substrates nitrate, ethylamine, L-lysine, cadaverine, D-glucosamine, HCl and tryptophane were used. Peptone was used as positive control. Suspensions were applied in N-auxanograms in culture plates. After the medium was cooled and solidified, a small amount of each N-source was put on the medium. For fermentation, D-glucose, D-galactose, maltose, sucrose, lactose and raffinose were tested. Sugars solutions were 2 %, except for raffinose which 4 % solution was used. These solutions were sterilized in tubes with Durham inserts and suspensions of McFarland turbidity standard point 2 were added. The identification software BIOLMICS was used to score combined physiological results. Morphology was investigated to confirm the identifications (Kurtzman & Fell 1998).

RESULTS

Recovery efficiency

The recovery rate of *Exophiala dermatitidis* suspensions (10⁶ cells/mL) was not significantly altered by three days of incubation in Raulin’s solution when strain CBS 116014 (genotype B) was used. In contrast, cell counts increased with a factor 4.3 in CBS 207.35 (genotype A), while those of the non-capsular strain CBS 109143 (genotype B) was reduced to about 9.5 % (Table 1). *Aureobasidium pullulans* showed an 83.3 % reduction in colony-forming units (CFU) at 25 °C and did not grow at 40 °C. Average recovery rate in 0.1–0.5 g (wet weight) of faeces was between 0–3 colonies per culture plate, which corresponded to 0–3 CFU per gram original material for genotype B and 0–0.69 for genotype A, judging from isolation efficiency described above.

The isolation protocol applied to animal faeces and to fruits and berries collected in temperate and tropical climates proved to be highly selective, judging from the very few ubiquitous saprobes that were recovered. The rarity of *E. dermatitidis* was proven by selective isolation from a large diversity of environments in temperate (The Netherlands) and tropical (Thailand) climates, supplementing data
of Matos et al. (2002) which involved leaves, fruits and berries, animal faeces and soil in a temperate climate.

Genotyping

Nuclear rDNA ITS sequencing of 86 reference strains confirmed the existence of two major genotypes differing in three positions in ITS1 (Table 2). Genotype A was more common than B (A:B = 57:29). Two out of nine animal faeces samples from Thailand belonged to genotype A, while seven were B. Two sets of samples from bird guano in Khao Khaew Zoo (where occasional mechanic cleaning is carried out) and flying fox faeces at a temple complex in Thailand contained genotypes A and B, of which the latter was isolated more frequently.

Isolation in temperate climate

Fruits and berries

Two areas in The Netherlands were chosen for isolation from berries, namely Boswachterij Noordwijk, in a dune area near the Northsea coast near Leiden, and a lane planted with shrubs in a rural area in Maartensdijk in the central part of the country. In Noordwijk, samples were taken in Autumn, when berries were predominantly eaten by migratory frugivorous birds such as Turdus pilaris (fieldfare). Twenty-one samples were taken from berries of Rosa pimpinellifolia, 345 samples from Hippphoea rhamnoides and 187 samples from Ligustrum vulgare (Table 3). The shrubs near Maartensdijk were predominantly frequented by sedentary birds such as Corvus monedula (jackdaw) and Sturnus vulgaris (European starling). Thirty samples were taken from Crataegus monogyna, 92 samples from Viburnum opulus, 61 samples from Ilex aquifolium, 22 samples from Rosa canina, 20 samples Rosa rubiginosa, 36 samples Prunus spinosa, 19 samples Ligustrum vulgare and 51 samples from Taxus baccata. With our isolation protocol plates mostly remained blank, or white yeasts were encountered. No black yeast was isolated.

Faeces of omnivorous birds

Faeces mixed with soil under Thuja confers harbouring a large combined roosting site of Corvus monedula (jackdaw) and Sturnus vulgaris (European starling) in a park near Hilversum, The Netherlands, was sampled, as well as a roosting site of jackdaw alone. All samples were negative for E. dermatitidis (Table 4).

Intestinal contents from sectioned zoo animals

A total of 731 samplings from dead animals originating from different zoos in the Netherlands, were received at the Veterinary Faculty at Utrecht for autopsy. In addition to routine analysis, the contents of the intestines with visible disorders such as discoloration or halfway digested food was subjected to selective isolation for E. dermatitidis. Results are available from 16 reptiles, 406 birds, 183 mammals, 8 fishes, 3 turtles, 2 amphibians, 5 lizards and 11 snakes; these data will not be included in this article, but are available as attachment at www.cbs.knaw.nl. Culture plates mostly remained blank. White yeasts were common in the intestinal tract of frugivorous animals. A single strain of E. dermatitidis (genotype A) was obtained from a bonobo monkey (Pan paniscus) with diarrhoea in the Apeldoorn Zoo, The Netherlands. Bonobo’s are omnivorous with a marked preference of fruit.

Isolation in tropical climate

Fruits and berries

On grapes (Vitis vinifera) numerous white yeasts were isolated, which were not identified down to the species level. The only black fungus obtained was a Cladosporium species. On green papaya fruits (Carica papaya) mainly white yeasts occurred. Few filamentous fungi were obtained, mainly biverticillate Penicillium species, among which was Eupenicillium cinnamopurpureum (anamorph: P. phaeniceum). Three types of fruit were found positive on isolation for E. dermatitidis: papaya, pineapple (Ananas comosus) and mango (Mangifera indica). In papaya and pineapple, genotypes A and B were found, while in mango only genotype B was encountered. Mango fruits further contained white yeasts, a Rhizopus species, a recurrent Aspergillus species, a biverticillate Penicillium and Talaromyces intermedium (dH 13728). On lemon fruits (Citrus sp.) white yeasts were common, and a single colony of a white filamentous fungus was obtained. On fruits of tamarind (Tamarindus indica), Queen’s flower (Lagerstroemia calyculata) and Ficus lacor, only Aspergillus species were obtained. In contrast, fruits of Ficus annulata contained much more white yeasts in addition to Aspergillus species; three times a hitherto undescribed species of Munkovalsaria species was isolated. On fruits of yellow santol (Sarondonicum indicum) the main filamentous fungi acquired were Aspergillus species, and infrequently white yeasts were encountered. Fruits of rambutan (Nephelium lappaceum), pomelo (Citrus maxima) and mango palm (Nypa fruticans) contained many white yeasts only. Rose apple fruits (Syzygium jambos) contained biverticillate Penicillium species (Table 3).

Faeces of frugivorous birds

Samples were taken from faeces of a number of frugivorous birds from two zoos in Thailand. Bird species are described as follows. Columbiformes: Ducula bicolor (pied imperial-pigeon); Coraciciformes: Aceros undulatus (wreathed hornbill), Anorrhinus galantus (bushy-crested hornbill), Anorrhinus tickelli (rusty-cheeked hornbill), Anthracoceros albirostris (oriental pied-hornbill), Anthracoceros malayanus (black hornbill), Berenicornis comatus (white-crowned hornbill), Bucerovs bicornis (great hornbill), Buceros hydrocorax (rufous hornbill), Buceros rhinoceros (rhinoceros hornbill), Rhinopixis vigil (helmeted hornbill); Passeriformes: Acidotheres tristis (common myna), Sturnus burmannicus (vinous-breasted starling), Pycnonotus finlaysoni (stripe-throated bulbul), and Piciformes: Megalaima virens (great barbet). While yeasts were predominant on isolation media. Some of these were selected to be identified by ID32C and they invariably turned out to be Candida tropicalis, while a single strain was identified as Trichosporon loubieri. Exophiala dermatitidis (genotype B) was isolated from fresh faeces of Acidotheres tristis (common myna). In a feeding area for birds by fruits of papaya (Carica papaya), banana (kluai namwa; Musa ‘ABB’), two isolates of Exophiala dermatitidis, genotype B were found (dH 13132, dH 13134) and genotype A (dH 13135) (Fig. 2 D,E). Frugivorous bird faeces were also analyzed in the national park HalaBala Wildlife Sanctuary, established in 1996. Samples were taken in the Hala portion of the Sanctuary, approximately 22 km west from the Malaysian border, comprising a mix of forest broadly classified as tropical lowland evergreen forest, and small-scale agricultural land. The area is particularly famous for harbouring nine species of hornbill birds being one of the richest areas for these birds in Southeast Asia (Fig H). Exophiala dermatitidis (dH 13148 genotype B) was found from the faeces of Buceros rhinoceros (rhinoceros hornbill) (Table 4).
### Table 1. Efficiency of live recovery of *E. dermatitidis* after Raulin’s incubation, verified on ECA, PDA and SGA at 25 °C and 40 °C.

|                | Pre-Raulin: | Post-Raulin: |
|----------------|-------------|--------------|
| CBS 207.35 (genotype A, capsular) | 10^6 | 0.43 x 10^7 |
| CBS 109143 (genotype B, non-capsular) | 10^6 | 0.95 x 10^5 |
| dH 13133 (genotype B, capsular) | 10^6 | 0.83 x 10^5 |

*Exact localities available upon request.

**Faeces of frugivorous bats**

On leaves and branches of boh tree (*Ficus religiosa*) contaminated with faeces of Lyte’s flying foxes (*Pteropus lylei*) we repeatedly encountered *Exophiala dermatitidis*. Sequencing showed that three of these were genotype A and B. Soil samples at from a temple in Chachoengsao were mixed with faeces of flying foxes provided white yeasts, among which were *Exophiala dermatitidis*.

**Faeces of granivorous birds**

Faeces samples were collected from two zoos in Thailand and involved the bird species Galliformes: *Pavo cristatus* (Indian peafowl); Psittaciformes: *Cacatua ducorpsii* (Ducorps’ cockatoo), *Cacatua goffinii* (Goffin’s cockatoo), *Cacatua moluccensis* (Moluccan cockatoo), *Cacatua sulphurea* (yellow-crested cockatoo), *Cacatua tenuirostris* (long-billed corella), *Calyptrorychnus magnificus* (red-tailed black cockatoo), *Electus auratus* (eclectus parrot), *Psittacos geaterinus* (palm cockatoo), *Psittacula alexandri* (red-breasted parakeet), *Psittacula eupatria* (Alexandrine parakeet), *Psittacus erithacus* (African grey parrot), and *Psittrichas fulgidus* (Pesquet’s parrot). Very few white yeasts were encountered, but filamentous fungi were relatively common. No *Exophiala* was isolated (Table 4).

**Faeces of insectivorous bats**

Thirteen mostly limestone caves were chosen for sampling of insectivorous bat faeces from different geographical regions in Thailand. Most of them were located in montane rain forest, about 1 000−1 900 meters above sea level. Others were touristic places surrounded by agricultural land, or were part of a temple complex. Numerous filamentous fungi were obtained (Table 4), most of these being rapidly growing *Aspergillus* species, biverticillate penicillia and zygomycetes. No black yeasts were detected (Table 4) (Fig. 2 F, G).

**Public toilets**

Public toilets of gas stations can be found along many highways in Thailand. They differ only slightly with the company with respect to building structure, hygienic level and intensity of warding. Most of them are pedestal squat toilets, which means that there is no
flushing system installed to clean the toilet after use. Instead, water is collected from a tap into a bucket placed close to the squat toilet. Due to this situation, most of the time floors in the toilets were wet, and the hygienic level was low. Samples were taken at different points, such as the floor in the toilet room, the wall, as well as swabs taken from the bowl above the water level. The occurrence of fungi which grew after incubation of swabs in Raulin’s solution and incubation on ECA at 40 °C was similar in all toilets: we found *Aspergillus* species and some white yeasts, but no *Exophiala* (Table 5) (Fig. 2 J, K).

### Table 5. Overview of public toilet sampling locations in Thailand*.

| No. | Public toilets | Source | Province / country | No. of samples | *Exophiala dermatitidis* |

**Sauna facilities**

The saunas in Thailand that were chosen for this experiment were dry sauna with continuous heating. The room was located inside the building complex with other steam baths and Gyms for sport entertainment. Inside the sauna room, seats and walls were made of wood. The steam rooms were also included in this experiment; these were mostly located on the same floor as the sauna room. The walls and floors were made of tiles while the seats were made from polyvinyl chloride. Black yeasts appeared abundantly in the

isolated from human sputum, particularly from CF patients, from deep infections, particularly from brain, from stool, from bathing facilities, from fruits and berries, and from creosote-treated wood (http://www.cbs.knaw.nl). This remarkably discontinuous spectrum of sources of isolation of *E. dermatitidis* suggests that the organism might be adapted to a particular, hitherto undiscovered habitat, rather than being a saprophyte on dead plant material, as is frequently suggested in the literature (Gold *et al.* 1994). Based on its physiology, we hypothesized a niche containing a number of key elements. First, it must be dynamic, with simultaneously or consecutively occurring phases differing in environmental conditions, since the organism itself is polymorphic, exhibiting yeast-like, filamentous and meristematic phases (de Hoog *et al.* 1994). Second, the phases are likely to be nutritionally diverse, as is concluded from the fungus’ consistent occurrence as an endophyte on low-nitrogenous substrates such as fruit surfaces – promoted by its moderate osmotolerance – and bath tiles (Mayr 1999) combined with equally consistent occurrence in faeces (de Hoog *et al.* 2005). Third, the latter environment, combined with a consistent tolerance of *E. dermatitidis* of 40 °C (Padhye *et al.* 1978) and of very low pH values (de Hoog *et al.* 1994) led to the supposition of passage of the digestive tract of warm-blooded animals (G.S. de Hoog unpublished data). Fourth, the organism shows strong adhesion to artificial surfaces (Mayr 1999), probably promoted by production of sticky extracellular polysaccharides (Yurlova *et al.* 2002). An occurrence on wild fruits and berries that are subsequently ingested by frugivorous animals and dispersed via their faeces thus seems to provide a possible connection of the divergent sources of isolation. The hypothesis led to the successful development of a selective protocol used in this study, which involved an acidic enrichment step (Booth 1971) followed by a high temperature step on a nutritionally specific medium (de Hoog & Haase 1993). The protocol enabled the isolation of minute quantities of the fungus. Massive isolation studies further underlined that *E. dermatitidis* is a rare species in most outdoor environments. We believe our recovery data broadly reflect the actual presence of *E. dermatitidis* in the environment, for two reasons. (1) Environments known to harbor the species were indeed found to be positive at rates comparable to those published earlier (Matos *et al.* 2002). (2) Recently Zhao *et al.* (2008) applied a new, Chaetothyriales-specific isolation method based on toluene-enrichment at ambient temperature to the same shrubs near Maartensdijk and indeed found numerous mesophilic *Exophiala* species, but never the thermophilic species *E. dermatitidis*. The recovery rate was tested experimentally and on average found to reflect the number of cells present prior to incubation in acid. However, slight differences were noted among the three strains analyzed. The representative of ITS-genotype A (CBS 207.35) was stimulated with a factor 4.3 by incubation in Raoulin’s solution, whereas genotype B (CBS 1160124) remained practically unaltered. The non-capsular strain (CBS 109143) was inhibited tenfold, but since such strains are extremely rare in the natural environment (Matos *et al.* 2002, Yurlova *et al.* 2002) we believe that this more vulnerable phenotype has little effect on the recovery rate of the species.

We analyzed a large diversity of substrates using a highly selective protocol, with accent on substrates bearing similarity to origins of reference strains (Table 2). Despite that, isolation was mostly unsuccessful outdoors in the temperate climate of The Netherlands (Table 3). Only a single strain from a berry of Sorbus aucuparia had been found (CBS 109142, genotype B) by Matos *et al.* (2002). The negative samples included berries commonly eaten by migratory and sedentary birds such as Turdus pilaris, Corvus monedula and Sturnus vulgaris, as well as faeces from several of these birds. From these extended environmental studies including 944 samples it may be concluded that *E. dermatitidis* does not occur naturally in temperate climates.

In contrast, the fungus was confirmed to reside consistently and abundantly from known foci in several artificial, indoor environments, such as steam rooms (Matos *et al.* 2002), in Slovenia, Austria, Thailand as well as in The Netherlands. Several of the negative
berry-sampling locations were only a few kilometers away from steam baths that proved to be highly positive. The species was recovered at high frequency (about 1 000 CFU cm\(^{-2}\)) from thirteen bathing facilities. Steam baths (and not the adjacent sauna’s) of public bathing facilities represent an artificial environment with conditions thought to be similar to parts of the natural habitat of *E. dermatitidis*, where high (body) temperature and epiphytic adhesion to (fruit) surfaces play a significant role.

In tropical Thailand, most fruits and berries were also negative (Table 3), although the species was encountered a few times on mango and pineapple. Positive samples were more regularly derived at low frequencies from animal faeces (Table 4). The consistent presence of *E. dermatitidis* in bat faeces and bird guano analyzed is demonstrated by the sample from guano-littered soil in the Khao Khaew Zoo in Chonburi, Thailand, and from flying fox faeces at the temple complex in Chachongsao, Thailand, where both genotypes A and B were recovered (Table 4), despite the overall environmental scarcity of *E. dermatitidis* (Fig. 2 A–C). Recovery rates were low, with a maximum of three colonies per culture plate. The isolation method used reflects the real frequency of genotype B in the original samples (Table 2), which means that positive samples contain maximally 3 CFU per gram faeces. Positive samples were obtained from birds as well as mammals such as flying foxes.

Sampling of autopsied zoo animals was almost always negative for black yeasts. The great majority of these animals fed on corn and seeds, and also yielded very few white yeasts or filamentous fungi. The single black yeast-positive animal intestinal sample (www.cbs.knaw.nl) was a bonobo monkey, which is a largely frugivorous animal. A common factor linking this sample with positive samples elsewhere in the study is the diet of the animals: *E. dermatitidis* was almost exclusively found in animals that fed partially or entirely on wild fruits and berries. Herbivores have a large caecum, where digestion of food is enhanced by fermentation aided by a resident bacterial flora and white yeasts. Frugivorous animals, as those that feed on honey and nectar, may have problematic yeast overgrowth due to a high sugar content in the intestinal tract. *Exophiala dermatitidis* has a slight preference for osmotic environments. In clinical practice this was noted with its occurrence in the lungs of patients with cystic fibrosis, a disease characterized by an elevated salt content of tissues (de Hoog & Haase 1993).

De Hoog et al. (2005) found that *E. dermatitidis* occurs at a low incidence in the intestinal tract of humans. This matches with the abundant presence of *E. dermatitidis* on railway ties in Thailand, which are heavily contaminated by faeces (Fig. 2 L). Similar samples were taken in The Netherlands (data not shown), and these were positive for black yeasts other than *E. dermatitidis*. This situation is comparable with our isolation data from berries, which were negative in temperate but positive in tropical climates. Apparently the environmental temperature plays a significant role in the life cycle of *E. dermatitidis*. Public toilets in Thailand (Fig. 2 J, K) were, somewhat against expectations, also negative. This may be explained by competition of other, rapidly growing saprobes in this environment, such as white yeasts and *Aspergillus* species.

*Exophiala dermatitidis*, similar to other *Exophiala* species, is an oligotroph, as shown in vitro by Satow et al. (2008) on the basis of the ability of growth utilizing inoculum cells only. The property may be useful for growth on fruit surfaces, but is particularly expressed, in combination with thermotolerance, in abundant replication on the smooth surface of tiles and plastics of steam bath walls. The fungus was detected in large numbers in nearly all bathing facilities investigated located in temperate as well as in tropical climates. The species was also occasionally encountered in natural hot springs, which may be somewhat more difficult to colonize for the fungus due to their relative richness in nutrients. A single strain of *E. dermatitidis* was found in one of the hot springs but its presence might be explained by local people using the spring to clean and boil bamboo shoots after harvest from the forest. The sugary shoots may have been contaminated by *E. dermatitidis* and the fungus may have survived for a short period without significant colonization. A second sampling one year later without human activities was negative (Fig. 2 I).

Combining thermotolerance of the species with the knowledge that *E. dermatitidis* tolerates very acidic conditions (de Hoog et al. 1994), it is hypothesised that the fungus is able to pass through the intestinal tract of warm-blooded animals. About 80 % of positive hosts had diarrhoea at the moment of isolation of *E. dermatitidis*, a condition also encountered in positive bonobo. This suggests that the fungus may be present at a higher frequency but can only be isolated when the host has diarrhoea. De Hoog et al. (2005) reported isolation of the fungus at 3-wk-intervals from the faeces of a single hospitalized patient with diarrhoea, which indicates that maintenance in the intestines is possible. As a route of infection, translocation from the intestines may thus be supposed. For pulmonary cases an inhalative route would be more logical, but the apparent absence of *E. dermatitidis* from air remains in conflict with this explanation. Other similar phenomenon which support this hypothesis was the strain which was successful isolated from the bonobo from the zoo in the Netherlands. At that time, the sample was taken from the bonobo with the presence of diarrhoea (G. Dorrestein, personal information). Unfortunately, further sampling could not be continued due to the fact that the monkey had returned to the mother.

Reis & Mok (1979) and Muotle-Okafor & Gugnani (1993) repeatedly found the species in internal organs of tropical frugivorous bats (*Phyllostomus discolor, Sturnira lilium* and *Eudolon helvum*) in American as well as African tropical rain forests. Representative isolates were verified to be *E. dermatitidis* genotype B (Table 4). Despite isolating the fungus from bat organs, Mok (1980) failed to isolate it from roosting sites. This may have been due to the use of inadequate isolation procedures. Reis & Mok (1979) also reported the species from two insectivorous bats (*Myotis albescens* and *M. molossus*), but the identity of these strains could not be verified.

Since in the reference set genotype A is about twice as common as genotype B and genotype A shows a higher recovery rate with the used isolation method (Table 2), our technique would expect to yield an A : B ratio of 10:4 : 1 would be expected in the fruit-eating animal faeces from Thailand. However, these samples showed a ratio A : B = 2 : 7, which would mean that the frequency of genotype B in tropical fruit-eating animal faeces samples deviates with a factor 36.4 from the average of all other sources of isolation.

This model study aims to prove the supposition that aspects of human behaviour i.e. the creation of environment that are extreme from a fungal perspective, by being hot, poor in nutrients, or poisonous, lead to the emergence of new, potentially virulent genotypes. The fungus under study causes a potentially fatal brain disease in otherwise healthy humans; this clinical picture is known in eastern Asia only (Horré & de Hoog 1999). Understanding the origin and course of this evolution may eventually lead to the development of measures which can realize speciation processes into a direction which is less harmful to humanity. The human community creates opportunities for adaptation and the emergence of pathogenic host races. Artificial, human-made environments may stimulate evolution and generate pathogenic genotypes which otherwise would not
have evolved. The source of contamination of a potentially harmful microorganism and its routes on infection and transmission will be studied, potentially leading to protocols for hygiene and prevention. This may be particularly significant in bathing facilities connected to hospitals, where susceptible populations of patients with cystic fibrosis or, in Asia, with immunosuppression are ward. Though the disease under study is extremely rare, our approach can be viewed as a model study for understanding emergence of new microbial pathogens in general and their translocation from the tropical rain forest to the human environment.

ACKNOWLEDGEMENTS

A. Mayr (Innsbruck, Austria) is thanked for data on the occurrence of black yeasts in bathing facilities in Austria, and M. de Boer (Rotterdam, The Netherlands) for help during sampling in an artificial bat cave. P. Puunfsawat, S. ToaDam, Haila-Bala Wildlife Sanctuary, Dusit zoo and Khoao Khaoew Open Zoo are acknowledged for facilities during sampling. K. Assawouchong (Bangkok, Thailand) for water sampling, and T. Seelanan (Bangkok, Thailand) for background information for the manuscript. Thanks are also due to K. Sudhadham and T. Sudhadham for their help with isolation work elsewhere in Thailand. We are grateful to A. van Belkum (Rotterdam, The Netherlands) and R.C. Summerbell (Toronto, Canada) for comments on the manuscript and to M.T. Smith (CBS) for help with yeast identification. H. Ansink, A.H.G. Gerrits van den Ende and A. Cegcel are thanked for technical assistance, and the technical service department at CBS for preparing large amounts of media. A.H.G. Gerrits van den Ende AHG, and M. de Boer (Rotterdam, The Netherlands) is thanked for collaboration with sectioning animals. This work was financially supported by WOTRO (Netherlands Foundation for the Advancement of Tropical Research, WB 93-421). We also acknowledge a manuscript and to M.Th. Smith (CBS) for help with yeast identification. H. Ansink, A.H.G. Gerrits van den Ende AHG, and M. de Boer (Rotterdam, The Netherlands) is thanked for collaboration with sectioning animals.

Sudhadham for their help with isolation work elsewhere in Thailand. We are grateful to A. van Belkum (Rotterdam, The Netherlands) and R.C. Summerbell (Toronto, Canada) for comments on the manuscript and to M.T. Smith (CBS) for help with yeast identification. H. Ansink, A.H.G. Gerrits van den Ende and A. Cegcel are thanked for technical assistance, and the technical service department at CBS for preparing large amounts of media. A.H.G. Gerrits van den Ende AHG, and M. de Boer (Rotterdam, The Netherlands) is thanked for collaboration with sectioning animals. This work was financially supported by WOTRO (Netherlands Foundation for the Advancement of Tropical Research, WB 93-421). We also acknowledge a travel grant from the Johanna Westerdijk Foundation (W0312).
