The longest spin lifetimes in bulk \( n \)-GaAs exceed 100 ns for doping concentrations near the metal-insulator transition (J.M. Kikkawa, D.D. Awschalom, Phys. Rev. Lett. 80, 4313 (1998)). The respective electronic states have yet not been identified. We therefore investigate the energy dependence of spin lifetimes in \( n \)-GaAs by time-resolved Kerr rotation. Spin lifetimes vary by three orders of magnitude as a function of energy when occupying donor and conduction band states. The longest spin lifetimes (> 100 ns) are assigned to delocalized donor band states, while conduction band states exhibit shorter spin lifetimes. The occupation of localized donor band states is identified by short spin lifetimes (∼ 300 ps) and a distinct Overhauser shift due to dynamic nuclear polarization.

Within the framework of the emerging field of spintronics, the spin degree of freedom is exploited for information storage as well as processing and could serve as a qubit for quantum computation. Spin coherence and long spin lifetimes are a prerequisite for novel spintronic devices. Electron spins in Si-doped bulk \( n \)-GaAs drew attention, when long spin lifetimes \( T_2^* > 100 \text{ ns} \) and coherence lengths larger than 100 \( \mu \text{m} \) were determined using time-resolved Faraday rotation. Since then \( n \)-GaAs was used as a model system to investigate spin injection and spin transport phenomena. The long \( T_2^* \) of bulk \( n \)-GaAs, however, is restricted to a doping concentration in the vicinity of the metal-insulator transition (MIT) and shortens dramatically towards both sides of the transition. Similar results in \( n \)-type GaN, and \( n \)-type Si point to a universal phenomenon. However, the respective electronic states yielding these long \( T_2^* \) near the MIT have not been identified so far.

Various spin relaxation mechanisms have been considered to explain the dependence of \( T_2^* \) on carrier concentration, temperature, and magnetic field. The relevant relaxation mechanisms differ substantially for delocalized spins with, e.g., the D’yakonov-Perel’ (DP) dephasing mechanism, and for spins localized at impurity sites with, e.g., relaxation by hyperfine interaction. Concerning the electronic states of \( n \)-type semiconductors, the MIT was shown to occur within the donor band (DB), which is separated from the conduction band (CB). Near the Fermi level \( E_F \), the electronic structure is governed by both doping induced disorder and local Coulomb correlation. The former yields Anderson-localized states in the upper and lower donor band-tails, which are separated from extended states in the center by mobility edges. The latter may lead to a Coulomb gap \( U \) at \( E_F \). Both interactions yield a complex electronic structure with coexisting localized and delocalized DB states as well as CB states. Spin dephasing in \( n \)-GaAs has mostly been investigated for states at \( E_F \). There is, however, no energy-resolved study of \( T_2^* \), which would allow to assign spin lifetimes to the respective electronic states of both the donor and the conduction band. We expect that this assignment helps to identify the dominant spin relaxation mechanisms in the vicinity of the MIT.

In this Letter, we study the spin lifetime \( T_2^* \) of coherent electron spin states in \( n \)-GaAs, which are optically excited in both the donor and conduction band and probed by time-resolved Kerr rotation (TRKR) at 6 K. Due to the coexistence of distinct electronic states, the sample is not characterized by a single \( T_2^* \): \( T_2^* \) varies by three orders of magnitude as a function of photon energy. The longest \( T_2^* \) values which may exceed 100 ns are found for delocalized donor band states, while free conduction band states exhibit shorter spin lifetimes. Our time-resolved Kerr signal shows up to three exponential decay regimes with different precession frequencies. The latter can change due to an additional nuclear magnetic field arising from dynamically polarized nuclei, when resonantly pumping spins into localized DB states.

Two (001)-oriented, 500 \( \mu \text{m} \) thick GaAs wafers with different Si-doping concentrations have been investigated: Sample A with a carrier concentration of \( (2.4 \pm 0.2) \times 10^{16} \text{ cm}^{-3} \) is doped close to the MIT (critical carrier concentration in \( n \)-GaAs \( n_c \approx 1.5 \times 10^{16} \text{ cm}^{-3} \)) and is therefore degenerated. Reference sample B has a carrier concentration of \( (1.5 \pm 0.4) \times 10^{18} \text{ cm}^{-3} \) and is therefore degenerated. We used two tuneable, mode-locked Ti:Al\(_2\)O\(_3\) lasers providing ∼150 fs optical pulses corresponding to a spectral width of \( \approx 6 \text{ nm} \) at a repetition frequency of 80 MHz. Electronic phase-locking of both lasers enables us to employ one laser for spin pumping at an energy \( E_{pu} \) and the other one for probing the spin orientation at an energy \( E_{pr} \) after a variable delay time \( \Delta t = 0...16 \text{ ns} \). The normal-incident pump pulses, which were circularly polarized by a photo-elastic modulator (PEM), excite spin-polarized electrons and holes oriented along the beam...
direction in the strain-free mounted samples with an average power $\langle P \rangle = 50$ W/cm$^2$. The projection of the pump induced spin magnetization onto the surface normal of the sample is determined with linearly polarized laser pulses by Faraday rotation $\theta_F$ in transmission and by Kerr rotation $\theta_K$ in reflection. Transverse magnetic fields $B$ are applied in the plane of the sample.

In Figure 1(a), we plot $\theta_K(\Delta t)$ of sample A measured for various photon energies $E = E_{pu} = E_{pr}$ at $B = 1$ T and at $T = 6$ K. Obviously, the spins precess at all energies $E$, but the damping of the oscillations and thus $T_2^*$ is $E$-dependent: for $E$ below the CB edge $T_2^*$ is long, whereas for the highest $E$, at which CB states are pumped, $T_2^*$ is much reduced. Strikingly, a node in the oscillation envelope (red line in Fig. 1(a)) near the band edge indicates that the spins precess with at least two Larmor frequencies $\omega^{(i)}$. Therefore, $\theta_K(\Delta t)$ is described by $n$ decay components

$$\theta_K(\Delta t) = \sum_i A^{(i)} \exp \left(-\frac{\Delta t}{T_2^{(i)}}\right) \cos \left(\omega^{(i)} \Delta t + \phi^{(i)}\right), \tag{1}$$

where $A^{(i)}$, $T_2^{(i)}$ and $\phi^{(i)}$ are the initial amplitude, the spin lifetime and the phase of component $i$, respectively. Since this beating node shifts with increasing $E$ towards $\Delta t = 0$, the difference of the two $\omega^{(i)}$ increases. The Larmor frequencies $\omega^{(i)} = g^{(i)} \mu_B B/\hbar$ depend upon component-specific effective g-factors $g^{(i)}$. Note that the pump-induced spin packets, which exhibit a continuous distribution of g-factors, precess with only one energetically averaged $g^*$ but with reduced $T_2^*$ due to inhomogeneous dephasing [2]. Thus, electronic states with two g-factor dispersions like, e.g., DB and CB states are pumped simultaneously to yield separated $\omega^{(i)}$. Figure 1(b) displays $\theta_K(\Delta t, E)$ of sample A in a false color plot. The $E$-dependence of $\omega^{(i)}$ is obvious from horizontal variations of maxima and minima of $\theta_K$ and most distinct at the band edge (horizontal arrow). Non-vanishing $\theta_K$ at $\Delta t < 0$ evidence long $T_2^*$ > 6 ns, since the signal stems from spins exited by the previous pump pulse. In Figure 1(c), this result is compared to $\theta_K(\Delta t, E)$ of the degenerate sample B, for which $E_F$ lies well within the CB. For this sample, both $T_2^*$ and $g^*$ depend strongly on $E$ in the absorbing energy regime. However, there are no nodes in the oscillation envelope at any energy (see Fig. 1(c)). Note that the identity of DB states is completely lost in this degenerate sample. This indicates that the multi-component decay as well as the nodes in the oscillation amplitude of sample A may arise from distinct DB and CB states.

To further support these findings, we plot in Figure 2 both $T_2^{(i)}(E)$ and $\omega^{(i)}(E)$ values as determined from least-squares fits of $\theta_K(\Delta t, E)$ according to Eq. 1 for both samples and for various $B$ fields. The values of long $T_2^* > 20$ ns observed at $B = 0$ T are extracted from fits of resonant spin amplification scans [2]. For sample A, $T_2^*$ drops by more than 3 orders of magnitude as a function of photon energy $E$, however, three energy regions can be distinguished marked by red, green and blue symbols. At low $E$ (red), $T_2^*$ is nearly independent of $E$ but decreases rapidly with the increase of $B$. In this regime we also observe $T_2^* \approx 110$ ns at $B = 0$ T at reduced pump power $\langle P \rangle = 10$ W/cm$^2$ (not shown) similar to Ref. [2]. Approaching the CB edge $T_2^*$ drops at all $B$, but the Larmor frequency for the whole range (red) is almost...
constant and exhibits $|g^*| = |g_0| = 0.43$. Near the CB edge (green), $T$-independent values of $T^{\ast 1}_2 \sim 100\ldots300$ ps are determined, which distinguish themselves by a rapid decrease of $\omega(E)$. At the beginning of the third region (blue), $T^{\ast 2}_2$ sets-in at $\sim 6$ ns and decreases with increasing $E$. The corresponding $\omega$ decreases slightly and saturates at high $E$. The overlap in energy of the second and third region, which occurs due to the spectral width of the laser pulses, generates the node in the oscillation envelope shown in Figure 1. For the degenerate sample B, $T^{\ast (i)}_n(E)$ can be fitted by one component $i$. As expected $T^{\ast (i)}_n$, $T^{\ast 2}_2$ is over-all shorter compared to sample A and $T^{\ast 2}_2$ increases with the increase of $B$, which is typical for the DP dephasing mechanism.

In the following, we assign the $T^{\ast (i)}_2$ of the spins observed in the three energy ranges to carriers occupying different electronic states. Since hole spins relax quickly $\lesssim 10$ ps in GaAs and excitons are broken up at high magnetic fields $B \gtrsim 1$ T [20], we consider single electron states. Since the carrier concentration of sample A is slightly above $n_c$, $E_F$ lies within the delocalized DB states as sketched in Figure 3. Thus delocalized DB states are pumped at lowest $E$, which exhibit the longest $T^{\ast 2}_2$ (red component in Fig. 2). However, to our knowledge there is no relaxation mechanism of spins, which accounts for their distinct $B$-dependence. We assign the second energy range (green), which is missing for the degenerate sample B, to Anderson localized electronic states at the DB tail. Their distinct $E$-dependence of $\omega$ and $T^{\ast 2}_2$ can be linked to the decrease of localization length upon approaching the DB tail. The localization of electrons yields spin relaxation due to hyperfine interaction with the nuclei [14, 15]. This gives rise to dynamic nuclear polarization and a nuclear field, which alters $\omega$ (Overhauser shift) [21]. However, from Ref. [14] long $T^{\ast 2}_2 \sim 300$ ns are expected for localized electron spins, although we could not reproduce this result with insulating $n$-GaAs samples using TRKR. In Ref. [15], an additional short $T^{\ast 2}_2 \sim 100$ ps component is predicted, when both localized and delocalized spins are pumped. This is assigned to their cross-relaxation rate. Whereas this might explain our short $T^{\ast 2}_2$, it does not account for the distinct $\omega(E)$ dependence. In the third energy regime (blue), electrons are pumped in the CB. The decrease of $\omega$ observed for both samples is due to $g^*$: The absorption of the pump pulse lifts the local chemical potential, thus reducing the absolute value of the energetically averaged $g^*$ factor according to its dispersion in the CB [20]. The apparent decrease of $T^{\ast 2}_2(E)$ might be explained by carrier cooling and interband relaxation. Due to both, the carriers relax below the probed energy.

This notion can be confirmed by sweeping $E_{pu}$ with $E_{pr}$ fixed at the bottom of the CB. The corresponding fits of $T^{\ast (i)}_2(E_{pu})$ and $\omega^{(i)}(E_{pu})$ of sample A at $B = 1$ T are shown in Figure 3(a) and (b). Indeed, this method allows to correct $T^{\ast 2}_2$ for energy relaxation, since $T^{\ast 2}_2(E_{pu})$ (blue full symbols) decreases only slightly compared to Figure 2. However, there is an additional short $T^{\ast (i)}_2(E_{pu})$ (green full symbols), which results from probing localized spins at the DB tail because of the spectral width of the probe pulses. To clarify this point, $E_{pr}$ is fixed at an energy even lower than the band gap (Fig. 3(c)-(e)). For this $E_{pr}$, the longest $T^{\ast (i)}_2(E_{pu})$ (red) attributed to delocalized DB states is observed, which turned out to be nearly constant at $B = 0$ T. Note that the average pump power is held constant, but the excited carrier density changes by orders of magnitude in the absorbing regime. This has a negligible effect on the longest $T^{\ast 2}_2$. More strikingly, additional components $i$ become observable, when $E_{pu}$ passes the localized and CB states. Thus, different electronic states become occupied either due to direct optical excitation or carrier relaxation as sketched in Figure 3-upper left). From the onset of the $\theta_F$ signal (not shown), we deduce that the delocalized DB states are occupied within $\Delta t < 10$ ps for all $E_{pu}$. At $B = 1$ T (Fig. 3(d)) and $E_{pu}$ beyond the band edge, the two long $T^{\ast (i)}_2$ components (blue and red) generate nodes in the oscillation envelope (Fig. 3(a)) and can be separated by their $\omega^{(i)}$ (Fig. 3(e)). For fitting, however, the longest $T^{\ast 2}_2$ (red) of delocalized DB had to be fixed with minor influence on the blue component. The lat-
Faraday rotation $\theta_F(\Delta t)$ of sample A for left ($\sigma^-$) and right ($\sigma^+$) circularly polarized pump pulses (red arrows) at $B = 1$ T, $E_{pu} = 1.514$ eV and $E_{pr} = 1.494$ eV. Inset: fitted normalized Larmor frequencies $\omega^{(i)}$ and corresponding lateral nuclear magnetic fields $B_N^i$ for both polarizations as a function of the average pump power.
