Abstract: This paper presents a micro coordinate measuring machine capable to measure and reconstruct three dimensional surfaces of micro parts. The uniqueness of the proposed machine lies in its small foot print with ability to displace micro objects beneath the measuring probe for continuous surface characterisation with micrometer level resolution. Its miniature measuring probe enables its easy integration into several micro applications. In addition, the multiple surface stitching algorithm used in the micro-coordinate measuring machines enhances its capability to reconstruct and measure large 3D surfaces.

1. INTRODUCTION

Nowadays, Coordinate Measuring Machines (CMMs) are widely adopted in numerous manufacturing industries such as aeronautics, automobile, etc., to achieve high quality and precision standards in manufacturing and assembly processes of three-dimensional mechanical components. The distinct ability of these machines to measure geometrical parameters of the tridimensional mechanical parts or assemblies against the design intent, has greatly revolutionized current mechanical products to meet high quality manufacturing standards, Sudatham et al. (2015).

In general, CMMs are typically used with contact sensors (i.e., measurement probe) to retrieve physical measurements of the mechanical parts and/or assemblies. In practice, these CMMs deliver high accuracy and repeatability during measurement. However, due to their contact-type measurement approach, their application to measure small mechanical pieces having volume from few cubic micrometers to few cubic millimeters is limited, Yang et al. (2011). This is mainly due to the difficulties such as deterioration of small mechanical parts as a result of the measurement probe’s contact during physical measurement, the limited measurement resolution due to the size of the measurement probe used in the contact-type CMMs, etc.

In order to solve the aforementioned constraints, contactless CMMs based on optical technology (i.e., interferometry, triangulation, stereo imaging based on structured light, etc.) are often employed to measure mechanical parts having small volume. The advantages of contactless CMMs is twofold. First, no additional geometrical information is needed regarding the mechanical part prior to the measurement, and second, it delivers fast measurements by eliminating the need of point-by-point measurements as essential in contact-type CMMs.

Apart from the advance features incorporated into the contactless CMMs, their huge size and excessive energy consumption for measuring micro mechanical parts yield an expensive solution. In addition, the ever-growing micro factory concept introduced in 1990, to economize the low and mid-volume production cost of the customized products, has led to great challenges by miniaturize pre-exiting conventional machines, e.g., milling machine, drilling machine, etc., Hofmann et al. (2011); Siltala et al. (2011); Kobel and Clavel (2011). So, being an essential device of the current high quality production environment, the downsizing of typical contactless CMMs demands innovative technological solutions to miniaturize various components (i.e., actuation platform, measurement probe, feedback control, etc.) without diminishing their output characteristics such as measurement resolution, measurement speed, etc.

In this paper, a Micro Coordinate Measuring Machine (μCMM) prototype capable to measure small mechanical piece and reconstruct its 3D image is presented. The planar actuator of the μCMM is able to move a miniature mechanical piece beneath the contactless measurement probe in horizontal plane. The measurement probe takes multiple images during actuator’s movement and reconstructs a long surface of the piece using image stitching technique. In addition, during reconstruction process, the planar ac-
tuator can easily position the mechanical piece beneath the measurement probe to take high quality measurement with respect to the information deduced via image processing. In second section, the description of the \( \mu \)CMM is provided. In the third section, planar actuator is discussed and 3D measurement system and the used image stitching technique is presented in the fourth section. At the end conclusion and perspective is provided.

2. DESCRIPTION OF MICRO COORDINATE MEASURING MACHINE

The proposed \( \mu \)CMM consists of a planar actuation system, a 3D measurement system and an Input/output hardware and software control modules as depicted in the Fig.1. The planar actuation system includes a planar electromagnetic actuator capable to displace a specimen (i.e., mechanical piece, etc.) beneath the measurement probe. In addition, a position control unit manages the motion of the planar actuator to achieve desired trajectories in horizontal plane.

The 3D measurement system of the \( \mu \)CMM consists of a active stereovision principle based measurement probe as shown in the Fig.2. A dedicated 3D measurement probe control unit handles the functioning of the measurement probe by projecting the structured light and measuring the pattern’s distortion on a small objects such as a euro coin as shown in the Fig.2. The I/O hardware and software modules integrated in a Personal Computer (PC) assist in generating the desired motion trajectories for the planar actuator and analyze the measured information from measurement probe. In order to realize a long measured surface, the software modules combines complex algorithms to stitch measured surface data. The detail description of these components is provided in the following sections.

3. PLANAR ACTUATOR

The planar actuator of the \( \mu \)CMM consists of a mobile part and a fixed part, see Fig. 3. The mobile part integrates Permanent Magnet Arrays (PMAs) into a light weight microfabricated silicon cross structure, see Khan et al. (2010). A single PMA consists of a set of 14 Permanent Magnets (PMs) in North-South (NS) configuration. The dimensions of each PM are \( 1 \text{mm} \times 1 \text{mm} \times 6 \text{mm} \) and provide a remanent magnetization of \( 1.43 \text{T} \) along \( z \)-axis. The NS pole configuration helps in self-assembly of the PMs without needing any bonding agent, see Khan et al. (2012).

The fixed part of the planar actuator, having dimensions of \( 80 \text{mm} \times 80 \text{mm} \), consists of a pair of Planar Drive Coils (PDC) along \( x \)-axis and \( y \)-axis in \( xy \)-plane. A single PDC includes two copper coils for routing two phase driving currents (\( I_1 \) and \( I_2 \)), independently. The fixed part has been fabricated into 1.5 mm thick double side FR4 printed circuit board. In addition, to achieve smooth motion surface and insulation between the mobile and fixed part of the planar actuator, each PDC is covered with a 130 \( \mu \text{m} \) thick flat glass layer.

In the planar actuator design, the combination of each PMA facing corresponding PDC, acts as a Linear Motor (LM). From Fig.3, it can be seen that two orthogonally arranged pairs of the LMs in \( xy \)-plane aid to translate and rotate the mobile part of the planar actuator over the fixed part about its central axis in \( xy \)-plane.

3.1 Working principle of the planar actuator

The working principle of each LM of the planar actuator is based on the generation of the Lorentz forces. When sinusoidal currents are injected into the fixed PDCs of the LM, a Lorentz force appears over each PMA due to the interaction between the magnetic field from the PMs and currents in the PDCs. The resulting electromagnetic force tends to translate the mobile part (i.e., PMA) over the fixed part (i.e., PDC covered with glass layer). The translation force \( (F_x) \) and levitation force \( (F_z) \) are the
The injected currents is changed from +/2 to π/2. Furthermore, to achieve forward (i.e. along +x-axis) and backward (i.e. along −x-axis) motion along x-axis, the phase difference of the injected currents is changed from +π/2 to −π/2, see Khan et al. (2012).

In order to achieve multiple precise measurements of the micro object, the motion path of the planar actuator needs to be controlled using non-contact feedback displacement sensors, see Prelle et al. (2006). In addition, by adopting a closed loop control for the planar actuator, the planned motion trajectories can be achieved with nanometer level precision, see Khan et al. (2016). However, in order to validate the concept and minimize the experimentation time, the motion of the planar actuator have been realized with open-loop control in this study. For this, the pre-planned motion path of the actuator has been generated by sampling the desired millimetric xy-displacement trajectory with 10 μm step resolution. Based on the obtained displacement trajectory samples, the regulated sinusoidal currents (i.e., I1 + ∆I1 and I2 + ∆I2) with respect to the actuator’s position, are injected into PDCs to drive the mobile part of the planar actuator to the desired position on the motion trajectory. For our initial study, this approach aids in achieving complex motion trajectories (e.g., circular, square, etc.) in xy-plane without implementing feedback sensors. However, in future, a feedback displacement sensor that is essential to realize motion trajectories with nanometer level positioning resolution will be implemented in the planar actuation system.

4. 3D MEASUREMENT SYSTEM

In this section, the detail description of the 3D measurement system along with its measurement principle and point cloud fusion technique is discussed.

4.1 Measurement probe architecture

The 3D measurement system consists of a miniaturized measurement probe. Its architecture is presented in Fig. 5, see Hou et al. (2014). The measurement principle is based on active stereovision that takes the projection of structured light patterns on the object to be analyzed into account. The measurement and analysis of the patterns’ distortion lead to the reconstruction of 3D object shape.

In order to design an active stereovision system, the device is divided in two channels. The first is the projection channel where a pattern is generated and focused on the measured object, and the second is the capture channel where a camera measure the projected pattern image. A triangulation angle between the two channels encodes the depth information.

To develop the measurement system, the projecting and capturing opto-electronic devices are optically connected to the 2m long image guides (FIGH-70-1400N, Fujikura Inc.). Each image guide consists of a fiber bundle having 70000 optical fibers within a total diameter of 1.4 mm.

Furthermore, to generate the projected patterns, a Digital Micro-mirror Device (DMD), fabricated by Texas Instrument Inc, is used. This is a MEMS device composed of 1024×768 squared mirrors of 10.8 mm pitch. A white light source is used to illuminate the DMD. This light is structured and injected into the first image guide. The light received from the other end of the first image guide is then projected through a Triplet Steinhel lens, a mirror and finally focused on the desired area to be measured. Afterwards, the structured light patterns reflected from the measured object area are re-injected into a second image guide (identical to the first) through the capture channel composed of a mirror and a Triplet Steinhel lens as shown in Fig. 5(b). Finally, the other end of the second image guide is optically connected to a CCD Camera (Flea 2 Camera, Point Grey Inc.), where the image of the object to measure and the projected patterns are captured.

Using this miniaturized measurement probe, a time multiplexed patterns sequence is projected on the object to measure it, as explained on the following subsection.

4.2 3D measurement principle

The 3D measurement principle used to reconstruct the object shape is based on a time multiplexing method adapted for structured light projection, also named as phase shifting, see Salvi et al. (2010). In this method, a sequence of vertical sinusoidal patterns are projected. And between each pattern, the signal phase is shifted by small increments. For each pixel of the camera sensor, the phase detection allows to calculate one 3D point coordinate and
for the whole sensor, a global height map representing the measured surface is calculated, see Fig. 6.

The intensity of each captured pixel is calculated using (1).

\[ I_i(x, y) = L_p(x, y) \sin(\varphi(x, y) + \delta_i) + L_a(x, y) \]  (1)

Where \( x \) and \( y \) are the pixel coordinates of the \( i \)th captured image, \( L_a \) is the intensity due to the ambient lighting, \( L_p \) is the intensity due to the projection lighting, \( \delta_i \) is the phase of the \( i \)th pattern and the \( \varphi(x, y) \) phase encodes the 3D depth information for the pixel \((x, y)\). For \( N \) phase shifting, the value of the phase \( \varphi \) can be computed using (2).

\[ \varphi(x, y) = \tan^{-1}\left( \frac{-\sum_{i=1}^{N} I_i(x, y) \sin(\delta_i)}{\sum_{i=1}^{N} I_i(x, y) \cos(\delta_i)} \right) \]  (2)

Next, a phase unwrapping method is applied on \( \varphi(x, y) \) and this unwrapped phase is finally converted into a 3D coordinate value using the system calibration. Finally, a 3D point cloud representing the measured area shape is calculated. Once a 3D reconstruction process is finished, the following step is to move the planar actuator to measure a second area adjacent to the first one. Each measured area need to overlapped with the precedent one, so that it can be algorithmically aligned to stitch multiple measurements. This 3D stitching principle results in acquiring the whole surface of the object.

### 4.3 Point cloud fusion

#### 4.3.1. Surface stitching principle

The concept of stitching elements with their overlapping fields was first introduced for 2D panoramic imaging with two or more images and was then applied in the 3D scope with surface stitching. The goal of this method is to find the position and orientation of 3D point clouds in a global coordinate system, such that the intersecting areas between the point clouds overlap perfectly.

The 3D stitching process is divided into three main steps which are key-point detection, registration and estimation of the final transformation. Firstly, for the key-point detection algorithm, an appropriate mathematical model is needed to associate effective 3D points from one surface to the other so that the matching features can be determined easily. These associated 3D points are called correspondences. They are used in the registration process to search for surface alignments that minimizes the overall sum of distances between corresponding 3D points. Then, a transformation estimation is applied to align the two consecutive point clouds into a single wider surface.

#### 4.3.2. Iterative Closest Point with Normal method

In order to determine the overlapping parts in the point cloud pair data acquired via two measures, corresponding features must be found. For X,Y and Z coordinates used as the only features to compare the point cloud pair data, nearest neighbor search method can be applied. Using this principle, one popular method is the Iterative Closest Point (ICP) method (see Salvi et al. (2007)) which consists of iteratively applying estimation and error reduction algorithms to finally align two point clouds into one final model. The ICP method minimize a weighted sum of squares of the distances between the source data points and the target corresponding closest points.

An efficient variant of ICP is named ICPN (Iterative Closest Point with Normal) and based on point-to-plane minimization. In addition of the three coordinates points in \( \mathbb{R}^3 \) used by ICP, the ICPN algorithm also handles the surface normal values. The purpose of this specific algorithm is to minimize the squared distance sum between the first cloud source points and the tangent plane at its corresponding target point on the second cloud. Both, ICP and ICPN methods were tested experimentally in our study and ICPN proved to be more precise although slower than ICP.

#### 4.3.3. Result of stitching using ICPN method

The registration algorithm was experimentally tested with the 3D probe (see paragraph 4.1) on a 10 cent euro coin as shown in Fig. 7. From the results, it can be observed that two overlapping surfaces were reconstructed one after the other. Each 3D measure of point clouds contains around 308000 points, covering an elliptic area of 2.4 mm x 2.2 mm and a total depth of 0.8 mm. Hence, the average density of the acquired point cloud is 70000 points per millimeter.

The 3D rendering of the measured two point clouds stitching is illustrated in Fig. 8(a). A horizontal section of the point clouds stitching is presented in Fig. 8(b). Furthermore, the results of the error distance between the two point clouds are shown in Fig. 8(c). The ICPN registration process computation time was found to be 87.4 seconds using an Intel Xeon E5-1620 processor with 8 cores each having 3.60 GHz frequency. Moreover, the average error on the measured profile between the two point clouds is found to be 1.65 \( \mu \)m with a standard
deviation of 1.04 µm. The computation time can be further reduced by optimizing certain parameters such as down-sampling the input and output point clouds, making the algorithm efficient by exploiting the multi-threaded feature of all processor cores, etc.

4.3.4. Automatic registration algorithm

After the stitching process, an automatic registration algorithm is developed to align multiple point clouds, one after the another to cover the whole measured surface. The algorithm inputs are the point clouds data files and the displacements values. Using the developed algorithm, 16 point clouds with a total of 4931243 3D points are aligned in 839 seconds using an ICPN method, see Fig. 9.

5. CONCLUSION AND FUTURE WORK

In this work, a compact design of a µCMM to measure small mechanical parts is presented. The small foot print (i.e., 80 mm × 80 mm) of the µCMM makes it suitable for easily integrating it into small working space. In addition, the high speed dynamics and 3DOF motion capability of the electromagnetic planar actuator enhances its ability to precisely position the small objects for analysis beneath the measurement probe with micrometer level resolution. In addition, a 3D probe using active stereovision was designed to measure elliptic areas of 2.4 × 2.2 mm² over a depth of 0.8 mm with a micrometer level resolution and based on a phase-shift reconstruction algorithm. In order to measure larger areas than the probe field of view, the control of actuator using point cloud information is also designed.
In future, we planned to implement a control feedback on the planar actuator using the position and orientation values provided by the stitching algorithm. Also, the 3D reconstruction results will be analyzed during the measuring process and used as an input to adopt the planar actuator trajectory in order to optimize the final 3D point cloud quality. Furthermore, dedicated position control algorithms will be developed and integrated into the developed stitching algorithm while optimizing measurement parameters such as, measurement speed, etc.
