We present a semi-anisotropic interfacial potential (SAIP) designed to classically describe the interaction between gold and two-dimensional (2D) carbon allotropes such as graphene, fullerenes, or hydrocarbon molecules. The potential is able to accurately reproduce dispersion corrected density functional theory (DFT+D3) calculations performed over selected configurations: a flat graphene sheet, a benzene molecule, and a C_{60} fullerene, physisorbed on the Au(111) surface. The effects of bending and of hydrogen passivation on the potential terms are discussed. The presented SAIP potential provides a noticeable improvement in the state-of-the-art description of Au-C interfaces. Also, its functional form is suitable to describe the interfacial interaction between other 2D and bulk materials.

I. INTRODUCTION

The reproducibility of phenomena emerging at the interface between two bodies in contact is often limited by the availability of clean and well controllable surfaces. Gold and graphene are two very stable materials that can be produced with a high level of crystallinity and cleanliness over large surface areas. For these reasons the gold/graphene interface has been the prototypical choice for a large number of case studies, including diffusing and sliding gold nanoclusters [1–6], nanomanipulation [7–9], plasmon-enhanced optics and enhanced Raman scattering [13, 14], among many others.

Despite the vast interest expressed in this composite system by the scientific community, to date no reliable classical force field is available for computational simulations involving interfaces of gold with graphitic systems. Since the interaction between graphene and metals is mainly governed by van der Waals forces [15, 16], a simple two-body Lennard-Jones (LJ) potential, often expressed in the form \( V_{LJ}(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^{6}] \), has been so far employed and parametrized in order to fit observations from specific experimental setups [6, 7]. However, the oversimplified nature of the LJ potential, with just \( \epsilon \) and \( \sigma \) setting the two-body dissociation energy and equilibrium length, respectively, makes it extremely challenging to fit more than a few among the several physical quantities impacting the static and dynamical properties of a gold/graphene assembly. As a consequence, previous studies have employed very different parametrizations to match some particular quantities of interest, with \( \epsilon \) varying from 2.5 to 90.0 meV and \( \sigma \) varying from 2.5 to 3.2 Å [1, 2, 6, 7, 17], making a straightforward comparison among these studies often impractical.

Beside quantitative errors, even a qualitative description in LJ terms is questionable. For a single gold atom residing on a graphene surface, typical pairwise isotropic potential (i.e., depending only on the distance between pairs of atoms), such as the LJ potential, would find the minimum energy position where the gold atom is located over a graphene hexagon center (hollow position). Nevertheless, experiments and first-principle calculations have demonstrated that the atop position, where the Au atom resides over a C atom, is energetically favorable [18, 19]. This exemplifies the need for an anisotropic potential to describe the gold/graphene interfacial energy landscape.

Beyond the single-atom contact, when an extended gold/graphene interface is considered, the sliding energy landscape becomes much more complex due to the intrinsic incommensurability of the contact. In fact, nanoscale graphene flakes and ribbons residing over the (111) surface of gold can be found in both the epitaxially aligned R0 and the R30 tilted orientations [7, 20]. Extended contacts, on the other hand, were predicted to prefer intermediate misfit angles 0 < \( \theta \) < 30° [21]. This, in turn, is expected to be manifested in the interfacial tribological properties, where the combination of the weak Au-C interactions and the strong internal cohesive forces of gold and graphene may lead to exceptionally low friction coefficients (<10^{-3}) – a condition often referred to as structural superlubricity [6, 22, 23]. In superlubric systems the corrugation energy (CE) – the energy barrier resisting sliding – can decrease to values much below the meV per interface atom. Therefore, studies aiming at describing superlubricity, often considering a combination of metals and graphitic materials [3, 7–9, 24–26], are critically sensitive to the chosen experimental or theoretical setup.

It is therefore evident that there is an urgent need to develop a new force field able to reliably describe the interaction between graphene and gold. Unfortunately, there is only a handful of experimental studies providing data that can be directly employed to parametrize...
such a force field. For example, Torres et al. measured an adhesion energy (AE) $E_a = 7687.1 \text{ mJ} \cdot \text{m}^{-2}$ in the case of graphene-covered gold nanoparticles [27], while a pull-off force of $F_a = 45.7 \pm 5.1 \text{ nN}$ was measured by Li et al. for gold-coated AFM probes forming a $\sim 200 \text{ nm}^2$ contact with a graphite substrate [23]. Other experiments provide only indirect information based on empirically fitted models or simulations [6, 7, 9, 28]. The comparison with experiments is further complicated by the presence of surface reconstruction at the gold surface, usually neglected in first-principles calculations due to the large supercell size required to encompass its long ($\sim 6.3 \text{ nm}$) wavelength. Leaving out such reconstruction effects potentially overestimates the computed interaction energies, but in most cases this approximation yields only minor structural modifications in the model systems[29].

Due to the lack of direct experimental measurements and accurate computational reference data for the adhesion and corrugation energies of graphene/gold interfaces, we performed dispersion corrected density functional theory (DFT+D3) calculations on the R30 tilted graphene/gold heterojunction. This reference dataset allowed us to parametrize a newly-developed semi-anisotropic interfacial potential (SAIP) that is able to simultaneously reproduce the DFT+D3 adhesion energy curves and sliding potential energy surfaces (PES). The developed SAIP and its suggested parameterization present a significant advancement with respect to the present stand of classical description of the interfacial interactions in gold and graphene junctions. Furthermore, the SAIP formulation provides a general tool for describing interfaces formed between two-dimensional (2D) materials and bulk solids.

II. POTENTIAL DESCRIPTION

The presented SAIP is based on the concept of anisotropic interlayer potentials (ILP) for 2D materials [30–34]. The potential consists of two terms: an isotropic term that describes the long-range attractive dispersive interactions, and an anisotropic term that describes the Pauli-type repulsion between the graphene $\pi$ electrons and the gold surface electron density. The dispersive term treats long-range van der Waals interactions via a $C_6/r^6$ LJ type potential, dampened in the short range with a Fermi-Dirac type function similar to that introduced in dispersion corrected DFT calculations to avoid double counting of correlation effects [35]:

$$E_{\text{dis}}(r_{ij}) = \text{Tap}(r_{ij}) \left\{ \frac{1}{1 + e^{-d[(r_{ij}/(s_Rr_{ij}^2))]-1}} \right\} \cdot \frac{C_{6,ij}}{r_{ij}^6} \right\} \cdot$$

Here, $r_{ij}$ is the distance between carbon or hydrogen atom $i$ and gold atom $j$, $d$ and $s_R$ are unit-less parameters determining the steepness and onset of the short-range Fermi-type dampening function, and $C_{6,ij}$ and $s_R$ are the sum of effective atomic radii and the pair-wise dispersion coefficients, respectively. The Tap($r_{ij}$) function provides a continuous (up to 3$^{rd}$ derivative) long-range cutoff at $r_{ij} = R_{\text{cut}}$ to the potential aiming to reduce computational burden:[36]

$$\text{Tap}(r_{ij}) = \frac{20}{R_{\text{cut}}^5} r_{ij}^5 - \frac{70}{R_{\text{cut}}^6} r_{ij}^6 + \frac{84}{R_{\text{cut}}^7} r_{ij}^7 - \frac{35}{R_{\text{cut}}^8} r_{ij}^8 + 1$$

Following the Kolmogorov-Crespi (KC) [30] scheme, the anisotropic term of the potential is constructed from a Morse-like exponential isotropic term, multiplied by an anisotropic correction in which the orientation of graphene is described by normal vectors associated to each carbon or hydrogen atom:

$$E_{\text{ani}}(r_{ij}) = \text{Tap}(r_{ij}) e^{\alpha_{ij} \left( 1 - \frac{r_{ij}}{R_{\text{cut}}} \right)} \times \left[ \epsilon_{ij} + C \left( e^{-\left( \frac{r_{ij}}{\gamma_{ij}} \right)^2} + e^{-\left( \frac{r_{ij}}{\gamma_{ij}} \right)^2} \right) \right]$$

Here, Tap($r_{ij}$) is the cutoff smoothing function of eq 2, $\alpha_{ij}$ and $\beta_{ij}$ set the slope and range of the potential, and $\gamma_{ij}$ sets the width of the Gaussian decay factors in the anisotropic correction term and thus determines the sensitivity to the transverse distance, $\rho_{ij}$, between carbon or hydrogen atom $i$ and gold atom $j$ (see Figure 1). $C$ and $\epsilon_{ij}$ are constant scaling factors bearing units of energy. The normalized normal vectors $n_i$ (i.e., $|n_i| = 1$) serve to calculate the transverse distance $\rho_{ij}$ between pairs of carbon or hydrogen atom ($i$) and gold atom ($j$),

$$\rho_{ij}^2 = r_{ij}^2 - (n_i \cdot r_{ij})^2$$

$$\rho_{ij}^2 = r_{ij}^2 - (n_j \cdot r_{ij})^2$$

Each normal vector $n_i$ defines the local normal direction to the graphene sheet (or to the benzene molecule) at the position of its atom $i$ (see Figure 1). Note that the definition of the normal vector is not unique, and can follow different schemes [30]. For example, one can calculate the
normal vector of atom $i$ by averaging the three normalized cross products of the vectors connecting atom $i$ to its three nearest neighbors $k,l,m$, or in a more simple way, by calculating it as $n_i = (r_{ki} \times r_{mi})/\left(\|r_{ki}\| \|r_{mi}\|\)$ [see Figure 1(a)]. In our implementation the former definition is adopted. However, when dealing with a flat graphene (or benzene molecule) lying on the $xy$ plane, all definitions of the normal vector should give $n_i = \hat{z}$, making the specific choice irrelevant. In the case of curved graphene, such as for nanotubes, all normal vector definitions should produce very similar results except for extremely small radii of curvature $[30, 37]$.

To account for the isotropic nature of the isolated gold atoms electron cloud, their corresponding normal vectors are assumed to lie along the interatomic vector $r_{ij}$. Notably, this assumption is suitable for many bulk materials surfaces, e.g. for systems possessing s-type valence orbitals or metallic surfaces, whose valence electrons are mostly delocalized, such that their Pauli repulsions with the electrons of adjacent surfaces are isotropic. Caution should be used in the case of very small gold contacts, e.g. nanoclusters, where edge effects may become relevant.

Following the above assumption, $n_i || r_{ij}$, one gets $\rho_{ji} = 0$. The latter simplification reduces the anisotropic term to the following final form:

$$E_{ani}(r_{ij}) = T_{ap}(r_{ij}) e^{\alpha_{ij}} (1 - e^{-\gamma_{ij}}) \times \left[ \epsilon_{ij} + C \left( e^{-\alpha_{ij}} \right)^2 + 1 \right] .$$

III. MODEL SYSTEMS AND METHODS

A. Model systems

As model systems for the parameterization process we choose the two interfaces depicted in Figure 2. The first is composed of a graphene layer positioned at the R30 stacking configuration over three Au(111) layers $[20]$. The second is composed of a benzene molecule residing over three Au(111) layers. DFT spin-polarized calculations were performed by the Perdew-Burke-Ernzerhof (PBE) exchange-correlation functional within the generalized gradient approximation (GGA) augmented by Grimme’s D3 long-range dispersion correction and the Rappe-Rabe-Kaxiras-Joannopoulos (RRKJ) ultra-soft core-corrected pseudopotentials, as implemented in the Quantum Espresso software.$[38–41]$ Previous benchmark DFT calculations of metallicorganic frameworks (MOFs) indicate that the PBE exchange correlation density functional approximation with the D3 dispersion correction can accurately describe the energetics of complex systems involving organic and inorganic components $[39, 42, 43]$. However, whether this is the best DFT approach (out of tens of currently available dispersion oriented density functional approximations) for the system under consideration cannot currently be concluded, mainly due to the lack of experimental results or high-accuracy computational reference data.

Kinetic-energy cutoffs of 600 eV for the wavefunctions and 4952 eV for the density were employed, with a reciprocal-space mesh of $7 \times 7 \times 1$ k-points for the Au(111)/graphene interface and $3 \times 3 \times 1$ k-points for the Au(111)/benzene system (see below). Convergence of total energy over the above cutoffs and k-points grid was established. Periodic boundary conditions were applied in all directions. In all the calculations graphene or benzene were kept flat $[15]$ and the gold atoms were maintained in the fcc bulk configuration.

In the Au(111)/graphene case, the lateral stress was minimized by iteratively rescaling the system size. The final supercell vectors length and angles were $a = b = 4.965638 \text{ Å}, c = 30 \text{ Å}, \alpha = \beta = 90^\circ, \gamma = 60^\circ$ (see Figure 2a-b). The out-of-plane periodicity $c$ was chosen to be as large as possible to avoid interactions with replicas along the vertical direction. The calculated lattice constants of the isolated bulk gold and graphene systems were $2.8825$ and $2.4652 \text{ Å}$, corresponding to a final strain of $-0.54\%$ and $+0.7\%$, respectively, in the relaxed composite system. In the Au(111)/benzene and Au(111)/C_{60} cases we have employed a supercell with $a = b = 14.896914 \text{ Å}, c = 30 \text{ Å}, \alpha = \beta = 90^\circ, \gamma = 60^\circ$ (see Figure 2c-d). Equilibrium distances of 3.5 Å between graphene and gold, of 3.3 Å between benzene and gold, and of 3.3 Å between $C_{60}$ and gold were found by rigid vertical displacement.
of the adsorbate molecule.

B. Fitting protocol

The parameters of the SAIP were determined against reference $M = M_b + M_s$, DFT datasets including $M_b$ AE curves and $M_s$, sliding PESs. The AE curves were calculated for five high-symmetry stacking modes (see top panel of Figure 3), which are concisely denoted by $r_m$, where $m \in [1, M_b]$, such that $r_m \in \mathbb{R}^{3N_m}$ and $N_m$ is the number of atoms in configuration $m$. Each AE curve includes 15 data points as a function of the gold-graphene (gold-benzene, or gold-fullerene) distance. The sliding PESs were obtained at a fixed vertical ($z$) distance of 3.5 Å, by rigidly shifting the adsorbate along the lateral ($x$-$y$) direction with respect to the gold substrate. The single-point total energy at each of 441 points of an uniform mesh grid was recorded. The origin $(0,0)$ configurations of the PESs correspond to those presented in Figure 2.

Optimal SAIP parameters were obtained by minimizing the following objective function that quantifies the difference between the DFT reference data and the potential predictions:

$$
\Phi(\xi) = \sum_{m=1}^{M_b} w^b_m \| E^b_m(r_m, \xi) - E^b_{m,\text{DFT}} \|_2 + \sum_{m=1}^{M_s} w^s_m \| E^s_m(r_m, \xi) - E^s_{m,\text{DFT}} \|_2
$$

Here, $\| \cdot \|_2$ is the Euclidean norm (2-norm) that measures the difference between the SAIP predictions and the DFT reference data, $\xi$ represents the set of potential parameters, and $E^b_m(r_m, \xi)$ and $E^s_m(r_m, \xi)$ represent the $M_b$ AE curves and $M_s$, sliding PES data sets, respectively. $w^b_m$ and $w^s_m$ are the corresponding weighting coefficients. The reference DFT interfacial energies, $E^b_m, E^s_m, E^b_m$, and $E^s_m$, are obtained as follows: For any given configuration $m$ of the heterostructure, the total energy is first obtained from DFT+D3 calculation: $E^b_{m,\text{DFT, total}}$. Then the energy of the isolated graphene, $E^b_{m,\text{DFT, graphene}}$, and of isolated gold, $E^b_{m,\text{DFT, gold}}$, are computed separately using the same cell as that of the composite system. The DFT interfacial energy appearing in eq 6 is then defined as:

$$
E^b_{m,\text{DFT,s}} = E^b_{m,\text{DFT, total}} - E^b_{m,\text{DFT, graphene}} - E^b_{m,\text{DFT, gold}}.
$$

Since the AE – defined as the difference between maximum and minimum PES energy – is much smaller than the AE (~1 vs. hundreds of meV/cell) the weight factors for the AE curve were set to $w^b_m = 1$ ($m = 1, \ldots , 5$), and those of the sliding PESs were chosen as $w^s_m = 100$, thus providing comparable precision. The optimization was carried out using MATLAB with an interior-point algorithm [44, 45] (further details are provided in Refs. [34, 37]). To obtain transferable parameters that can account for varying gold thickness, we first parameterized the potential for the heterostructure with trilayer gold using the objective function defined in eq 6, then we added the training sets of the heterostructure with bilayer and single layer gold and reparameterized the potential following the same procedure.
TABLE I. Potential parameters – List of SAIP (eqs 1 and 5) parameters for the interfacial Au-C and Au-H interactions.

| atoms | α  | β (Å) | γ (Å) | ϵ (meV) | C (meV) | d   | $s_R$ | $r_{eff}$ (Å) | $C_6$ (eV·Å$^6$) |
|-------|----|-------|-------|---------|---------|-----|------|---------------|-----------------|
| Au–C  | 13.56556 | 3.69133 | 1.01755 | 7.09648 | -1.03683 | 11.05865 | 1.06356 | 3.75526 | 81.58471 |

FIG. 4. Graphene on gold: PES – Sliding potential energy surfaces (PES) of the graphene/gold heterostructure, calculated at an interface separation of 3.5 Å. The upper, middle, and bottom rows are for trilayer, bilayer, and single layer gold, respectively. The left, center, and right columns present the PES calculated using DFT+D3, SAIP, and their difference, respectively. In the latter, the differences are magnified $\times 10$ to clearly present the fine features. For better visibility a 4×4 linear interpolation has been applied to all the PES maps. The minimum of the PES was shifted to zero for clarity.

IV. RESULTS AND DISCUSSION

The fitted parameters for Au-C and Au-H interactions are reported in Table I. We note that the negative sign in the $C$ parameter can be attributed to the fact that the atop position of an Au atom on graphene is energetically favorable with respect to the hollow position [18, 19], where the Au atom resides over the graphene hexagon center (see top panel of Figure 3). When applying this potential to describe the interfacial interaction in other 2D and bulk material interfaces, the parameter $C$ can be either positive or negative, depending on the sliding energetics [30, 37].

A. Graphene on Gold

Figure 3 shows the comparison between the AE curves of the Au(111)/graphene heterostructure with trilayer (Figure 3a), bilayer (Figure 3b) and single layer gold (Figure 3c) obtained using DFT+D3 (symbols) and the SAIP using the parameters provided in Table I (solid lines), calculated at different stacking modes. Good agreement between the DFT and SAIP is obtained es-
FIG. 5. Benzene on gold — (a) Adhesion energy curve, and (b) a zoom-in around its minimum, of a benzene molecule residing over a trilayer gold surface at the configuration depicted in Figure 2c and d. Symbols and lines represent DFT+D3 reference data and SAIP results, respectively. The corresponding sliding PESs calculated using (c) DFT+D3, (d) SAIP, and (e) their difference are obtained at a benzene-gold separation of 3.3 Å. For better visibility, isoenergetic contour lines are superposed on the PES maps, which were smoothened by a 8×8 linear interpolation. The minimum of the PES was shifted to zero for clarity.

especially in the tri- and bi-layer case, while for the single layer a larger discrepancy is found. Note that the DFT calculations show a similar AE regardless of the number of gold layers, while the SAIP predicts a reduced adhesion in the case of a single gold layer. We associate the former with the fact that decreasing the number of layers reduces the adhesive interactions, but at the same time the under coordinated Au surface becomes more chemically reactive. This is also related to the known increased atomic density of gold surfaces with respect to bulk [46–49]. Such compensation yields an almost unchanged AE value, just slightly reduced with respect to the 2-layers case. This change of reactivity is lacking in the present form of the SAIP. Here, the reduced adhesion obtained in the case of the gold monolayer is clearly due to the reduced number of Au-C interacting pairs, whereas the binding energies obtained for the 2- and 3-layer substrates are very similar being the third layer also dominated by vdW interactions.

As mentioned earlier, comparison with experiment is challenging due to the limited availability of measured AE values for the graphene/gold interface. Specifically, Torres et al. found an AE of $E_a = 7687.1 \text{ mJ/m}^2 = 48 \text{ eV/nm}^2$ in an experiment exploring graphene-covered gold nanoparticles [27], whereas Li et al. found a pull-off force of $\approx 0.23 \text{ nN/nm}^2 = 1.44 \text{ eV/nm}^2$ for gold-graphite interfaces [23]. Notably, in order to obtain the AE measure by Torres et al. this force (even if assumed to remain constant) has to be applied along a distance of $\approx 33 \text{ nm}$, way beyond the interlayer interaction range. This indicates a discrepancy between the two experimentally measured values. We note that our calculated AE of about $0.5 \text{ eV/cell} (375 \text{ mJ/m}^2)$ obtained for the trilayer gold/graphene interface model (Fig. 3a) is lower than that found by Torres et al. while the corresponding pull-off force of $2.04 \text{ nN/nm}^2$, evaluated from the first derivative of the SAIP AE curves, is larger than the experimental value of Li et al., suggesting that the SAIP provides values within the experimentally available range. A much better agreement is obtained between the SAIP predictions and previous computational results, such as the AE of 467 mJ/m$^2$ calculated by Tesch et al. for graphene nanoflakes on Au(111) [15], and 394 mJ/m$^2$ recently calculated for the Cu(111)/graphene interface [50] that is also dominated by vdW interactions.

The sliding PESs calculated using the SAIP parametrization show good agreement with the reference DFT+D3 data (see Figure 4), as well, with an error of 7.8%, 11%, and 10% for the PES corrugation of the trilayer, bilayer, and single layer gold, respectively, and corresponding average deviations of 0.010, 0.020, and 0.044 meV/cell, respectively. When comparing the AE of the different stacking modes considered (see Fig. 3a) one finds that the maximum difference is about 0.5 meV/cell. The latter value is related to the CE as shown in Fig. 4. We note that the CE is of the order of 0.075 meV per C-atom, indicating an exceptionally lubric contact [22]. We would like to note that we obtain CE and AE values
using energy differences of nearly identical systems, thus we expect a very high numerical accuracy. Furthermore, in the case of rigid contacts considered herein, such small CE ensues from the approximation employed to describe the lattice mismatch between gold and graphene. A truly incommensurate lattice mismatch, only obtainable in the thermodynamic limit of an infinite supercell size, would in fact yield a vanishing CE regardless of the potential parameters.

A LJ fitting of the DFT+D3 tri-layer gold/graphene PES resulted in $\epsilon = 14.86$ meV and $\sigma = 3.8$ Å, in agreement with previous semi-empirical LJ parameterizations used to reproduce experimental results of gold clusters diffusion on graphene [1, 6]. Notably, a LJ fitting of the AE curves results in substantially different values, $\epsilon = 8.50$ meV and $\sigma = 3.37$ Å, confirming that the isotropic LJ description is incapable of simultaneously describing the binding and sliding physics of vdW interfaces.

**B. Benzene on gold**

Going beyond the periodic interface, we next consider the case of a benzene molecule residing atop a gold surface. Figure 5 reports the AE curves (Figure 5a,b) and sliding PES (Figure 5c-e) of the benzene/Au(111) heterostructure obtained using DFT+D3 and the SAIP using the parameters provided in Table I. Good agreement between the DFT and SAIP results is found for both the AE curve and the sliding PES, with average deviations of 28.0 meV/cell ($\sim$4% of the AE) and 0.73 meV/cell ($\sim$1.4% of the CE) for the AE curve and the PES, respectively, and a deviation of 1.7% in the overall PES corrugation. The obtained AE value of 0.689 eV is in good agreement with a reference experimental value of $\sim$0.64 eV at finite temperature. [51]

The SAIP parameterization yields a smaller Au-H $C_6$ coefficient and a larger $d$ value than those of the corresponding Au-C parameters, suggesting a weaker and shorter-range dispersion term for the former. Furthermore, the Au-H anisotropic repulsive term (eq 5) is considerably weaker than the corresponding Au-C term. This results from the tenfold larger $\gamma$ parameter of the former (see Table I) that yields $e^{-(\rho_{ij}/\gamma)} \sim 1$ for any reasonable value of $\rho_{ij}$ in eq 5. Together with the fact that $\epsilon \approx 2|C|$ in the Au-H case (see Table I) the square brackets appearing in eq 5 are small in magnitude and quite insensitive to the value of the lateral interatomic distance. This indicates that the Au-H interaction has minor effect on the lateral shear motion and that most of the lateral forces originate from the Au-C interaction. Therefore, we expect that the present parametrization should hold for other planar benzenoid systems.

**C. $C_{60}$ on gold**

Finally, we challenge our developed SAIP against extremely bent graphitic systems. In this case, one might expect significant deviations of the interfacial energy profiles from the ideally flat graphene case discussed above. In particular, it is known that mechanical bending can alter the reactivity of graphene sheets [52], and introduce additional interfacial effects, such as curvature-induced structural lubricity [53]. Since the latter effects should mainly depend on the structural properties (geometry) of the adjacent surfaces, they should be captured by the SAIP with the parameterization presented in Table I. However, accounting for the different reaction energy of the curved graphene requires a full quantum-mechanical treatment, and thus a reparameterization of the SAIP for the curved system. To demonstrate this, we considered the case of a $C_{60}$ fullerene physisorbed over an Au(111) surface in two different orientations, marked as $\alpha$ and $\beta$, as depicted in Figure 6a-(d). By performing DFT+D3 calculations at different separations from the Au(111) surface we obtained the adhesion curves, reported in Figure 6e, showing adhesion energies of 1.2545 eV and 1.2373 eV for the $\alpha$ and $\beta$ configurations, respectively. On average, the $C_{60}$ AE is larger than that of benzene by about 80%, thus supporting the need to provide a separate parameterization for curved systems. This is in agreement with previous calculations indicating an increased reaction energy for NTs of smaller curvature radius [52].

The increased surface reactivity is manifested also in the equilibrium distance from the gold surface, which reduces from 3.48 Å for flat graphene to 2.6 and 2.8 Å for $C_{60}$ at the $\alpha$ and $\beta$ configurations, respectively (see Figure 6e). The simultaneous fitting of the two adhesion curves for $C_{60}$ produced a distinct set of SAIP parameters, reported in Table II. In comparison with the graphene/Au(111) interface, the larger $C_6$ and smaller $d$ parameters indicate a stronger and longer range vdW dispersion term. Nonetheless, the anisotropic term reduces significantly, mostly due to a $\epsilon \approx 2|C|$ balance (see discussion above), indicating that the Au-C interaction is weekly dependent on shear motion in this highly curved system and that the sliding energy surface corrugation is expected to be very small. Similar considerations could be made in the case of very small-diameter carbon nanotubes (CNTs) on gold, for which Table II could apply. However, the SAIP parameters should approach those of Table I as the CNT diameter increases. The possibility of including such parameter transition in a revised SAIP functional form capable of describing general CNT/gold assemblies [54] is presently under investigation.

**V. CONCLUSIONS**

The results presented above indicate that the proposed semi-anisotropic interface potential (SAIP) is able to accurately reproduce the energetics of graphene-gold,

benzene-gold, and C_{60}-gold interactions, as obtained from DFT+D3 calculations. While the functional form of the SAIP is suitable to treat many interfaces between graphitic systems and gold surfaces, system specific parametrizations of the SAIP are recommended in order to obtain optimal accuracy. However, the presented potential is expected to describe the structural and dynamical response to external forces of a large number of prototypical systems, such as gold nanoclusters on graphite [3, 4], graphene nanoribbons on Au(111) [7–9], and C_{60} on Au(111) [55, 56], among others, with much improved accuracy with respect to previous classical models. Furthermore, our formulation can be generalized to describe a wide variety of interfaces between hexagonal two-dimensional materials and bulk solids, such as MoS_{2}/Au [25], h-BN/Au [24, 26], or graphene/Ag [15]. This, in turn, will considerably increase the scope of material interfaces that can be treated using reliable dedicated classical force-fields.

ACKNOWLEDGMENTS

We acknowledge fruitful discussions with (in alphabetical order): Neil Drummond, Leeor Kronik, Ryo Mazzono, Kida Noriko, Alexandre Tkatchenko, and Keishu Utimula. W.O. acknowledges financial support from the starting-up fund of Wuhan University and the National Natural Science Foundation of China (nos. 11890673 and 11890674). O.H. is grateful for the generous financial support of the Israel Science Foundation under grant no.1586/17, Tel Aviv University Center for Nanoscience and Nanotechnology, and the Naomi Foundation for generous financial support via the 2017 Kadar Award. R.G. acknowledges financial support from Università degli Studi di Milano, grant no.1094 SEED 2020 - TEQUAD, support by the Italian Ministry of University and Research through PRIN UTFROM no. 20178PZCB5, and computational support from the Center for Complexity and Biosystems.

AUTHORS CONTRIBUTIONS

RG designed the research and performed the DFT calculations. WO fitted the parameters, coded the potential into LAMMPS, and performed the MD simulations. WO, OH, and RG participated in the force-field development, scientific discussions, and writing of the paper.
