Abstract

\textbf{Background/Aims:} The mechanisms involved in endothelial barrier dysfunction induced by hypoxia are incompletely understood. There is debate about the role of hypoxia-inducible factor-1α (HIF-1α) in endothelial barrier disruption. The aim of this study was to investigate the effect of genetic overexpression of HIF-1α on barrier function and the underlying mechanisms in hypoxic endothelial cells. \textbf{Methods:} The plasmid pcDNA3.1/V5-His-HIF-1α was stably transfected into human endothelial cells. The cells were exposed to normoxia or hypoxia. The mRNA and protein expressions of HIF-1α were detected by RT-PCR and Western blot respectively. The barrier function was assessed by measuring the transendothelial electrical resistance (TER). The Western blot analysis was used to determine the protein expression of glucose transporter-1 (GLUT-1), zonular occludens-1 (ZO-1), occludin, and myosin light chain kinase (MLCK) in endothelial cells. The mRNA expression of proinflammatory cytokines was detected by qRT-PCR. \textbf{Results:} Genetic overexpression of HIF-1α significantly increased the mRNA and protein expression of HIF-1α in endothelial cells. The overexpression of HIF-1α enhanced the hypoxia-induced increase of HIF-1α and GLUT-1 protein expression. HIF-1α overexpression not only exacerbated hypoxia-induced endothelial barrier dysfunction but also augmented hypoxia-induced up-regulation of MLCK protein expression. HIF-1α overexpression also enhanced IL-1β, IL-6 and TNF-α mRNA expression. \textbf{Conclusion:} We provide evidence that genetic overexpression of HIF-1α aggravates the hypoxia-induced endothelial barrier dysfunction via enhancing the up-regulation of MLCK protein expression caused by hypoxia, suggesting a potential role for HIF-1α in the pathogenesis of endothelial barrier dysfunction in hypoxia.
Introduction

The vascular endothelial barrier is a physiological barrier important for maintaining vascular homeostasis and regulating trafficking of macromolecules and blood cells across the vessel wall in the body [1]. Under normal conditions, the vascular endothelial barrier integrity is primarily maintained by tight junction complexes between adjacent endothelial cells, which selectively permit paracellular movement of molecules across the endothelial barrier [1-3]. Disruption of the endothelial barrier function often leads to serious pathophysiological consequences. For example, the increase of endothelial permeability may cause capillary leakage syndrome and tissue edema [4], which may impair the function of vital organs.

There are many stressors that lead to endothelial barrier dysfunction. Among these stressors disrupting the endothelial barrier integrity, hypoxia is the most frequently encountered stress. Hypoxia has been reported to impair the endothelial barrier function, resulting in increased endothelial permeability, and contributing to the development and progression of several diseases involving disrupted vascular homeostasis [5, 6]. Although previous studies have brought some valuable information on the endothelial barrier disruption caused by hypoxic insult [5, 7-9], the precise mechanisms underlying the hypoxia-induced endothelial barrier disruption remain largely unclear.

Hypoxia-inducible factor-1 (HIF-1) is a crucial regulator of the response to hypoxia in mammalian organisms. HIF-1 is a heterodimeric transcription factor consisting of two subunits, HIF-1α and HIF-1β. HIF-1β is constitutively expressed, whereas HIF-1α is the regulatory subunit that senses tissue oxygen level. The stability, DNA binding capability, and transcriptional activity of the HIF-1α are directly controlled by the intracellular oxygen concentration [10-14]. Although it is conclusive that the expression of HIF-1α is induced by hypoxia, ischemia, and inflammation, the role of HIF-1α in the regulation of endothelial barrier function is still controversial. Therefore, the aim of this study was to investigate the effects of genetic overexpression of HIF-1α on endothelial barrier function in response to hypoxic insult. The results demonstrated that genetic overexpression of HIF-1α exacerbated the hypoxia-induced barrier dysfunction by up-regulating myosin light chain kinase (MLCK) in endothelial cell monolayers.

Materials and Methods

Cell culture and monolayer

Endothelial cell line VE purchased from KeyGEN Technologies (Nanjing, Jiangsu, China) [15] was maintained at 37°C in a culture media composed of RPMI 1640 (Invitrogen, CA), 10% fetal bovine sera (Invitrogen), 100 U/ml penicillin, and 100 µg/ml streptomycin. Culture media were changed every 2 days. The cells were subcultured by partial digestion with 0.25% trypsin and 0.53 mM ethylenediamine-tetraacetic acid (EDTA) in Ca²⁺- and Mg²⁺-free PBS. To prepare monolayer, VE cells were seeded at 1.5×10⁵/cm² and grown as monolayers on 0.1% collagen-coated permeable polycarbonate membrane Transwell supports (Corning-Costar, MA) with 0.4 µm pores, and used for experiments after confluence.

Generation of cells stably overexpressing HIF-1α

Plasmid pcDNA3.1 vector was purchased from Invitrogen. Plasmid pcDNA3.1/V5-His-HIF-1α containing full length of human HIF-1α cDNA was described previously [16], and kindly provided by Dr. Richard K. Bruick at University of Texas Southwestern Medical Center. For stable transfection, VE cells grown on culture dish were transfected with pcDNA3.1 or pcDNA3.1/V5-His-HIF-1α by Lipofectamine 2000 (Invitrogen). The neomycin-resistant clones were selected in media containing 500 µg/ml G418 (Merck, Germany), and transferred into 24-well culture plate with cloning discs (Sigma, MO). The selected clones were expanded in media containing 200 µg/ml G418, and identified by detecting both mRNA and protein expressions of HIF-1α.
Wang et al.: HIF-1α Overexpression Exacerbates Endothelial Barrier Dysfunction in Hypoxia

**Treatment of cells with dimethyloxaloyl glycine (DMOG) or hypoxia**

To induce HIF-1α protein accumulation under normoxic condition, cells were treated with or without 1 mmol/L DMOG (Cayman Chemical, USA) for 12 hours in normoxia. For hypoxia treatment, cells were cultured under hypoxic condition for indicated hours. Briefly, cells were put into a sealed modular incubator chamber (Billups-Rothenberg, CA) purged with 1% O₂, 5% CO₂, and 94% N₂, and then the chamber was maintained at 37°C. Control cells were cultured under normoxic condition.

**RNA isolation and RT-PCR analysis**

Cells were washed with ice-cold PBS, and lysed in Trizol (Invitrogen) for total RNA isolation. Cell lysates in TRIzol were sonicated using a sonicator (Tomy Seiko, Tokyo, Japan), and total RNA was extracted with chloroform, precipitated with isopropyl alcohol, and resuspended in diethyl pyrocarbonate (DEPC)-treated water. cDNA was generated from total RNA using reverse transcriptase and random hexamer primers included in Thermoscript RT-PCR System (Invitrogen). The reaction was performed in thermocycler (Bio-Rad, CA) at 25°C for 10 min, 50°C for 45 min, and 85°C for 5 min. PCR reaction was performed using Thermoscript RT-PCR System according to the PCR protocol (94°C for 5 min, and 35 cycles of 94°C for 45s, 50°C for 30s, 72°C for 45s, and 72°C for 10 min). Primers were 5'-TAA TGT GAG TTC GCA TCT TG-3' and 5' -CAG GTC ATA GGT GGT TTC TT-3' for detection of HIF-1α, and 5'-TCA ACG GAT TTG GTC GTC GTA TTG-3' and 5'-TGG AAG ATG GTG ATG GGA TT-3' for detection of GAPDH. The PCR products were electrophoresed on 1% agarose gels and imaging was performed with the ChemiDoc XRS System (Bio-Rad). Images were analyzed using the Quantity One software (Bio-Rad).

**Western blot analysis**

Cells were rinsed with ice-cold PBS, lysed in sodium dodecyl sulfate-poly-acrylamide gel electrophoresis (SDS-PAGE) sample buffer containing 50mM Tris-HCl, 2% SDS, 0.1% bromophenol blue, 5% ß-mercaptoethanol, 10% glycercine. After a brief sonication using a sonicator (Tomy Seiko, Tokyo, Japan), cell lysates were centrifuged at 12,000 rpm for 20min at 4°C. The supernatants were harvested to detect protein concentrations by RC DC kit (Bio-Rad). The proteins in supernatants were separated by SDS-PAGE and subsequently transferred to a polyvinylidene difluoride (PVDF) membrane (Millipore, MA). The membranes were blocked with 5% non-fat milk for 1 hour at room temperature, and then incubated with primary antibodies specific for HIF-1α (1:1000, Millipore), glucose transporter-1 (GLUT-1) (1:1000, Santa Cruz, CA), zonular occludens-1 (ZO-1) (1:1000, Invitrogen), occludin (1:1000, Invitrogen), MLCK (1:1000, Sigma), and ß-actin (1:5000, Sigma) overnight at 4°C, followed by incubation with horseradish peroxidase-conjugated secondary antibodies (Southern Biotech, Birmingham, AL) for 1 hour at room temperature. After thorough washing, the blots were visualized using Supersignal West Pico Chemiluminescent Kit (Pierce, IL), and imaged using the ChemiDoc XRS System (Bio-Rad). Band densities were quantified using Quantity One software from Bio-Rad.

**Measurement of transendothelial electrical resistance**

Transendothelial electrical resistance (TER) of VE monolayers grown on Transwell supports with 6.5 mm diameter was determined using a Millicell-ERS voltohmmeter (Millipore) as we described previously [17]. TER was calculated by subtracting the resistance value of the filters and fluids, and normalized to initial value.

**Quantitative RT-PCR analysis of proinflammatory cytokines**

Total RNA was extracted from cells using TRIzol reagents (Invitrogen). cDNA was generated from total RNA using First-Strand cDNA Synthesis Kit (OriGene Technologies, Rockville, MD). Quantitative real-time PCR was performed by qSTAR SYBR Master Mix-Low Rox Kit (OriGene Technologies) using the ABI 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, CA). Analysis was performed according to the manufacturer’s protocol. The gene expression of proinflammatory cytokines including IL-1β, IL-6 and TNF-α was quantified relative to the expression of GAPDH. The primers used in this study were as follows: IL-1β; (Sense) 5'-CCA CAG ACC TTC CAG GAG AAT G-3', (Antisense) 5' -GTG CAG TTC AGT GAT CGT ACA G-3', IL-6; (Sense) 5'-GCC CAG CTA TGA ACT CCT TCT G-3', (Antisense) 5'-GAA GGC AGC AGG CAA CAC-3', TNF-α; (Sense) 5'-CGA GTG ACA AGC CTG TAG C-3', (Antisense) 5'-GTT GTG GGT GGT GAG CAC AT-3', GAPDH; (Sense) 5'-AAG AAG GTC GGA GTC AA-3', (Antisense) 5'-AAT GAA GGG GTC ATT GAT GG-3'.
Statistical analysis

Results are presented as the means ± SEM. The statistical significance of differences among groups was assessed with One-way ANOVA by SPSS 13.0. Differences between two groups were determined by the Student’s t test. * p<0.05, compared with VE control. #, p<0.05, compared with control transfectants treated with DMOG.

Results

Identification of cells overexpressing HIF-1α

To generate endothelial cells overexpressing HIF-1α, the mammalian expression vector pcDNA3.1/V5-His-HIF-1α containing the full length of human HIF-1α cDNA was stably transfected into VE cells, and neomycin resistant clones were selected and expanded. We first examined the HIF-1α mRNA by RT-PCR analysis. No difference in HIF-1α mRNA expression was seen between non-transfected VE cells and transfection control VE cells transfected with empty vector pcDNA3.1 (data not shown). However, as illustrated in Fig. 1A and B, transfection of VE cells with pcDNA3.1/V5-His-HIF-1α encoding human HIF-1α clearly demonstrated that HIF-1α mRNA expression was significantly enhanced in selected cells.

We next assessed HIF-1α protein expression in these stable transfectants overexpressing human HIF-1α gene. As shown in Fig. 1C and D, without DMOG treatment, there was no significant difference in HIF-1α protein expression between non-transfected VE cells and HIF-1α transfectants. After treatment with DMOG in normoxia for 12 hours, HIF-1α protein...
expression in both non-transfected VE cells and HIF-1α transfectants increased significantly. In addition, HIF-1α protein expression in HIF-1α transfectants treated with DMOG for 12 hours was significantly higher than that in non-transfected VE cells treated with DMOG for 12 hours. Collectively, these data demonstrate that both mRNA and protein expressions of HIF-1α are enhanced in endothelial cells stably transfected with human HIF-1α gene.
HIF-1α overexpression enhances hypoxia-induced HIF-1 activation

We have previously demonstrated that HIF-1α is activated by hypoxia in VE endothelial cells [15]. Thus, in a set of experiments we explored the possibility that HIF-1α overexpression might enhance the hypoxia-induced HIF-1α activation in VE cells. As illustrated in Fig. 2A, the expression of HIF-1α protein was significantly increased in control VE cells exposed to hypoxia as compared with control VE cells exposed to normoxia, which is consistent with our previous study [15]. However, the expression of HIF-1α protein in VE cells transfected with pcDNA3.1/V5-His-HIF-1α was significantly higher than that in control VE cells exposed to normoxia or hypoxia. Similarly, as shown in Fig. 2B, the protein expression of GLUT-1, an HIF-1 target gene, was also significantly increased in hypoxic VE cells. In addition, the expression of GLUT-1 protein in VE cells transfected with pcDNA3.1/V5-His-HIF-1α was significantly higher than that in control VE cells exposed to normoxia or hypoxia. These suggest that the transcriptional activity of HIF-1 in VE cells exposed to hypoxia is enhanced by the transfection with pcDNA3.1/V5-His-HIF-1α. Taken these results together, constitutively stable overexpression of HIF-1α enhances HIF-1α activation induced by hypoxia in endothelial cells.

HIF-1α overexpression exacerbates hypoxia-induced endothelial barrier dysfunction

Previous studies have demonstrated that hypoxia causes barrier dysfunction such as increased paracellular permeability and decreased TER in vascular endothelial cells both in vivo and in vitro. We have previously shown that HIF-1α is involved in endothelial barrier dysfunction induced by hypoxia [15]. Thus, we investigated the effect of HIF-1α overexpression on TER, a very sensitive indicator of endothelial barrier function. As shown in Fig. 3A, the TER of hypoxic VE monolayers was significantly lower than that of normoxic VE monolayers, and higher than that of hypoxic VE monolayers stably transfected with HIF-1α gene. This indicates that constitutively stable overexpression of HIF-1α enhances HIF-1α activation induced by hypoxia.

It has been reported that alteration of TJ protein expression plays an important role in endothelial barrier disruption induced by hypoxia [18, 19]. Therefore, to determine whether the augmentation of hypoxia-induced endothelial barrier dysfunction by HIF-1α overexpression is accompanied by the changed expression of TJ proteins, we analyzed the expression of TJ proteins ZO-1 and occludin by immunoblot assay. As illustrated in Fig. 3B, as compared with normoxia, hypoxia did not cause a significant change in the protein expression of both ZO-1 and occludin. Similarly, HIF-1α overexpression also did not remarkably change the protein expression of ZO-1 and occludin. This is in agreement with the previous study revealing that hypoxia alone has little effect on the expression of TJ proteins including claudin-1, occludin, ZO-1, and ZO-2 while it causes barrier disruption in microvascular endothelial cells [20].
HIF-1α overexpression augments hypoxia-induced up-regulation of MLCK protein expression

MLCK, a predominant determinant of MLC phosphorylation, has well been reported to be critical to the disruption of barrier function in both vascular endothelia and intestinal epithelia [15, 21-24]. We, along with other investigators, have demonstrated that up-regulation of MLCK protein expression plays an essential role in mediating epithelial or endothelial barrier dysfunction caused by a myriad of conditions such as inflammation, hypoxia and burn injury [15, 21-29]. Thus, we considered the possibility that up-regulation of MLCK protein expression is involved in the aggravation of hypoxia-induced endothelial barrier dysfunction caused by HIF-1α overexpression. As revealed in Fig. 4, the expression of MLCK protein in VE cells was significantly increased by hypoxia treatment. The hypoxia-induced increase of MLCK protein expression was markedly augmented by overexpressing HIF-1α in VE cells. This is consistent with our previous findings that the hypoxia-induced up-regulation of MLCK protein expression in endothelial is inhibited by genetic knockdown of HIF-1α [15], and that the cytokine-induced increase of MLCK protein in intestinal epithelial cells is suppressed by chemical inhibitors of HIF-1α [25, 26].

A number of proinflammatory cytokines such as IFN-γ, TNF-α and IL-1β have been shown to induce barrier dysfunction via MLCK [17, 21-26, 28, 29]. Thus, we finally analyzed the mRNA expression of IL-1β, IL-6 and TNF-α to determine if proinflammatory cytokines are associated with the enhancement of MLCK up-regulation. As shown in Fig. 5, hypoxic treatment of VE cells for 6 hours decreased IL-1β mRNA expression, increased IL-6 mRNA expression, but did not affect TNF-α mRNA expression, as compared with normoxia. However, the mRNA expression of IL-1β, IL-6 and TNF-α in hypoxic VE cells overexpressing HIF-1α was significantly higher than that in normoxic or hypoxic VE cells. This indicates that HIF-1α overexpression enhances the expression of proinflammatory cytokines IL-1β, IL-6 and TNF-α in hypoxic condition.
Discussion

In this study we evaluated the effects of overexpression of HIF-1α on barrier function in endothelial cell monolayers exposed to hypoxic insult. The present study reveals two novel findings. First, we show that overexpression of HIF-1α exacerbates the endothelial barrier dysfunction induced by hypoxia in vitro. Second, we demonstrate that HIF-1α overexpression augments the hypoxia-induced up-regulation of MLCK protein expression in endothelial cell monolayers. Thus, it is suggested that HIF-1α may play a critical role in the regulation of endothelial barrier function in response to hypoxic challenge.

HIF is a member of the Per-ARNT-Sim family of basic helix-loop-helix transcription factors that bind specifically to hypoxia response elements at target genes under hypoxia [14]. HIF-1α, the inducible subunit of HIF-1, heterodimerizes HIF-1β, the constitutive subunit of HIF-1, forming the functional nuclear transcription factor HIF-1. Over the past two decades HIF-1 has been viewed as a master transcription factor in regulating the hypoxic responses. In addition to hypoxic stress, a variety of factors have been shown to be able to elicit HIF-1 activity even under normoxic conditions. Upon activation, HIF-1α regulates a wide range of genes involved in many cellular processes such as angiogenesis, glycolytic energy metabolism, oxygen delivery, cell proliferation, and survival, which collectively lead to the adaptive response of cells and tissues [10-14]. Previous reports have shown that the expression of HIF-1α protein is remarkably increased in endothelial cells exposed to hypoxia [15, 30, 31]. In accordance with the data from these previous studies, our present study demonstrates that hypoxia treatment induced a significantly increased protein expression of HIF-1α and GLUT-1, an HIF-1 target gene. In addition, genetically constitutive overexpression of HIF-1α enhanced the protein expression of both HIF-1α and GLUT-1 in endothelial cells exposed to hypoxia. This suggests that HIF-1α overexpression enhances HIF-1 activation induced by hypoxia in endothelial cells.

The activation of HIF-1 is currently believed to play both a beneficial as well as detrimental role in ischemic or hypoxic insult, which may depend on the severity of ischemia/hypoxia and the specific cell types [32]. Thus, although it is conclusive that ischemia/hypoxia induces the expression of HIF-1α, the role of HIF-1α in the regulation of barrier function is still controversial. On the one hand, several previous studies have demonstrated that HIF-1α is protective to endothelial or epithelial barrier function under some pathophysiological conditions such as hypoxia or inflammation [33-37]. On the other hand, growing evidence demonstrates that HIF-1α is deleterious to endothelial or epithelial barrier function during hypoxic, ischemic or inflammatory insult [15, 25, 26, 38-41]. Chemical inhibition of HIF-1α by HIF-1α inhibitors such as YC-1, 2-methoxyestradiol and oligomycin attenuates the endothelial or epithelial barrier dysfunction induced by hypoxia, ischemia or proinflammatory cytokines. In addition, more interesting is the fact that up-regulation of HIF-1α expression by cobalt chloride, an HIF-1α inducer, is able to cause endothelial barrier disruption even in normoxia in vitro, as evidenced by the increased paracellular permeability of endothelial cell monolayers treated with cobalt chloride [38, 42]. Furthermore, an in vivo study has revealed that the endothelial barrier disruption and brain edema induced by hypoxic-ischemic injury are exacerbated by up-regulating HIF-1α expression with DMOG, an HIF-1α inducer [43]. Here in this study, we show that hypoxia causes endothelial barrier dysfunction, and that genetic overexpression of HIF-1α exacerbates the hypoxia-induced endothelial barrier dysfunction in vitro. This coincides with previous report demonstrating that chemical up-regulation of HIF-1α augments endothelial barrier disruption caused by hypoxia-ischemia [43]. The results from our present study taken together with previous studies by other investigators suggest that HIF-1α overexpression is deleterious to endothelial barrier function in ischemia or hypoxia, and that HIF-1α inhibition might be a therapeutic strategy for endothelial barrier dysfunction induced by ischemic or hypoxic injury.

The endothelial barrier function is primarily regulated by intercellular tight junction, which is mainly composed of cytoplasmic proteins, including ZO proteins, and two distinct transmembrane proteins, occludin and claudin [1-3]. Theoretically, the expression alteration
of the tight junction proteins may lead to endothelial barrier dysfunction. However, conflicting reports have raised debates on the exact role of altered tight junction protein expression in endothelial barrier dysfunction caused by hypoxia. For instance, previous studies have shown that the reduced expression of ZO-1 and claudin-5 is involved in endothelial barrier disruption caused by hypoxia [18, 19]. On the contrary, increase of occludin expression has been reported to be associated with the hypoxia-induced endothelial barrier dysfunction [44]. In our present study, we demonstrate that neither hypoxia nor HIF-1α overexpression causes a significant change in the protein expression of both ZO-1 and occludin while they jeopardize barrier function in endothelial cell monolayers. This is largely coincident with an earlier report that although hypoxia significantly impairs barrier function in microvascular endothelial cells, it does not affect the protein expression of ZO-1, ZO-2, occludin, and claudin-1 [20]. Similarly, it has been demonstrated that hypoxia does not change the mRNA expression of ZO-1, ZO-2, and occludin, whereas it causes barrier dysfunction in brain endothelial cells [45]. Therefore, further studies are needed to assess the effect of hypoxia on the expression of tight junction protein, as well as the exact role of altered tight junction protein expression in endothelial barrier dysfunction induced by hypoxia.

The mechanisms by which HIF-1α impairs endothelial barrier function are undoubtedly complex. Previous studies have demonstrated that HIF-1α is involved in barrier dysfunction by inducing the expression of HIF-1 target genes such as vascular endothelial growth factor, inducible nitric oxide synthase [38, 40, 46], aquaporin-4, matrix metalloproteinase-9 [39], macrophage migration inhibitory factor [47], as well as by repressing the expression of vasodilator-stimulated phosphoprotein [48]. However, the activation of MLCK, which in turn leads to an increase of MLC phosphorylation, has been reported to play a critical role in endothelial and intestinal barrier dysfunction induced by hypoxia or inflammation [21-24, 28, 29, 31, 49]. In addition, our previous studies have revealed that HIF-1α-dependent up-regulation of MLCK protein is involved in barrier dysfunction induced by hypoxia or proinflammatory cytokines [15, 25, 26]. Therefore, in this study we investigate the effect of HIF-1α overexpression on the expression of MLCK protein in endothelial cell monolayers exposed to hypoxia. The results show that hypoxia up-regulates the expression of MLCK protein, whereas genetic overexpression of HIF-1α enhances the hypoxia-induced up-regulation of MLCK protein. It is suggested that the mechanism by which HIF-1α overexpression exacerbates endothelial barrier dysfunction induced by hypoxia may, at least in part, be attributed to the enhanced up-regulation of MLCK protein expression.

We, along with other investigators, have previously demonstrated that some proinflammatory cytokines such as IFN-γ, TNF-α, IL-1β, IL-6 and TNF superfamily member LIGHT induce barrier disruption by activating MLCK-MLC phosphorylation signaling pathway [17, 21-26, 28, 29, 50]. Thus, in present study we look into the effect of HIF-1α overexpression on the expression of IL-1β, IL-6 and TNF-α to find out whether proinflammatory cytokines are associated with HIF-1α-mediated barrier dysfunction in endothelial cells. Our results demonstrate that HIF-1α overexpression enhances the expression of proinflammatory cytokines in hypoxia, which is coincident with the previous studies showing that HIF-1α induces the up-regulation of proinflammatory cytokines in hypoxia or ischemia [46, 51, 52]. For example, in vivo studies have revealed that partial HIF-1α deficiency reduces TNF-α, IL-1β and IL-6 mRNA levels in mice subjected to ischemia-reperfusion injury. Therefore, proinflammatory cytokines might be involved in the exacerbation of hypoxia-induced endothelial barrier dysfunction by HIF-1α overexpression.

In summary, our findings demonstrate that HIF-1α overexpression in endothelial cell monolayers aggravates the hypoxia-induced barrier dysfunction via enhancing the up-regulation of MLCK protein expression induced by hypoxia, suggesting a potential role for HIF-1α in the pathogenesis of endothelial barrier dysfunction in hypoxia.
