INTRODUCTION

COVID-19 has affected more than 222 million people and has caused more than 4.5 million deaths worldwide [1]. Although most patients with COVID-19 develop mild symptoms or are asymptomatic, the effects can be much worse, especially in people with chronic diseases, such as patients with diabetes [2]. Diabetes mellitus (DM) is a leading cause of morbidity and mortality worldwide [3]. The estimated global prevalence of diabetes in 2019 was 9.3% (463 million people), which was estimated to increase to 10.2% (578 million) by 2030 and 10.9% (700 million) by 2045 [4]. In Latin America alone, in 2019, 31.6 million people were diagnosed with some type of diabetes; this figure could increase to 40.2 million by 2030 and 49.1 million by 2045 [4]. Among Latin American countries, Cuba has a prevalence of 66.9 patients with DM per 1000 population [5].

It has been estimated that the prevalence of DM in patients with COVID-19 varies around 0.15% to 28.98% [6]. Previous studies indicate that diabetes is an independent risk factor predicting severity of COVID-19, increased admissions to intensive care units and increased mortality in patients with COVID-19 [7,8]. It has been observed that 1.5% of in-hospital deaths related to COVID-19 occurred in patients with type 1 DM.
and 31.4% in patients with type 2 DM; also, a mortality rate of 138 patients with type 1 DM per 100,000 people was observed [9]. Another study indicates that diabetic patients have almost four times the risk of severe disease and death from COVID-19 [10].

Additionally, people with diabetes present different psychosocial problems, which have been aggravated by the psychological stressors of the COVID-19 pandemic, social distancing and confinement [11]. During the current pandemic, it has been reported that 43% of diabetic patients had psychological distress, 75.8% had eating disorders, and 77.5% had moderate and/or severe sleep disorders [12]. Additionally, 28% of diabetic patients had generalized anxiety disorder [13], while, 34.1% and 27.3% reported stress and high anxiety respectively [14]. However, it has been estimated that approximately 45% of cases of mental health problems and psychological distress in people with diabetes go undetected [15]. Furthermore, people with diabetes are more concerned about becoming infected with COVID-19 than people without diabetes [16]. A study of people with diabetes in South and Central America indicated that the main fears of respondents were "being infected and not getting proper treatment" and/or "getting infected if you go to the hospital or doctor’s appointments" [17]. Worry or concern is one of the most common and important psychological responses during the COVID-19 pandemic and is associated with the practice of protective behaviors against the disease [18,19]. In this sense, a higher level of concern is associated with a higher perceived threat of COVID-19 and a greater engagement in performing self-protective behaviors [20].

The above information suggests that a proper understanding of the factors associated with the mental health of patients with diabetes in the midst of the COVID-19 pandemic is highly important. Previous studies have reported the presence of different sociodemographic and health variables associated with the mental health status of the general population during the pandemic [21,22]. In the case of patients with diabetes, sociodemographic variables such as being female, a student, a single person, and reporting low income have been associated with a higher likelihood of reporting mental health problems [23]. It has been suggested that, in patients with diabetes, women were approximately 2 times more fearful of COVID-19 compared to men [24]. Regarding age, some suggest that it has no significant association with fear of COVID-19 in patients with diabetes [24]. However, others point out that older people, compared to younger people, have a statistically significant decrease in quality of life [25]. In relation to worry, women reported being more concerned about being severely affected by COVID-19 due to diabetes [26]. Also, people with medical complications associated with diabetes had a greater concern about being affected by COVID-19 compared to people without such complications [26].

Despite the above information, the association of different factors, such as age, gender, and DM-associated illnesses with the presence of significant levels of mental health concerns, including concern about COVID-19 transmission, has not been uniformly addressed. While it has been noted that there are no unified theoretical models that explain emotional reactions during pandemics [27], COVID-19 may affect individuals differently based on some sociodemographic and health factors. In this sense, the present study aimed to determine the sociodemographic and health factors associated with concern about COVID-19 infection in Cuban patients with DM. It is important to know and understand the factors associated with concern related to the disease, specifically, the concern for COVID-19 contagion, since this can serve as a basis for the formulation of public health policies that implement intervention strategies in health emergency situations, such as the current pandemic.

**METHODS**

**Participants**

A total of 203 patients with type 2 diabetes mellitus who attended nine primary care areas in four Cuban provinces belonging to different regions of the country (Pinar del Río, La Habana, Ciego de Ávila and Santiago de Cuba) participated in the study. Participants were selected by non-probabilistic sampling based on the following inclusion criteria:

1. have a diagnosis of type 2 DM according to the World Health Organization criteria,
2. be older than 18 years old,
3. be patients of the health care areas mentioned above, and
4. be willing to participate in the study and to sign the informed consent form.

Patients with mental illness, cognitive deficit (dementia, psychosis or mental disability) or other apparent condition that prevents understanding and completion of the questionnaire were excluded. Although retrospective data on infection rates in diabetic patients suggest that people with type 1 DM are at higher risk for infectious diseases in general, and death rates are similar to those of people with type 2 DM [28], this study focused on the latter for two main reasons. First, patients with type 1 DM are mostly children and young people and the prevalence of this type of diabetes is lower compared to type 2 DM [29], which leads to a lower number of patients seen in consultation and primary health care. Second, the study was conducted in the context of the COVID-19 pandemic and patients with type 2 DM were the most accessible population to be surveyed by the research team in primary care areas.

The minimum sample size was calculated with the Soper software package [30] for a multiple regression study, according to the desired probability level (a=0.05), the number of predictors in the model (18 predictors), the anticipated effect size (F=0.15) and the desired statistical power level (1-β=0.80). The software suggested a minimum number of 118 participants; however, the final number was higher than the minimum required.

**Instruments**

**Socio-demographic and health information**

A questionnaire was developed specifically for this study, where participants were asked to provide information about their sex, age, educational level, type of work, cohabitation, marital status, presence of chronic complications, presence of comorbidities, family or friends infected with COVID-19, and time since diagnosis with DM.
Concern about COVID-19 contagion

We used the COVID-19 contagion concern scale (PRE-COVID-19) originally developed for the general population [31], which assesses worry about becoming infected with COVID-19 and its impact on people’s mood and ability to perform daily activities. In this study we used the version validated for Cuban patients with diabetes [32], which consists of 5 items. All items have 4 Likert-type response options, ranging from 1=never or rarely to 4=almost all the time. The PRE-COVID-19 has a unidimensional structure, where the total score is calculated by adding the scores of each of the 5 items. Higher scores indicate greater concern about becoming infected with COVID-19. The reliability of the PRE-COVID-19 for this study was very good (\(\omega=0.91\)).

Blood glucose level

Fasting blood glucose values were obtained from the patients’ clinical histories and from blood tests performed in the last three months in laboratories equipped for this purpose. Based on this, poor glycemict control was determined as fasting blood glucose greater than or equal to 7 mmol/L (126 mg/dl) in the last three months and good control as figures below this value.

The criterion based on glycosylated hemoglobin (HbA1c) could not be used because it is not a test regularly available in the primary health care system where the survey was applied. Other control criteria using continuous glucose monitoring systems were not possible either, as they are not generally available for patients with DM living in Cuba.

Procedure

The questionnaire was applied by properly trained researchers, who complied with strict COVID-19 prevention health protocols, between the months of January and April 2021. The questionnaire was administered during patients’ visits to primary care centers or in their homes. During this period of time, the fight against COVID-19 in Cuba suffered some setbacks, characterized by an increase in the number of infected people, even higher than that observed during the first stage of the disease, in 2020. Thus, during those dates, more than 64,414 positive diagnoses and 384 deaths were reported in the country.

Participation was voluntary and without any financial compensation. Participants signed the informed consent form and were informed that they could withdraw from the study at any time. Similarly, the reliability of the data was guaranteed. The study protocol was approved by the Ethics Committee of the Universidad Privada del Norte in Peru (registration number: 20213002).

Data Analysis

The frequencies and percentages of the categorical variables included in the model were examined. In the case of the outcome variable (concern about COVID-19 contagion), the mean±standard deviation (SD) was calculated for the total sample. These values were then also calculated for each category of each variable. For inferential purposes, bivariate associations were examined with a series of analyses of variance (ANOVA). The assumption of homoscedasticity was reasonably well met in most cases; however, a possible non-compliance with the assumption of normality of the residuals was observed. Therefore, we repeated the analyses after a power transformation of the outcome variable. Since the results were practically identical with both procedures, only those obtained with the variable in its original form are reported.

Variables that reached statistical significance (\(p<.05\)) in the ANOVAs were selected as potential predictors in a linear regression. Crude (simple) regressions were run, which replicated the ANOVAs but also allowed for a more detailed examination of between-group differences. Finally, a fitted (multiple) regression was run with all predictors simultaneously. Statistical significance was judged from the 95% CIs, which provide a set of possible values of the coefficient in the population. A CI that does not include zero is equivalent to a p<.05 [33].

RESULTS

Table 1 presents the general information of the study sample. As can be seen, the sample was mostly female (65.52%); in addition, the highest percentage was over 70 years old (30.05%) followed by people between 40 and 59 years old (28.57%).

Table 2. Participants by sociodemographic characteristics and the number of infected. For that purpose, it was also considered the age, sex, education level, occupation, having comorbidities, having a family member or friend who had COVID-19, and the difficulty in obtaining the necessary care.

| Sociodemographic Characteristics | Number of Participants |
|---------------------------------|------------------------|
| Age                             | Number of Participants |
| Gender                          | Number of Participants |
| Education level                 | Number of Participants |

Concern about contagion was a particularly relevant psychological aspect in a pandemic context, as it is associated with social reactions and behavioral changes [35]. Therefore, the present study sought to determine some sociodemographic and health factors associated with worry about COVID-19 infection in Cuban patients with DM.

DISCUSSION

People with DM are at increased risk of developing a severe case of COVID-19 [32] and suffer different psychosocial problems that are aggravated by pandemic stressors [34]. Concern about contagion is a particularly relevant psychological aspect in a pandemic context, as it is associated with social reactions and behavioral changes [35]. Therefore, the present study sought to determine some sociodemographic and health factors associated with worry about COVID-19 infection in Cuban patients with DM.

The results indicated that men were more concerned about the spread of COVID-19. This is at odds with some of the literature, where women with diabetes have higher levels of concern about contagion and general mental health problems [24,26]. A possible explanation for this result lies in the fact that men are at much higher risk of dying from COVID-19 than women, even after adjusting for differences in age or comorbidities [36].
### Table 1. General information on the sample and association of the variables with concern about COVID-19 infection

| Variable                                      | n   | %   | Concern about infection (M=2.79, SD=0.85) |
|-----------------------------------------------|-----|-----|------------------------------------------|
| Age                                           |     |     | M  | SD  | F  | p   | ω²  |
| <40                                           | 42  | 20.69 | 3.38 | 0.48 | 10.84 | <.001 | .13 |
| 40-59                                         | 58  | 28.57 | 2.79 | 0.84 |     |     |     |
| 60-69                                         | 42  | 20.69 | 2.46 | 0.92 |     |     |     |
| ≥70                                           | 61  | 30.05 | 2.63 | 0.83 |     |     |     |
| Sex                                           |     |     |    |     |    |     |     |
| Woman                                         | 133 | 65.52 | 2.70 | 0.87 | 4.72 | .031 | .02 |
| Man                                           | 70  | 34.48 | 2.97 | 0.80 |     |     |     |
| Education level                               |     |     |    |     |    |     |     |
| Secondary school or less                      | 35  | 17.24 | 2.57 | 0.76 | 8.01 | <.001 | .09 |
| Pre-university                                | 60  | 29.56 | 2.93 | 0.93 |     |     |     |
| Technical/Trade school                        | 37  | 18.23 | 3.27 | 0.61 |     |     |     |
| University                                    | 71  | 34.98 | 2.54 | 0.82 |     |     |     |
| Occupation                                    |     |     |    |     |    |     |     |
| State worker                                  | 67  | 33.00 | 2.95 | 0.80 |     |     |     |
| Self-employed                                 | 37  | 18.23 | 3.03 | 0.80 |     |     |     |
| Unemployed/student/homemaker                 | 27  | 13.30 | 2.80 | 0.84 |     |     |     |
| Retired/pensioned                             | 72  | 35.47 | 2.53 | 0.88 |     |     |     |
| Lives alone                                   |     |     |    |     |    |     |     |
| No                                            | 158 | 77.83 | 2.76 | 0.85 | 1.18 | .279 | .00 |
| Yes                                           | 45  | 22.17 | 2.92 | 0.84 |     |     |     |
| Time since diagnosis with DM                  |     |     |    |     |    |     |     |
| <5 years                                      | 44  | 21.67 | 2.95 | 0.85 | 0.99 | .374 | .00 |
| 5 to 10 years                                 | 61  | 30.05 | 2.78 | 0.84 |     |     |     |
| >10 years                                     | 98  | 48.28 | 2.73 | 0.86 |     |     |     |
| Chronic complications                         |     |     |    |     |    |     |     |
| No                                            | 146 | 71.92 | 2.73 | 0.88 | 2.83 | .094 | .00 |
| Yes                                           | 57  | 28.08 | 2.95 | 0.75 |     |     |     |

Increased risk for a severe disease case would likely generate increased fear related to COVID-19 as a functional concern [37]. This is understandable, as people are concerned about their health and do not want to be infected with a virus that has a relatively high risk of death [38]. However, the vast majority of men in Latin American cultures like Cuba’s have been socialized to cover up their fear, so it is important to understand how hiding fear affects men’s response to COVID-19. In this regard, it is also valuable to know whether the gender differences observed in this study are a product of concern about COVID-19 contagion, or are reflective of gender differences that arise independently of the problem.

Age is also a predictor of concern about contagion. In particular, a decrease in concern is observed with increasing age. This suggests that as people advance in age, they may be able to cope with the uncertain situation posed by the COVID-19 pandemic, unlike younger people who are worried about their future as well [39]. From the theory of socioemotional selectivity, differences in well-being according to age are generated by a change in the perspective of time throughout adulthood, where older people maximize positive experiences and avoid negative experiences [40]. In this sense, older people would be better able to regulate their emotions and cope with the stress of the pandemic [41].

Additionally, patients with diabetes and a technical level of education were significantly more concerned about the spread of COVID-19. Technical education in Cuba aims to provide initial and ongoing training for the skilled middle-level workforce, which will enable them to go on to university studies. Although, to our knowledge there are no similar findings in patients with diabetes or the general population, the literature suggests that people with better education are less concerned about COVID-19 infection [42]. This may reflect how different occupations are associated with different levels of prestige and access to resources or benefits that may be helpful in coping with stress or fear of COVID-19 and being less worried during a pandemic [43].

The presence of comorbidities in patients with DM also predicts a greater concern for contagion. The presence of comorbidities such as hypertension or cardiovascular disease in the majority of those people with diabetes who die from COVID-19 [44] may be associated with an increased risk of disease severity and fear [37]. The risk of health complications associated with diabetes may increase during a pandemic due to lower levels of control for the disease, which requires increased attention [45]. In addition, this risk may increase due to poor access to medications, syringes, medical consultations or laboratory results during a pandemic [17]. Thus, from a public health perspective, the identification and management of comorbidities and mental health problems among patients with diabetes should be a priority [46].

Finally, patients with DM who had family members or friends infected with COVID-19 presented greater concern about contagion. This is similar to what has been reported in other studies suggesting that people experienced greater fear and concern when contacting close people infected with COVID-19 [38,47]. Loss of contact with significant family and friends who have been infected with COVID-19 may decrease the perception of social support. This is important, as lack of social support from family or friends has been significantly associated with COVID-19-specific worry [42]. Diabetes has been referred to as a “family disease”, affecting all family members [48]. Because the treatment of diabetes is complicated and complex, support from family and friends can help patients ease the burden of living with the disease [49], allowing them to gain self-confidence [50].

Despite the importance of these findings, this study has some limitations: First, the non-probabilistic sample used does not allow us to generalize the results to all patients with COVID-19. Second, the data collection was conducted in a relatively short period of time, which prevented us from assessing the impact of predictors in different periods of the pandemic. Recent studies have shown that the psychological burden and fear of COVID-19 varies between different periods of the pandemic [51]. This should lead to future studies which could evaluate the impact of the pandemic on mental health indicators of patients with diabetes at different stages of the pandemic. Third, the fact that the sample is mostly made up of women leads to a selection bias. This may lead to an underestimation of the contagion concern of male patients with diabetes. Fourth, the results are based on cross-sectional and not longitudinal data. Therefore, causality between variables cannot be assumed. Fifth, the study only included a limited set of possible sociodemographic and health predictors. Further research on concern about COVID-19 transmission and other associated factors, such as beliefs about COVID-19, intolerance to uncertainty, prevention behaviors, treatment adherence, etc., is suggested [52]. Sixth, the use of a self-report measure of contagion concern raises the possibility of social desirability bias.

Despite these limitations, the results of this study allow us to conclude that age, technical education, having comorbidities and having a friend or family member with COVID-19 remained significant predictors of concern about COVID-19. Specifically, that male patients with diabetes, with a technical school education, with comorbidities and those who had infected family members or friends were more concerned about the transmission of COVID-19. Thus, public health policies should foster the development of strategies to assess the mental health of people belonging to vulnerable groups, such as patients with diabetes, and provide timely interventions to promote mental health in those who show symptoms of concern about infection. Therefore, future studies to mitigate the negative psychological effects of the COVID-19 pandemic in patients with diabetes should consider these sociodemographic and health factors.

Author contributions: All authors have sufficiently contributed to the study, and agreed with the results and conclusions.
