A seesaw mechanism is presented in the neutrino sector and a new phase of CP violation ($\alpha$) emerges in the interplay between the type-I and type-III seesaw schemes. This phase is inside the mixing term, and thus it cannot be rotated away in the Yukawa Lagrangian and, therefore, the heavy symmetry states cannot be in a diagonal weak basis in the broken phase. Some particular descriptions are analyzed suggesting that if the usual Yukawa couplings are suppressed, leptogenesis still occurs due to a new interacting vertex with fermion triplet $T$, fermion singlets $N$, and an ad-hoc scalar triplet, $\Sigma$, which now is included to mediate the interactions. The evaluated CP violation is enough to generate the observed matter-antimatter asymmetry even in the minimal $1N + 1T$ case (independently of $\alpha$) or in the $2N + 2T$ approach (controlled by $\alpha$). The latter introduces more CP contributions to leptogenesis due to new diagrams which are now possible even with the suppressed imaginary part of the standard Yukawa couplings and can induce the observed baryon-to-photon ratio.

I. INTRODUCTION

Minimal extensions of the standard model (SM) usually add heavy singlet fermions (commonly called as right-handed neutrinos) to the SM lepton sector, $N_{IR} \sim (1,0)$. They have very large Majorana masses and are linked to the light neutrinos realizing the type-I seesaw mechanism [1] and also producing the lepton asymmetry, which is transferred to the visible baryon sector, generating the baryon asymmetry of universe (BAU) [2]. It occurs due to sphaleron processes [3] in the so-called leptogenesis mechanism [4–6]. The existence of similar mechanisms of type-II [7] and type-III [8] adds to the standard model scalar triplets, $\Sigma \sim (3, +2)$, or right-handed fermion triplets, $T_R \sim (3, 0)$, respectively. Nevertheless, the hypercharge forbids their general interaction. These usual seesaw mechanisms describe a Majorana mass term for the neutrinos as $L_{\text{mass}} = \frac{1}{2} n_L^T C M^* n_L + H.c.$, where the neutrino mass matrix is constructed on the symmetry basis $n_L = (\nu_L, N_R, T_R^0)^T$ and the fields $\nu_L = (\nu_{1L}, \nu_{2L}, \nu_{3L})^T$ are the left-handed neutrino components, $N_R^* = (N_{1R}^c, N_{2R}^c, N_{3R}^c)$ are the heavy right-handed singlet components and $T_R^0 = (T_{1R}^c, T_{2R}^c, T_{3R}^c)$ are the neutral fermion triplet components in the most general three fermion family model. The full diagonalization of the general $M_{9\times9}$ allows one to obtain the physical neutrino eigenstates and generally carries enough phases to CP at low energies even in minimal setups [9]. Minimal versions of these extensions with only two heavy neutral fermions (general $M$ with only $5 \times 5$ entries) have been extensively studied in the literature [10] and are widely applied to the leptogenesis mechanism.

Since in the standard scheme there is nothing to forbid the use of a weak basis (WB) where the masses of heavy neutrinos ($M_N$) and heavy triplets ($M_T$) are real and diagonal, one can choose thisWB to easily diagonalize $M$. Once the components of $M_N$ and/or $M_T$ are much heavier than the Dirac of-diagonal components ($m_D$ and $m_D^t$) one can make a block diagonalization and, in very good approximation [11], the light neutrino sector has the non diagonal masses given by $m_\nu \simeq m_{11} - M_{ee} - m^2$, where $m = (m_D, m_D^t)$ and $M = \text{diag}(M_N, M_T)$. The full diagonalization is easily made since $D = M$ in this WB while the light neutrinos have the masses diagonalized by $d = K^T m_k K^*$, where $K$ is the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) mixing matrix. Even if we include more than one singlet and/or triplet, the structure of $M$ will still be the same, with $M_N$ and/or $M_T$ being the related diagonal submatrices. The off-diagonal zeros persist unless new content is added to the model.

Seesaw models introduce minimal modifications to SM content by some new particles. Here we need to go beyond and insert an interaction between these new species. In the minimal version at low energies, for example, the interaction between singlets and the neutral scalar component can generate nonzero matrix elements if this interaction receives a mass term from a vacuum expectation value (VEV) of a new ad hoc (nonusual) scalar triplet, $\Sigma \sim (3, 0)$, which can interact with $N_R$ and $T_R$ and, therefore, produces a new seesaw mechanism by the introduction of off-diagonal terms into $M$ (specifically into the submatrix $M$). This hybrid interaction of the types I and III seesaw mechanisms emerges naturally from the unification when the neutrino mass problem is solved by the inclusion of an adjoint fermion representation in the minimal $SU(5)$ [12]. The adjoint representation has a branch to the SM group, $SU(3) \otimes SU(2) \otimes U(1)$, given by $24 = (1,1)_{0} + (1,3)_{0} + (3,2)_{-5/6} + (\bar{3},2)_{5/6} + (8,1)_{0}$. Hence, an interaction term as $L^\text{int} \supset N_R Tr(T_R \Sigma)$ can be naturally
achieved from an interaction between two fermions and a scalar adjoint representation, like $\text{Tr}(24_F \cdot 24_F \cdot 24_S) \ni ((1, 1)_{DF}(1, 3)_{DF}(1, 3)_{DS})$ [12, 13]. This content is customarily necessary to save the unification in a variety of models based on $SU(5)$ [14].

Besides the similar aspects of type I and type III seesaw mechanisms, the introduction of this peculiar interaction generates new interferences between the tree and loop levels, which contribute to raise the CP violation in the lepton sector. Yet, the interplay of the different seesaw mechanisms may be important for the neutrino mass generation and should explain the small deviations from the tribimaximal mixing form of the PMNS matrix [15].

Such interactions can induce CP violation in both $N$ and $T$ decays and should be driven by a new CP source. Moreover, previous studies have shown that the second heavy eigenstate may be important for leptogenesis in the thermal scenario [16]. The asymmetry can be associated to $N$ (or $N_1$), which is heavier than $T$, however, playing the key role for CP violation to leptogenesis. From this point of view, all CP violation generated by the two lightest eigenstates among all heavy neutral fermions should be taken into account. On the other hand, the scalar triplet $\Sigma$ can naturally get a vanishingly small VEV since it may be inside of the $24_S$ in the unification in $SU(5)$ [12]. Thus, the study of CP in the decay of the new fermions to $S$ may be important if an interaction between a fermion singlet, fermion triplet, and scalar triplet is included. It provides a new relevant CP origin and complements the usual lepton asymmetries calculated in the standard seesaw mechanisms in leptogenesis [5].

To study the consequences of this kind of models we will focus on the minimal examples with only $1N_R$ and $1T_R$ (1N1T) and with $2N_R$ and $1T_R$ (2N1T). In this vein, the paper is organized as follows. In Sec. II we introduce the minimal 1N1T type I+III seesaw model and some aspects of the diagonalization mechanism for the Majorana sector. In Sec. III we show the CP violation generated in $T$ and $N$ decays for the 1N1T setup before $\Sigma$ gets a VEV (diagonal $M$ mass matrix). In Sec. IV the CP violation driven by $T$ and the $N_1$ decays is discussed in the 2N1T case (also in the symmetric phase) and some results are derived to generate the baryon-to-photon ratio in this case. Finally, our conclusions and outlook are given in Sec. V.

II. MINIMAL TYPE I+III SEESAW MODEL

For the following discussion let us concentrate on the case where only one fermion singlet and one fermion triplet are added to SM. In this footing, the most general lepton sector invariant Lagrangian is given by

$$-\mathcal{L} = y_{\ell i}^* \ell_i L_N R + \sqrt{2} y_{\ell i}^* \ell_i L_T R \tilde{H} + y_{v i}^* N_R^T C T (\Sigma T_R) + \frac{1}{2} M_N N_R^T C N_R + \frac{1}{2} M_T T (T_R^T C T_R) + \frac{1}{2} M_\Sigma^2 |\Sigma|^2 + V(H, \Sigma) + \text{H.c.},$$

where the fermion and scalar triplets are, respectively, defined as

$$T_R = \frac{1}{\sqrt{2}} \left( \begin{array}{c} T_R^0 \\ \sqrt{2} T_R^+ \end{array} \right) \sim (3, 0),$$

and

$$\Sigma = \frac{1}{\sqrt{2}} \left( \begin{array}{c} \Sigma_0^0 \\ \sqrt{2} \Sigma^+ \end{array} \right) \sim (3, 0),$$

where the scalar potential $V(H, \Sigma)$ encodes all purely scalar interactions. The other lepton fields are the same as in the SM with heavy Majorana neutrinos $[\ell \sim (2, -\frac{1}{2}), N_R \sim (1, 0)]$, where $H \sim (2, \frac{1}{2})$ is the scalar doublet and $\tilde{H} = i 0_2 H^*$. The Lagrangian in Eq. (1) does not conserve lepton number in either $N_R$ or $T_R$ decays. After all spontaneous symmetry breakings, $H$ gets a VEV $v$ and $\Sigma$ gets $v_\Sigma$. The neutrino mass term is given by $\mathcal{L}^{\text{mass}} = \frac{1}{2} y_{\ell i}^* C M_{\ell i}^* n_L + H.c.$, where the general neutrino mass matrix, $M$, is fulfilled with all seesaw mechanisms and can be written as follows $^1$:

$$M = \begin{pmatrix} m_{\ell i} & m_D & m_{D'} \\ m_D^T & M_N & M_{H_2} \\ m_{D'}^T & M_{H_2} & M_T \end{pmatrix}. \tag{4}$$

In the present case, the entries of the above $5 \times 5$ matrix are submatrices given by the following connection with the Lagrangian in Eq. (1):

$$m_{\ell i} = 0_{3 \times 3}, \quad m_{D i} = \frac{y_{\ell i} v}{\sqrt{2}}, \quad m_{D'} i = \frac{y_{v i}^* v}{\sqrt{2}}, \quad M_{H_2} = \frac{v_x y_{v c}}{\sqrt{2}}, \tag{5}$$

where $M_{H_2}$ is a scalar complex mass term in the minimal 1N1T model. Consequently, the heavy particles are not in the mass eigenstates and we have to diagonalize $M$ by an orthogonal transformation. Let $V$ be the matrix which does that,

$$D \equiv V^T M V = \text{diag} (m_1, m_2, m_3, M_1, M_2), \tag{6}$$

where the lowercase letters corresponds to light neutrino masses and uppercase letters denote the two effective heavy neutrino masses. This type of minimal setup usually induces a light neutrino to be massless [10].

The diagonalization of $M$ in Eq. (4) is similar to the one described in Ref. [11]. Let us rewrite $M$ disconnecting the heavy and light sectors,

$$M = \begin{pmatrix} 0 & m \\ m^T & M \end{pmatrix}, \tag{7}$$

where $m = (m_D, m_{D'})$ and $M$ is a complex submatrix given by

$$M = \begin{pmatrix} M_N & M_{H_2} \\ M_{H_2} & M_T \end{pmatrix}, \tag{8}$$

$^1$ Notice that this is similar to the structure obtained in the inverse seesaw mechanism [17].
with real elements in the diagonal. Assuming the form of \( V \) as in the type-I seesaw mechanism \([11]\),

\[
V = \begin{pmatrix} K & R \\ S & T \end{pmatrix},
\]

we find,

\[
\begin{align*}
\mathbf{d} & \simeq -K^T \mathbf{m} \mathbf{M}^{-1} \mathbf{m}^T \mathbf{K}, \\
\mathbf{D} & \simeq T^\dagger \mathbf{M}_\ast \mathbf{T},
\end{align*}
\]

where we should not generally use \( \mathbf{T} \approx 1 \) since in this case the nondiagonal entries can contribute in an unusual way depending on the strength of the coupling \( y^2 \). On the other hand, it is easy to show that \( \mathbf{S} \sim \mathbf{M}^{-1} \mathbf{m}, \mathbf{R} \sim \mathbf{m} \mathbf{M}^{-1} \), and (to a good approximation) \( \mathbf{V} \) can be written in terms of only two matrices, namely, \( \mathbf{K} \) and \( \mathbf{T} \), as follows:

\[
\mathbf{V} = \begin{pmatrix} \mathbf{K} & \mathbf{m} \mathbf{M}^{-1} \mathbf{T} \\ -\left( \mathbf{M}^{-1} \right)^T \mathbf{m}^\dagger \mathbf{K} & \mathbf{T} \end{pmatrix}. \tag{12}
\]

While \( \mathbf{K} \) is linked to the PMNS matrix and diagonalizes the light neutrino mass matrix, \( \mathbf{T} \) is the matrix which does the similar process in the heavy sector. The study of the connection of leptogenesis with light energy parameters has been extensively explored in the literature \([18]\) and we will not focus on it.

Let us assume a predictive point of view in which we have \( |M_N|, |M_T| \gg |m_{\text{hy}}| \). Generically speaking, the entries \( M_N \) and \( M_T \) can be complex constants; then, we can rotate the lepton fields to a WB where these quantities are real and absorb all Majorana phases into \( y^2 \). Therefore, we will start considering \( M_N \) and \( M_T \) just as real elements. Furthermore, these phases cannot be rotated away by a redefinition of both Majorana fields, allowing for a complex \( \mathbf{M} \). The matrix \( \mathbf{M} \) is correctly diagonalized if we define the Hermitian operator, \( \mathbf{H} = \mathbf{M} \mathbf{M}^\dagger \), through the unitary matrix \( \mathbf{T} \) as \( \mathbf{D}^2 = \mathbf{T}^\dagger \mathbf{H} \mathbf{T} \). The leptonic CP phases are now in \( \mathbf{m} \) and also in \( \mathbf{M} \), as can be seen from Eqs. (10) and (11). The four parameters in \( \mathbf{M} \) are now manifested as two heavy masses, \( M_1 \) and \( M_2 \), and two phases in the matrix \( \mathbf{T} \), for which we choose the following form:

\[
\mathbf{T} = \begin{pmatrix} \cos \theta & e^{-i\phi} \sin \theta \\ -e^{i\phi} \sin \theta & \cos \theta \end{pmatrix}. \tag{13}
\]

If we introduce the Majorana phase \( \alpha \) by doing an explicit phase extraction,

\[
M_{\text{hy}} \equiv m_{\text{hy}} e^{i\alpha} = \frac{\nu_{\Sigma}}{\sqrt{2}} |y^2| e^{i\alpha}, \tag{14}
\]

the general eigenvalues of \( \mathbf{H} \) are given by

\[
h_{\pm} = \frac{1}{2} \left( 2m_{\text{hy}}^2 + N_2^2 + M_T^2 + r \right), \tag{15}
\]

where

\[
r = \sqrt{\left( M_N^2 - M_T^2 \right)^2 + 4m_{\text{hy}}^2 (M_N^2 + M_T^2 + 2M_N M_T \cos 2\alpha)}. \tag{16}
\]

Thus, the effective physical masses are given by \( M_1 = \sqrt{h_-} \) and \( M_2 = \sqrt{h_+} \). If we assume that \( m_{\text{hy}} \) is suppressed compared to \( M_N \) and \( M_T \), then one gets \( M_1 \sim M_T \) and \( M_2 \sim M_N \) (exactly equal in the decoupled limit \( m_{\text{hy}} \to 0 \)). More generically, it can be expanded for \( m_{\text{hy}} \ll M_T \leq M_N \) as

\[
M_1 = M_T - \frac{M_T + \cos (2\alpha) M_N}{M_N - M_T^2} m_{\text{hy}}^2 + \mathcal{O} \left( \frac{m_{\text{hy}}^4}{M_N^4} \right), \tag{17a}
\]

\[
M_2 = M_N + \frac{\cos (2\alpha) M_T + M_N}{M_N - M_T^2} m_{\text{hy}}^2 + \mathcal{O} \left( \frac{m_{\text{hy}}^4}{M_N^4} \right). \tag{17b}
\]

If we use \( \mathbf{T} \mathbf{D}^2 = \mathbf{H} \mathbf{T} \) we find the following relations between the two pairs of parameters:

\[
\begin{align*}
\tan \phi & \simeq \frac{M_N - M_T}{M_N + M_T} \tan \alpha, \\
\tan \theta & \simeq \frac{M_T^2 + 2M_N M_T \cos 2\alpha + M_N^2}{M_T^2 - M_N^2} m_{\text{hy}}^2 \times \frac{M_N \cos (\alpha - \phi) + M_T \cos (\alpha + \phi)}{M_N \cos (\alpha - \phi) - M_T \cos (\alpha + \phi)}.
\end{align*} \tag{19}
\]

The physical eigenstates are now given by the application of \( \mathbf{T} \) in Eq. (13) to the symmetry states, \( \mathbf{T} \mathbf{N}_R \),

\[
\begin{pmatrix} N_{1R} \\ N_{2R} \end{pmatrix} = \begin{pmatrix} N_R \cos \theta + T_R^0 e^{-i\phi} \sin \theta \\ T_R^0 \cos \theta - N_R e^{-i\phi} \sin \theta \end{pmatrix}. \tag{20}
\]

Now, by using Eq. (17) it is easy to show that we can get \( M_N \) and \( M_T \) written in the mass eigenstate basis by the following nonlinear transformation up to the order \( \mathcal{O}(m_{\text{hy}}^2/M_N^2) \):

\[
\begin{align*}
M_T & \simeq M_1 \left( 1 + \frac{m_{\text{hy}}^2}{M_N^2 - M_T^2} \right) + M_2 \frac{m_{\text{hy}} \cos 2\alpha}{M_N^2 - M_T^2}, \tag{21a}
M_N & \simeq M_2 \left( 1 - \frac{m_{\text{hy}}^2}{M_N^2 - M_T^2} \right) - M_1 \frac{m_{\text{hy}} \cos 2\alpha}{M_N^2 - M_T^2}. \tag{21b}
\end{align*}
\]

We notice that these approximations are in great accordance for values of \( m_{\text{hy}} \lesssim 0.1 M_1 \). It should also be emphasized that the hybrid seesaw I+III only takes place when \( \Sigma \) gets a VEV. Without the symmetry breaking by \( \Sigma \), the model has diagonal heavy masses, but there are still new contributions to CP violation due to interferences of tree- and one-loop-level diagrams, as we will see below. The exact numerical relation between the ratios \( M_T^2/M_N^2 \) and \( M_T^2/M_N^2 \) is shown in Fig. 1 for \( m_{\text{hy}} \) in the range \( 0 < m_{\text{hy}} < 10 M_T \). Deviations from a straight line when \( m_{\text{hy}} \neq 0 \) shows that the CP violation may have an unexpected behavior in terms of \( M_T^2/M_N^2 \) since it may not be exactly written as a bijective function of \( M_T^2/M_N^2 \), giving rise to complications in the broken phase. Notice also that \( M_T^2/M_N^2 \) is very small for \( m_{\text{hy}} \simeq 1 M_T \).
III. CP VIOLATION IN THE 1N1T SETUP

Let us assume that the Universe is in the symmetric phase, specifically when Σ has not yet acquired a VEV, and therefore M is diagonal and real in this WB. Let us assume that T⁰ is always lighter than the singlet N and their decay channels at tree level are described in the diagrams showed in Fig. 2. The CP asymmetry is generally defined by [6]

$$\varepsilon^{(N)}_{j\rightarrow f, S} = \frac{\Gamma(N\rightarrow j, S) - \Gamma(N\rightarrow j, S^\dagger)}{\Gamma(N\rightarrow f, S) + \Gamma(N\rightarrow f, S^\dagger)},$$  \hspace{1cm} (22)

where $\Gamma(N\rightarrow f, S) \equiv \sum_{j=\text{all}} \Gamma(N\rightarrow j, S)$ is the total decay width of N. A similar expression gives the CP asymmetry in $T^0$ decays. Notice that the singlet N can also decay to a $T\Sigma$ final state. Thus, a kind of sequential decay mechanism can be applied here and the decay of N should not be erased by the late $T^0$ decays, as in the $N_2$-dominated scenario [16].

Nonvanishing CP asymmetry arises from the interferences of tree-level diagrams in Fig. 2b with their respective one-loop diagrams in Figs. 2c and 2d [5, 19]. In the present model the CP violation in the N decays reads as

$$\varepsilon^{(N)} = \frac{\text{Im} \left( (y^f y^\nu)^2 \right)}{8\pi (y^f y^\nu)} + \frac{12\pi \Im \left( w, y^\nu \right) \left( \sqrt{w} + 3f(w) \right)}{1 - w},$$  \hspace{1cm} (23)

where $w \equiv M_T^2 / M_N^2$ (notice that $w < 1$ due to the inversion of the usual definition). We have summed over the final states (vanilla leptogenesis) to elucidate the properties of this mechanism. Here $f(x)$ is the usual vertex one-loop function defined by

$$f(x) = \sqrt{x} \left[ 1 - (1 + x) \ln \left( 1 + \frac{1}{x} \right) \right].$$  \hspace{1cm} (24)

We have also defined the function $\Upsilon$ as

$$\Upsilon(w, y^\nu) = (w + 1) |y^\nu|^2 + \sqrt{w} \left( (y^\nu)^2 + (y^\nu)^2 \right),$$  \hspace{1cm} (25)

which means $\Upsilon(w, 0) = 0$ in the decoupling limit of both seesaw mechanisms. Notice that Fig. 2a does not have a nonvanishing one-loop counterpart, and thus it does not contribute to CP violation in 1N1T case, although it contributes to the total decay width, as can be seen in the denominator of Eq. (23).

The CP violation generated in $T^0$ decays is given by

$$\varepsilon^{(T)} = \frac{\text{Im} \left( (y^f y^\nu)^2 \right)}{8\pi (y^f y^\nu)} \left( \frac{\sqrt{w} - f \left( \frac{1}{w} \right) - \frac{3\sqrt{w} \Im \left( (y^f y^\nu)^2 \right)}{16\pi}}{(y^f y^\nu)} \right).$$  \hspace{1cm} (26)

If we take the limit for the lightest heavy state (triplet) ($w \ll 1$) in Eq. (26) the well-known result is recovered,

$$\varepsilon^{(T)} \approx \frac{3\sqrt{w} \Upsilon \left( (y^f y^\nu)^2 \right)}{16\pi}.$$  \hspace{1cm} (27)

In this case the CP asymmetry generated in N decays can be neglected, and we recover the usual approximation when the lightest heavy state dominates the leptogenesis. The difference in this case concerns only the neutrino mass generation when Σ gets a VEV.

To get some insight about the CP asymmetries, let us consider the following simplifications,

$$y^f = \mathcal{O}(y_t), \quad y^\nu = \mathcal{O}(y_\nu)(1 + i), \quad \frac{m_{\nu y}}{v_\Sigma} \sim \mathcal{O}(y_\nu).$$  \hspace{1cm} (28)

For $M_T^2 / M_N^2 = w \sim 10^{-3}$ and $\mathcal{O}(y_t) s \sim 10^{-3}$, we get $\varepsilon^{(T)} \sim 10^{-10}$ while $\varepsilon^{(N)}$ should be almost negligible [20]. In this decoupled limit there is no dependence on the $y^\nu$ coupling; then, the low-energy connection is almost the same as the standard type-I or type-III leptogenesis mechanisms. On the other hand, as the masses get closer the $\varepsilon^N$ is no longer negligible and can be higher than $\varepsilon^T$ for $\mathcal{O}(y_\nu) \lesssim 10^{-12} \mathcal{O}(y_t)$.

From Eq. (12) we can conclude that $y^\nu = \sqrt{2} (m_{\nu y} / v_\Sigma) e^{i\alpha}$, and thus using Eq. (28) we can rewrite $\Upsilon$ as

$$\Upsilon = 2 \left( \frac{m_{\nu y}}{v_\Sigma} \right)^2 \left[ 1 + w + 2\sqrt{w} \cos \alpha \right].$$  \hspace{1cm} (29)
Using the above equation, one can rewrite Eqs. (23) and (26) as
\[
\varepsilon^{(N)}(w, \alpha) \simeq \frac{1}{4\pi} \left( \frac{\sqrt{w}}{1-w} + 3f(w) \right) O(y_f^2),
\]
and
\[
\varepsilon^{(T)}(w) \simeq \frac{1}{4\pi} \left( \frac{\sqrt{w}}{1-w} - f \left( \frac{1}{w} \right) \right) O(y_f^2),
\]
respectively. In Fig. 3 we can see an example of the expression of \( \varepsilon^T \) compared to \( \varepsilon^N \) for the results presented in Eqs. (30) and (31), shown in the range \( 0.5 \leq w \leq 0.9 \), with \( O(y_e) = 10^{-4} \) and \( O(y_t) = 10^{-3} \). The study of a full set of Boltzmann equations could be necessary to investigate the baryon-to-photon ratio behavior since the corresponding CP asymmetries are generated displaced for a very small \( w (w \lesssim 0.5) \). We will not consider this possibility in this simplified example once 0.71M_N \leq M_T \leq 0.95M_N to avoid an extremely suppressed \( \varepsilon^N \).

**IV. CP VIOLATION IN THE 2N1T SETUP**

The next extension (with two fermion singlets and one fermion triplet) has the most general Lagrangian, which is similar to the one presented in Eq. (1) but with the following small changes: \( y_k \rightarrow y_{km}, y^\dagger \rightarrow y_m^\dagger, M_N \rightarrow M_{N_m} \) (all real), and \( N \rightarrow N_m \). We assume also that \( \Sigma \) has not yet acquired a VEV and the model starts with a diagonal \( M \) without the need for writing the broken mass eigenstates.

For the study of CP violation let us concentrate on the decays of the lightest heavy Majorana singlet, \( N_k \), and also on the neutral fermion triplet decays, as before. The CP violation generated by the \( N_k \) decays [Eq. (22)] is \( \varepsilon_{k,j}(fS) \): \( \Gamma(N_k \rightarrow fS) \equiv \sum_{j=allele} \Gamma(N_k \rightarrow f,S) \) is the total decay width of the \( N_k \). The first crucial difference between the 2N1T and 1N1T schemes is in the fermion propagator with heavy triplets inside the loop and the new final-state channel \( T\Sigma \) (also at one-loop level), as illustrated in Fig. 5 and Fig. 6, respectively, which increase the total CP asymmetry.

The \( N_k \) total width at tree-level is now settled by
\[
\Gamma(N_k \rightarrow all) = \Gamma(N_k \rightarrow \ell H) + \Gamma(N_k \rightarrow \bar{\ell}H) + \Gamma(N_k \rightarrow T\Sigma) + \Gamma(N_k \rightarrow \bar{T}\Sigma) \text{ and is explicitly given by}
\]
\[
\Gamma(N_k \rightarrow all) = \frac{M_{N_k}}{8\pi} \left( \frac{y^{\ell\bar{\ell}}}{y_k} \right)_{kk} + \frac{3}{16\pi} \left( \frac{M_{N_k}^2}{M_{N_k}^2} \right) |y_k^T|^2 
\]
\[
+ M_T \left[ (y_k^T)^2 + (y_k^S)^2 \right],
\]
where we have used the fact that \( \Gamma(N_k \rightarrow \ell H) = \Gamma(N_k \rightarrow \bar{\ell}H) \) and \( \Gamma(N_k \rightarrow T\Sigma) = \Gamma(N_k \rightarrow \bar{T}\Sigma) \) at lowest order.

The usual CP violation in the decay of \( N_k \) is due to the interference of the diagrams in Fig. 4a with Figs. 4b and 4c, which yields
\[
\varepsilon_{k,j}^{(SM)} = -\frac{1}{8\pi} \left( \frac{y^{\ell\bar{\ell}}}{y_k} \right)_{kk} + 12\pi \left( w_k, y_k \right) \times 
\]
\[
\sum_{m \neq k} \text{Im} \left\{ \left( \frac{y_k^{\ell\bar{\ell}}}{y_k^{m\bar{\ell}}} \right)_{km} \left( \frac{\sqrt{x_{km}}}{1-x_{km}} \right) + \left( \frac{y_k^{\ell\bar{\ell}}}{y_k^{m\bar{\ell}}} \right)_{mk} \frac{1}{1-x_{km}} \right\},
\]
and the modification in the denominator comes from the total width decay, given by Eq. (32). Here \( x_{km}^T \equiv \)

**FIG. 3.** Numerical CP violation in N and T decays [Eq. (30) and Eq. (31)] in terms of \( w = M_T^2/M_N^2 \). The dotted (green) line is the \( \varepsilon^T \), while the others are values of \( \varepsilon^N \) for \( \alpha = \pi/4, \pi/2, \pi, O(y_e) = 10^{-4} \), and \( O(y_t) = 10^{-3} \).

**FIG. 4.** Tree-level and one-loop-level diagrams contributing to CP asymmetry in the \( N_k \) decays with a \( \ell H \) final state.

The usual CP violation in the decay of \( N_k \) is due to the interference of the diagrams in Fig. 4a with Figs. 4b and 4c, which yields
\[
\varepsilon_{k,j}^{(SM)} = -\frac{1}{8\pi} \left( \frac{y^{\ell\bar{\ell}}}{y_k} \right)_{kk} + 12\pi \left( w_k, y_k \right) \times 
\]
\[
\sum_{m \neq k} \text{Im} \left\{ \left( \frac{y_k^{\ell\bar{\ell}}}{y_k^{m\bar{\ell}}} \right)_{km} \left( \frac{\sqrt{x_{km}}}{1-x_{km}} \right) + \left( \frac{y_k^{\ell\bar{\ell}}}{y_k^{m\bar{\ell}}} \right)_{mk} \frac{1}{1-x_{km}} \right\},
\]
and the modification in the denominator comes from the total width decay, given by Eq. (32). Here \( x_{km}^T \equiv \)

**FIG. 5.** One-loop-level diagrams contributing to CP asymmetry in the \( N_k \) decays with triplet components in the propagators.

\( M_{N_m}^2/M_{N_k}^2 \) and \( w_k \equiv M_T^2/M_N^2 \). The CP asymmetry given by the interference of the tree level in Fig. 4a with the one-loop levels in Figs. 5a and 5b is \( \varepsilon_{k,j}^{(1)} = \)

which corresponds to a permutation of $N_m$ and $T$ in Eq. (33) with suitable consideration of a factor $\sqrt{2}$ in the vertex with charged triplet components. The interference of the diagram in Fig. 4a and in Fig. 5c gives the new source of CP violation,

$$\varepsilon_{k,j}^{(1)} = - \frac{1}{8\pi (y^+y^r)_{kk} + 12\pi w (w_k, y_k^r)} \sum_{m \neq k} \text{Im} \left( y_{jk}^r y_m^r \left[ \frac{w_k}{1 - w_k} + 3f(w_k) \right] + \right. $$

$$+ \left. \left( y_{jk}^r y_k^r \right)_k \frac{1}{1 - w_k} \right) \right\}, \quad (34)$$

and it should be written explicitly as a function of $\alpha_i$ since the latter are the new CP-violating phases. Notice that we have not summed over the final flavors $j$ in the results given in Eqs. (34) and (35). These equations hold even for more than two singlets. However, these equations change if we introduce two or more triplets with two singlets and we will not address this general setup.

![Fig. 6. Tree-level and one-loop-level contributing to CP asymmetry in the $N_k$ decays with a $T\Sigma$ final state.](image)

The CP contribution that comes from the interference of the tree-level in Fig. 6a with the one-loop levels in Figs. 6b, 6c, and 6d vanishes since only one triplet has been taken into account. The diagram in Fig. 6b automatically cancels out the imaginary combination of couplings when it is summed over the lepton-flavor-conserving and -violating loop diagrams. Each of the diagrams in Figs. 6c and 6d has a vanishing imaginary interference combination of couplings with the tree-level diagram in Fig. 6a and do not contribute to CP asymmetry with only one triplet.

The CP violation in the interference of the tree-level diagram in Fig. 7a with the one-loop levels in Fig. 7b and 7c leads to

$$\varepsilon_j^{(T)} = - \frac{1}{8\pi (y^+y^r)} \sum_m \text{Im} \left( y_{jk}^r y_m^r \left[ \frac{w_k}{w_m} \right] + f(w_m) \right) + \left( y_{jk}^r y_k^r \right)_k \frac{w_m}{w_m - 1} \right\}, \quad (36)$$

For simplification, let us assume the hierarchical order $N_1, T_0, N_2$, from the lightest to the heaviest, to give some results in the unflavored regime (summing over the final flavors), considering only the rough order of couplings $y^s, y^f$ and $y^c$. If we consider the crude generalization of Eq. (28) for all matrix elements,

$$y_k^i = O(y_i), \quad y_{k1,2}^i = O(y_i)(1 + i), \quad y_k^c = \sqrt{2}e^{i\alpha}O(y_i), \quad (37)$$

then we get $\varepsilon_1^{(SM)} = 0$. For a realistic low-energy connection it should also be related to sin $\theta_13$ in general [6], but here the condition for (flavored) leptogenesis $\sin \theta_{13} \geq 0.09$ [18] does not necessarily take place. Thus, the simplified expressions for CP violation are roughly given by

$$\varepsilon_1^{(1)} \approx \frac{\sqrt{w}}{4\pi} \left[ 3f\left( \frac{x}{w} \right) + f\left( \frac{1}{w} \right) \right] O\left( y_1^2 \right) \quad (38)$$

and

$$\varepsilon_1^{(2)} \approx \frac{1}{4\pi \left( 3 + w + 2\sqrt{w\cos 2\alpha_1} \right)} \left[ \left( 1 - w \right) \frac{\sin (\alpha_1 - \alpha_2)}{\sqrt{1 + x}} \right] + \frac{2}{1 + \sqrt{x}} \sqrt{w} \sin (\alpha_1 + \alpha_2) \right\} O\left( y_1^2 \right). \quad (39)$$

Finally, the triplet gives rise to the following CP asymmetry:

$$\varepsilon(T) \approx - \frac{3}{8\pi} \left[ \frac{\sqrt{w}}{w - 1} + f\left( \frac{x}{w} \right) + \frac{\sqrt{wx}}{w - x} + f\left( \frac{1}{w} \right) \right] O\left( y_1^2 \right), \quad (40)$$

where we have unequivocally denoted $w \equiv w_1$ and $x \equiv x_1$. The final CP violation in the $N_1$ decays is given by $\varepsilon_1 = \varepsilon_1^{(SM)} + \varepsilon_1^{(1)} + \varepsilon_1^{(2)}$. If $\varepsilon(T)$ is suppressed or vanishes by decaying in the equilibrium stage [2], the $N_1$ drives the leptogenesis mechanism. Our numerical results are shown in Fig. 8 for $x = M_{N_1}/M_{N_1} = 10$. The naive approximations shown in Eqs. (38) - (40) may get corrections if we proceed to a flavored analysis [21]. It is straightforward to verify that if only one singlet and two
triplets are taking into account the result is still almost the same with minimal interchanges of couplings. On the other hand, if two singlets plus two triplets are included in the model, the results will change drastically due to the fact that nonvanishing contributions from the graphs in Figs. 6b–6d are not canceled out and may not be suppressed.

![Graph](image)

**FIG. 8.** Numerical CP violation in $N_1$ and $T$ decays [Eq. (38)-(40)] in terms of $w = M^2_3/M^2_{N_1}$ for $\alpha_1 = \pi/2, \alpha_2 = 0, x = M^2_{N_2}/M^2_{N_1} = 10$ and $O(y_\nu) = 10^{-3}, O(y_t) = 10^{-4}$.

Let us consider the very simplified limit, when $y^\nu$ and $y^t$ have all real entries and CP violation comes only from $y^z$. In this case all CP violation vanishes except $\xi_1^{(2)}$ in Eq. (35). Using Eq. (37) with a null imaginary part for $y^\nu$ and considering $y^\nu \sim y^t \sim (m_{y^\nu}/v_\nu) \sim O(y)$ and $\alpha = \alpha_1 = \alpha_2$, we can get the CP in $N_1$ decays as

$$\xi_1^{(2)} \sim \frac{3}{4\pi} \frac{\sin 2\alpha}{2 + w + 2\sqrt{w} \cos 2\alpha} \frac{\sqrt{w} (1 - w)}{(1 + \sqrt{x})} O(y^2).$$

The corresponding numerical result of Eq. (41) for $x = M^2_{N_2}/M^2_{N_1} = 10$ is shown in Fig. 9 with a close-up where a maximum is obtained.

![Graph](image)

**FIG. 9.** Numerical CP violation in $N_1$ decays [Eq. (41)] in terms of $w = M^2_3/M^2_{N_1}$ for $\alpha = \pi/3, \pi/4, \pi/6, x = M^2_{N_2}/M^2_{N_1} = 10$, and $O(y) = 10^{-3}$.

For leptogenesis to be successful it is important that the model reproduces the observed baryon-to-photon ratio [22],

$$\eta_B = (6.19 \pm 0.14) \times 10^{-10} \quad (42)$$

This can be analyzed by the out of equilibrium of Majorana decays. The out of equilibrium in $N_1$ decays is controlled by the decay parameter,

$$K_{N_1} = \frac{\Gamma_{N_1}}{H (T = M_{N_1})}, \quad (43)$$

where $H$ is the Hubble parameter, $m_{p1} = 1.22 \times 10^{19}$GeV is the Planck mass, and $g_s \simeq 110$ in the present model is the number of relativistic degrees of freedom in the thermal bath. The total decay width is given by Eq. (32). An estimate of $\eta_B$ can be obtained when the photon production is the standard until the recombinetion era as follows [20]

$$\eta_B \simeq 10^{-2} \kappa_1 \xi_1^{(2)}, \quad (44)$$

where the final expression for the efficiency factor, $\kappa_1$, has a very simplified form in the strong washout regime ($K \gg 1$),

$$\kappa_1 (K) \sim \frac{2}{z_B K} \left(1 - e^{-\frac{1}{2} z_B (K) K}\right), \quad (45)$$

with the parameter $z_B$,

$$z_B (K) \simeq 2 + 4 K^{-0.13} e^{-2.5/K}. \quad (46)$$

Equation (45) is calculated independently of the initial abundance of the heavy neutral fermions and, using Eq. (46), it may be approximated by $\kappa_1 (K) \simeq 0.5/K_{1.2}^{1.2}$ [23]. Without assumptions of any low-energy constraints on Yukawa couplings, let us roughly assume $x = 10$ and $M_{N_1} \simeq 3.5 \times 10^{13}$GeV with the CP given by Eq. (41) and maximized for $\alpha = \pi/3$. Using $O(y) \sim 0.5$, we get $\eta_B \max \simeq 6.1 \times 10^{-10}$ for $w \simeq 0.3$ ($M_T \simeq 1.9 \times 10^{13}$GeV). It agrees with the experimental value in Eq. (42). Our numerical estimate for $\eta_B$ using Eq. (44) is shown in Fig. 10 as a function of $w$. The asymmetry generated in $N_1$ decays can be erased by the late decay of $T$, and a further comparative analysis on a full set of Boltzmann equations to study the efficiency factors could elucidate this question about the final baryon asymmetry [16].

**V. CONCLUSION**

We have considered a new source of CP violation in the interplay between the type-I and type-III seesaw mechanisms. Two minimal models with one fermion triplet plus one and two fermion singlets were studied. We have shown that the CP asymmetry generated can be enhanced to produce the expected matter-antimatter asymmetry through the leptogenesis mechanism. The main
feature is due to the new Majorana phase $\alpha$ which is responsible for the new CP asymmetry and cannot be absorbed by field redefinitions in the Lagrangian, as well as the fact that the heavy neutrinos cannot be in a natural diagonal basis after $\Sigma$ gets a VEV. Other connections of $\alpha$ with phenomenological constraints may or may not discard the present model. Hence, a low-energy connection should be necessary to restrict the model. Yet, the acceptable range of $\sin \theta_{13}$ should be used to restrict the $\bar{\epsilon}_1^{(1)}$ and also to better understand the $\bar{\epsilon}_2^{(1)}$, which also may depend on $\sin \theta_{13}$ if the imaginary part of standard Yukawa couplings is nonvanishing. There is no straightforward relation to low-energy parameters since the Lagrangian in Eq. (1) (especially with more than two $N$’s and/or $T$’s) mixes all heavy and light eigenstates, making necessary the reconstruction of the leptonic matrix mixing in terms of known neutrino data.

By a simplified analysis we have calculated the relevant CP asymmetry considering only unflavored leptogenesis and we observed that a sufficient amount of CP violation can be obtained even if all Yukawa couplings are real, whereas $\alpha_i \neq 0$. A sufficient baryon-to-photon ratio is obtained if we consider a heavy $N_1$ ($M_{N_1} \gtrsim 10^{13}$GeV). This bound can be lowered if one considers the different initial abundances for $N_1$ and their connection with low-energy parameters by Yukawa couplings [24]. It is required to avoid the so-called cosmological gravitino problem, which occurs if our scheme is embedded in a supergravity inflation theory, where the reheating temperature has an upper bound $T_{\text{reh}} \lesssim 10^6 - 10^9$ [25]. The flavored investigation should point out some new aspects of leptogenesis in the context of the type I+III seesaw mechanism. In this way, the study of leptogenesis in second heavier neutral fermion ($N_2$-dominated) scenario may appropriately constrain this model.

Finally, let us remark that the present study was made with only one fermion triplet. The inclusion of a second fermion triplet will give rise to new graphs and interferences which could be very tricky. The new graphs contributing to CP asymmetry arise due to the propagator of fermion triplet components and final states as well as scalar triplets. Yet, a better understanding of this mechanism would be given when the broken phase is considered and $\mathbf{M}$ is not diagonal in general. This modifies the mechanism presented as we rewrite the Lagrangian in the mass eigenstates and may increase the final CP asymmetry.
