Sparse Generalized Eigenvalue Problem via Smooth Optimization

Junxiao Song, Prabhu Babu, and Daniel P. Palomar, Fellow, IEEE

Abstract—In this paper, we consider an $\ell_1$-norm penalized formulation of the generalized eigenvalue problem (GEP), aimed at extracting the leading sparse generalized eigenvector of a matrix pair. The formulation involves maximization of a discontinuous nonconcave objective function over a nonconvex constraint set, and is therefore computationally intractable. To tackle the problem, we first approximate the $\ell_0$-norm by a continuous surrogate function. Then an algorithm is developed via iteratively majorizing the surrogate function by a quadratic separable surrogate function. Then an algorithm is developed via iteratively majorizing the nondifferentiable surrogate function. For sparse GEPs with special structure, algorithms that admit a closed-form solution at every iteration are derived. Numerical experiments show that the proposed algorithms match or outperform existing algorithms in terms of computational complexity and support recovery.

Index Terms—Minorization-maximization, sparse generalized eigenvalue problem, sparse PCA, smooth optimization.

I. INTRODUCTION

The generalized eigenvalue problem (GEP) for matrix pair $(A, B)$ is the problem of finding a pair $(\lambda, x)$ such that

$$ Ax = \lambda Bx, \quad (1) $$

where $A, B \in \mathbb{R}^{n \times n}$, $\lambda \in \mathbb{R}$ is called the generalized eigenvalue and $x \in \mathbb{R}^n, x \neq 0$ is the corresponding generalized eigenvector. When $B$ is the identity matrix, the problem in (1) reduces to the simple eigenvalue problem.

GEP is extremely useful in numerous applications of high dimensional data analysis and machine learning. Many widely used data analysis tools, such as principle component analysis (PCA) and canonical correlation analysis (CCA), are special instances of the generalized eigenvalue problem [1, 2]. In these applications, usually $A \in \mathbb{S}^n$, $B \in \mathbb{S}_{++}^n$ (i.e., $A$ is symmetric and $B$ is positive definite) and only a few of the largest generalized eigenvalues are of interest. In this case, all generalized eigenvalues $\lambda$ and generalized eigenvectors $x$ are real and the largest generalized eigenvalue can be formulated as the following optimization problem

$$ \lambda_{\text{max}}(A, B) = \max_{x \neq 0} \frac{x^T Ax}{x^T Bx}, \quad (2) $$

or equivalently

$$ \lambda_{\text{max}}(A, B) = \max_x \{ x^T Ax : x^T Bx = 1 \}. \quad (3) $$

Despite the simplicity and popularity of the tools based on GEP, there is a potential problem: in general the eigenvector is not expected to have many zero entries, which makes the result difficult to interpret, especially when dealing with high dimensional data. An ad hoc approach to fix this problem is to set the entries with absolute values smaller than a threshold to zero. This thresholding approach is frequently used in practice, but it is found to be potentially misleading, since no care is taken on how well the artificially enforced sparsity fits the original data [3]. Obviously, approaches that can simultaneously produce accurate and sparse models are more desirable.

This has motivated active research in developing methods that enforce sparsity on eigenvectors, and many approaches have been proposed, especially for the simple sparse PCA case. For instance, Zou, Hastie, and Tibshirani [4] first recast the PCA problem as a ridge regression problem and then imposed $\ell_1$-norm penalty to encourage sparsity. In [5], d’Aspremont et al. proposed a convex relaxation for the sparse PCA problem based on semidefinite programming (SDP) and Nesterov’s smooth minimization technique was applied to solve the SDP. Shen and Huang [6] exploited the connection of PCA with singular value decomposition (SVD) of the data matrix and extracted the sparse principal components (PCs) through solving a regularized low rank matrix approximation problem. Journ ée et al. [7] rewrote the sparse PCA problem in the form of an optimization problem involving maximization of a convex function on a compact set and the simple gradient method was then applied. Although derived differently, the resulting algorithm GPow turns out to be identical to the rSVD algorithm in [6], except for the initialization and post-processing phases. Very recently, Luss and Teboulle [8] introduced an algorithm framework, called ConGradU, based on the well-known conditional gradient algorithm, that unifies a variety of seemingly different algorithms, including the GPow method and the rSVD method. Based on ConGradU, the authors also proposed a new algorithm for the $\ell_0$-constrained sparse PCA formulation.

Among the aforementioned algorithms for sparse PCA, rSVD, GPow and ConGradU are very efficient and require only matrix vector multiplications at every iteration, thus can be applied to problems of extremely large size. But these algorithms are not well suited for the case where $B$ is not the identity matrix, for example, the sparse CCA problem, and direct application of these algorithms does not yield a
simple closed-form solution at each iteration any more. To deal with this problem, [9] suggested that good results could still be obtained by substituting in the identity matrix for \( B \) and, in [8], the authors proposed to substitute the matrix \( B \) with its diagonal instead. In [10], [11], an algorithm was proposed to solve the problem with the general \( B \) (to the best of our knowledge, this is the only one) based on D.C. (difference of convex functions) programming and minorization-maximization. The resulting algorithm requires computing a matrix pseudoinverse and solving a quadratic program (QP) at every iteration when \( A \) is symmetric and positive semidefinite, and in the case where \( A \) is just symmetric it needs to solve a quadratically constrained quadratic program (QCQP) at each iteration. It is computationally intensive and not amenable to problems of large size. The same algorithm can also be applied to the simple sparse PCA problem by simply restricting \( B \) to be the identity matrix, and in this special case only one matrix vector multiplication is needed at every iteration and it is shown to be comparable to the GPower method regarding the computational complexity.

In this paper, we adopt the MM (majorization-minimization or minorization-maximization) approach to develop efficient algorithms for the sparse generalized eigenvalue problem. In fact, all the algorithms that can be unified by the ConGradU framework can be seen as special cases of the MM method. Since the ConGradU framework is based on maximizing a convex function over a compact set via linearizing the convex objective, and the linear function is just a special minorization function of the convex objective. Instead of only considering linear minorization function, in this paper we also consider quadratic separable minorization that is related to the well known reweighted least squares (IRLS) algorithm [12]. By applying quadratic minorization functions, we turn the original sparse generalized eigenvalue problem into a sequence of regular generalized eigenvalue problems and an efficient preconditioned steepest ascent algorithm for finding the leading generalized eigenvector is provided. We call the resulting algorithm IRQM (iteratively reweighted quadratic minorization); it is in spirit similar to IRLS which solves the \( \ell_1 \)-norm minimization problem by solving a sequence of least squares problems. Algorithms of the IRLS type often suffer from the infamous “singularity issue”, i.e., when using quadratic majorization functions for nondifferentiable functions, the variable may get stuck at a nondifferentiable point [13]. To deal with this “singularity issue”, we propose a systematic way via smoothing the nondifferentiable surrogate function, which is inspired by Nesterov’s smooth minimization technique for nonsmooth convex optimization [14], although in our case the surrogate function is nonconvex. The smoothed problem is shown to be equivalent to a problem that maximizes a convex objective over a convex constraint set and the convergence of the IRQM algorithm to a stationary point of the equivalent problem is proved. For some sparse generalized eigenvalue problems with special structure, more efficient algorithms are also derived which admit a closed-form solution at every iteration.

The remaining sections of the paper are organized as follows. In Section [II] the problem formulation of the sparse generalized eigenvalue problem is presented and the surrogate functions that will be used to approximate \( \ell_0 \)-norm are discussed. In Section [III] we first give a brief review of the MM framework and then algorithms based on the MM framework are derived for the sparse generalized eigenvalue problems in general and with special structure. A systematic way to deal with the “singularity issue” arising when using quadratic minorization functions is also proposed. In Section [IV] the convergence of the proposed MM algorithms is analyzed. Section [V] presents numerical experiments and the conclusions are given in Section [VI].

Notation: \( \mathbf{R} \) denotes the real field. \( \mathbf{R}^n \) (\( \mathbf{R}_+^n \), \( \mathbf{R}_{++}^n \)) denotes the set of (nonnegative, strictly positive) real vectors of size \( n \). \( \mathbf{S}^n \) (\( \mathbf{S}_+^n \), \( \mathbf{S}_{++}^n \)) denotes the set of symmetric (positive semidefinite, positive definite) \( n \times n \) matrices defined over \( \mathbf{R} \). Boldface upper case letters denote matrices, boldface lower case letters denote column vectors, and italics denote scalars.

The superscripts \((j)^T\) denote transpose. \( X_{i,j} \) denotes the \((i, j)\)-th element of matrix \( X \) and \( x_i \) denotes the \( i\)-th element of vector \( x \). \( X_{i,:} \) denotes the \( i\)-th row of matrix \( X \), \( X_{:,j} \) denotes the \( j\)-th column of matrix \( X \). \( \text{diag}(X) \) is a column vector consisting of all the diagonal elements of \( X \). \( \text{Diag}(x) \) is a diagonal matrix formed with \( x \) as its principal diagonal.

Given a vector \( x \in \mathbf{R}^n\), \( |x| \) denotes the vector with \( i\)-th entry \( |x_i| \), \( \|x\|_0 \) denotes the number of non-zero elements of \( x \), \( \|x\|_p := (\sum_{i=1}^n |x_i|^p)^{1/p} \), \( 0 < p < \infty \). \( \mathbf{I}_n \) denotes an \( n \times n \) identity matrix. \( \text{sgn}(x) \) denotes the sign function, which takes \(-1, 0, 1\) if \( x < 0, x = 0, x > 0 \), respectively.

II. PROBLEM FORMULATION

Given a symmetric matrix \( A \in \mathbf{S}^n \) and a symmetric positive definite matrix \( B \in \mathbf{S}_+^n \), the main problem of interest is the following \( \ell_0 \)-norm regularized generalized eigenvalue problem

\[
\begin{align*}
\max_x & \quad x^T A x - \rho \|x\|_0 \\
\text{subject to} & \quad x^T B x = 1,
\end{align*}
\]

where \( \rho \) is the regularization parameter. This formulation is general enough and includes some sparse PCA and sparse CCA formulations in the literature as special cases.

The problem (4) involves the maximization of a non-concave discontinuous objective over a nonconvex set, thus really hard to deal with directly. The intractability of the problem is not only due to the nonconvexity, but also due to the discontinuity of the cardinality function in the objective. A natural approach to deal with the discontinuity of the \( \ell_0 \)-norm is to approximate it by some continuous function. It is easy to see that the \( \ell_0 \)-norm can be written as

\[
\|x\|_0 = \sum_{i=1}^n \text{sgn}(|x_i|).
\]

Thus, to approximate \( \|x\|_0 \), we may just replace the problematic \( \text{sgn}(|x_i|) \) by some nicer surrogate function \( g_p(x_i) \), where \( p > 0 \) is a parameter that controls the approximation. In this paper, we will consider the class of continuous even functions defined on \( \mathbf{R} \), which are differentiable everywhere except at 0 and concave and monotone increasing on \((0, +\infty)\).
and $g_p(0) = 0$. In particular, in this paper we will use the following three surrogate functions:

1) $g_p(x) = |x|^p$, $0 < p \leq 1$
2) $g_p(x) = \log(1 + |x|/p)/\log(1 + 1/p)$, $p > 0$
3) $g_p(x) = 1 - e^{-|x|/p}$, $p > 0$.

The first is the $p$-norm-like measure (with $p \leq 1$) used in [13], [14], which is shown to perform well in promoting sparse solutions for compressed sensing problems. The second is the penalty function used in [11] for sparse generalized eigenvalue problems that are too difficult to solve directly. The principle generalization of the well known expectation maximization method or the minorization-maximization method, which is a penalty function used in [11] for sparse generalized eigenvalue solutions for compressed sensing problems. The second is the surrogate function

\[ g(x) = \frac{\log(1 + 1/p)}{\log(1 + 1)} \]

which is shown to perform well in promoting sparse solutions for compressed sensing problems. The third is the surrogate function

\[ g(x) = 1 - e^{-|x|/p} \]

which is shown to perform well in promoting sparse solutions for compressed sensing problems.

With the approximation, the problem (6) is still a non-convex nondifferentiable optimization problem, but it is a convex problem and when used to replace the $\ell_1$-norm in basis pursuit, it leads to the well known itteratively reweighted $\ell_1$-norm minimization algorithm [17]. The last surrogate function is used in [18] for feature selection problems, which is different from the first two surrogate functions in the sense that it has the additional property of being a lower bound of the function $\text{sgn}(|x|)$. To provide an intuitive idea about how these surrogate functions look like, they are plotted in Fig. 1 for fixed $p = 0.2$.

![Figure 1](image1.png)

Figure 1. Three surrogate functions $g_p(x)$ that are used to approximate $\text{sgn}(|x|)$, $p = 0.2$.

By approximating $\|x\|_0$ with $\sum_{i=1}^n g_p(x_i)$, the original problem (4) is approximated by the following problem

$$
\begin{align*}
\text{maximize} & \quad x^T Ax - \rho \sum_{i=1}^n g_p(x_i) \\
\text{subject to} & \quad x^T B x = 1.
\end{align*}
$$

With the approximation, the problem (6) is still a non-convex nondifferentiable optimization problem, but it is a convex problem and when used to replace the $\ell_1$-norm in basis pursuit, it leads to the well known itteratively reweighted $\ell_1$-norm minimization algorithm [17].

III. SPARSE GENERALIZED EIGENVALUE PROBLEM VIA MM SCHEME

A. The MM method

The MM method refers to the majorization-minimization method or the minorization-maximization method, which is a generalization of the well known expectation maximization (EM) algorithm. It is an approach to solve optimization problems that are too difficult to solve directly. The principle behind the MM method is to transform a difficult problem into a series of simple problems. Interested readers may refer to [19] and references therein for more details.

Suppose we want to minimize $f(x)$ over $\mathcal{X} \in \mathbb{R}^n$. Instead of minimizing the cost function $f(x)$ directly, the MM approach optimizes a sequence of approximate objective functions that majorize $f(x)$. More specifically, starting from a feasible point $x^{(0)}$, the algorithm produces a sequence $\{x^{(k)}\}$ according to the following update rule

$$x^{(k+1)} \in \arg\min_{x \in \mathcal{X}} u(x, x^{(k)}),$$

where $x^{(k)}$ is the point generated by the algorithm at iteration $k$, and $u(x, x^{(k)})$ is the majorization function of $f(x)$ at $x^{(k)}$. Formally, the function $u(x, x^{(k)})$ is said to majorize the function $f(x)$ at the point $x^{(k)}$ provided

$$\begin{align*}
&u(x, x^{(k)}) \geq f(x), \quad \forall x \in \mathcal{X}, \\
&u(x^{(k)}, x^{(k)}) = f(x^{(k)}).
\end{align*}$$

In other words, function $u(x, x^{(k)})$ is a global upper bound for $f(x)$ and coincides with $f(x)$ at $x^{(k)}$.

**Example 1.** A majorization function of the function $g_p(x) = |x|^p$, $0 < p \leq 1$ that coincides with $g_p(x)$ at $x_0$ is

$$u(x, x_0) = \frac{p}{2} \frac{x^2}{|x_0|^{2-p}} + (1 - \frac{p}{2}) |x_0|^p$$

as illustrated in Fig. 2 for the case $p = 0.5$ and $x_0 = 2$.

![Figure 2](image2.png)

Figure 2. The function $g_p(x) = |x|^p$ with $p = 0.5$ and its quadratic majorization function at $x_0 = 2$.

To summarize, to minimize $f(x)$ over $\mathcal{X} \in \mathbb{R}^n$, the main steps of the majorization-minimization scheme are

1) Find a feasible point $x^{(0)}$ and set $k = 0$.
2) Choose $u(x, x^{(k)})$ such that
   a) $u(x, x^{(k)}) \geq f(x)$, $\forall x \in \mathcal{X}$
   b) $u(x^{(k)}, x^{(k)}) = f(x^{(k)})$
3) Let $x^{(k+1)} \in \arg\min_{x \in \mathcal{X}} u(x, x^{(k)})$.
4) If some convergence criterion is met, exit, otherwise, set $k = k + 1$ and go to step (2).

It is easy to show that with this scheme, the objective value is decreased monotonically at every iteration, i.e.,

$$f(x^{(k+1)}) \leq u(x^{(k+1)}, x^{(k)}) \leq u(x^{(k)}, x^{(k)}) = f(x^{(k)}).$$

(11)
The first inequality and the third equality follow from the properties of the majorization function, namely 3 and 9 respectively and the second inequality follows from (7).

Note that with straightforward changes, similar scheme can be applied to maximization. To maximize a function \( f(x) \), we need to minorize it by a surrogate function \( u(x, x^{(k)}) \) and maximize \( u(x, x^{(k)}) \) to produce the next iterate \( x^{(k+1)} \). A function \( u(x, x^{(k)}) \) is said to minorize the function \( f(x) \) at the point \( x^{(k)} \) if \(-u(x, x^{(k)}) \) majorizes \(-f(x)\) at \( x^{(k)} \). This scheme refers to minorization-maximization and similarly it is easy to shown that with this scheme the objective value is increased at each iteration.

### B. Quadratic Minorization Function

Having briefly discussed the general MM framework, let us return to the approximate sparse generalized eigenvalue problem (SGEP) in 6. To apply the MM scheme to solve the maximization problem, we need to minorize the objective at each iteration and hopefully after minorization the resulting problem is easier to solve. Therefore the key step is to find an appropriate minorization function for the objective of (9). In section 11, a minorization function is obtained via linearizing both the quadratic term and the penalty term for the special case with \( A \in S^n_+ \). But in our case, we would like to keep the quadratic term \( x^T A x \) and only minorize the penalty term \(-\rho \sum_{i=1}^n g_p(x_i) \). The idea is, at iteration \( k \), if we can majorize each of the surrogate functions \( g_p(x_i), i = 1, \ldots, n \) (i.e., minorize \(-g_p(x_i)\)) with some quadratic function \( u_i(x_i) = x_i^2 + c_i \) at \( x_i^{(k)} \), where \( w_i^{(k)} \) and \( c_i^{(k)} \) are some constant coefficients that depend on the value of \( x_i^{(k)} \). Then, the minorized problem that we need to solve at iteration \( k \) is (with the constant term ignored)

\[
\begin{align*}
\text{maximize} & \quad x^T A x - \rho x^T \text{Diag}(w^{(k)}) x \\
\text{subject to} & \quad x^T B x = 1, \tag{12}
\end{align*}
\]

which amounts to finding the generalized eigenvector corresponding to the largest generalized eigenvalue of the matrix pair \((A - \rho \text{Diag}(w^{(k)}), B)\). So the remaining problem is whether there exists such a quadratic function, if the answer is yes, how can we find the coefficients \( w_i^{(k)} \) and \( c_i^{(k)} \). Fortunately, for the class of surrogate functions considered in Section 11 the answer is affirmative and to determine the coefficients, we can use the following two conditions:

\[
\begin{align*}
g_p(x_i^{(k)}) &= w_i^{(k)} x_i^{(k)}^2 + c_i^{(k)}; \tag{13} \\
g_p(x_i^{(k)}) &= 2w_i^{(k)} x_i^{(k)}; \tag{14}
\end{align*}
\]

i.e., the quadratic function coincides with the surrogate function \( g_p(x_i) \) at \( x_i^{(k)} \) and is also tangent to \( g_p(x_i) \) at \( x_i^{(k)} \). The second condition comes from the fact that the surrogate functions of interest are differentiable and concave for \( x_i > 0 \) (also for \( x_i < 0 \)). With the equations (13) and (14), we can easily compute the coefficients \( w_i^{(k)} \) and \( c_i^{(k)} \). For example, for the surrogate function \( g_p(x_i) = |x_i|^p, 0 < p \leq 1 \), we have the following quadratic majorization function \( u(x_i, x_i^{(k)}) \) at \( x_i^{(k)} \):

\[
u(x_i, x_i^{(k)}) = \frac{p}{2} \left| x_i^{(k)} \right|^{p-2} x_i^{(k)} + \left(1 - \frac{p}{2}\right) \left| x_i \right|^p. \tag{15}
\]

The idea of majorizing some penalty functions by quadratic separable functions is well known in robust regression 20. It was proposed to solve the absolute deviations curve fitting problem (i.e., regression with \( \ell_1 \)-norm cost function) via iteratively solving a series of weighted least squares problems which have closed-form solutions 12. The method is thus called Iteratively Reweighted Least Squares (IRLS). Later the idea was applied in signal processing for sparse signal reconstruction in 15, 21. Recently, the IRLS approach has also been applied in Compressed Sensing 16. Algorithms based on this idea often have the infamous singularity issue 13, that is, the weight \( w_i^{(k)} \) is not defined for \( x_i^{(k)} = 0 \), as you can see in 15. The authors of 13 proposed to define the majorization function at the particular point \( x_i^{(k)} = 0 \) as

\[
u(x_i, 0) = \begin{cases} +\infty, & x_i \neq 0 \\
0, & x_i = 0,
\end{cases}
\]

which implies that once \( x_i^{(k)} = 0 \), the next iteration will also be zero, i.e., \( x_i^{(k+1)} = 0 \). This may impact the convergence of the algorithm to a minimizer of the objective, if the corresponding element of the minimizer is in fact not zero. Another common approach for dealing with this singularity issue is to incorporate a small \( \epsilon > 0 \), for example, for the surrogate function \( g_p(x_i) = |x_i|^p, 0 < p \leq 1 \), choose

\[
w_i^{(k)} = \frac{p}{2} \left( \left( x_i^{(k)} \right)^2 + \epsilon \right)^{\frac{p-2}{2}}, \tag{16}
\]

which is the so called damping approach used in 16. A potential problem of this approach is that although \( \epsilon \) is small, we have no idea how this small \( \epsilon \) will affect the convergence of the algorithm, since the corresponding quadratic function is no longer a majorization function of the surrogate function.

### C. Smooth Approximations of Non-differentiable Surrogate Functions

To attack the singularity issue of IRLS type algorithms, in this paper we propose to incorporate a small \( \epsilon > 0 \) in a more systematic way, which amounts to solving the problem 6 with a smooth approximation of the non-differentiable surrogate function. The idea is to approximate the non-differentiable surrogate function \( g_p(x) \) with a differentiable function of the following form

\[
g_p^\epsilon(x) = \begin{cases} ax^2, & |x| \leq \epsilon \\
g_p(x) - b_x, & |x| > \epsilon, \end{cases} \tag{17}
\]

which aims at smoothing the non-differentiable surrogate function around zero by a quadratic function. To make the following function \( g_p^\epsilon(x) \) continuous and differentiable at \( x = \pm \epsilon \), the following two conditions are needed \( a\epsilon^2 = g_p^\epsilon(\epsilon) - b, 2a\epsilon = g_p^\epsilon(\epsilon), \) which lead to \( a = \frac{g_p^\epsilon(\epsilon)}{2\epsilon^2}, b = g_p(x) - \frac{g_p^\epsilon(\epsilon)}{2} \epsilon. \) Thus, the smooth approximation of the surrogate function we will employ is

\[
g_p^\epsilon(x) = \begin{cases} \frac{g_p^\epsilon(\epsilon)}{2\epsilon^2} x^2, & |x| \leq \epsilon \\
g_p(x) - g_p(\epsilon) + \frac{g_p^\epsilon(\epsilon)}{2} \epsilon, & |x| > \epsilon, \end{cases} \tag{18}
\]
where \( \epsilon > 0 \) is a constant parameter.

**Example 2.** The smooth approximation of the function \( g_p(x) = |x|^p \), \( 0 < p \leq 1 \) is

\[
g_p^\epsilon(x) = \begin{cases} 
\frac{2}{2-p} |x|^2, & |x| \leq \epsilon \\
|x|^p - (1 - \frac{p}{2}) \epsilon^p, & |x| > \epsilon. 
\end{cases}
\]  
(19)

The case with \( p = 0.5 \) and \( \epsilon = 0.05 \) is illustrated in Fig. 3. When \( p = 1 \), the smooth approximation \( g_p^\epsilon(x) \) is the well known Huber penalty function and the application of Huber penalty as smoothed absolute value has been used in [22] to derive fast algorithms for sparse recovery.

![Figure 3](image-url)

**Figure 3.** The function \( g_p(x) = |x|^\frac{1}{2} \) with \( p = 0.5 \) and its smooth approximation \( g_p^\epsilon(x) \) with \( \epsilon = 0.05 \).

With this smooth approximation, the problem (6) becomes the following smoothed one:

\[
\begin{align*}
\text{maximize} & \quad x^T A x - \rho \sum_{i=1}^n g_p^\epsilon(x_i) \\
\text{subject to} & \quad x^T B x = 1,
\end{align*}
\]  
(20)

where \( g_p^\epsilon(\cdot) \) is the function given by (18). We can now apply the quadratic majorization to the smoothed surrogate functions \( g_p^\epsilon(x_i) \) and the coefficients of the quadratic majorization functions are given in Table I (we have omitted the coefficient \( \epsilon^{(k)} \) since it is irrelevant for the MM algorithm). Now the weight \( w_i^{(k)} \) is well defined for \( x_i^{(k)} = 0 \). Thus, the smooth approximation we have constructed can be viewed as a systematic way to incorporate a small \( \epsilon > 0 \) to deal with the singularity issue of IRLS type algorithms.

Although there is no singularity issue when applying the quadratic majorization to this smoothed problem (20), a natural question is if we solve the smoothed problem, what can we say about the solution with regard to the original problem (6). In the following, we will present some results which aim at answering the question.

**Lemma 3.** Let \( g_p(\cdot) \) be a continuous even function defined on \( \mathbb{R} \), differentiable everywhere except at zero, concave and monotone increasing on \( [0, +\infty) \) with \( g_p(0) = 0 \). Then the smooth approximation \( g_p^\epsilon(\cdot) \) defined by (18) is a global lower bound of \( g_p(x) \) and \( g_p^\epsilon(x) + g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \) is a global upper bound of \( g_p(x) \).

**Proof:** The lemma is quite intuitive and the proof is omitted for lack of space.

**Proposition 4.** Let \( f(x) \) be the objective of the problem (6), with \( g_p(\cdot) \) as in Lemma 3 and \( f_\epsilon(x) \) be the objective of the smoothed problem (20) with \( g_p(\cdot) \) as in (13). Let \( x^* \) be the optimal solution of the problem (6) and \( x^*_\epsilon \) be the optimal solution of the smoothed problem (20). Then \( 0 \leq f(x^*) - f(x^*_\epsilon) \leq \rho \max \left( g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \right) \).

**Proof:** From Lemma 3 it is easy to show that

\[
f_\epsilon(x) \geq f(x) \geq f_\epsilon(x) - \rho \max \left( g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \right), \quad \forall x \in \mathbb{R}^n.
\]  
(21)

Since problems (6) and (20) have the same constraint set, we have

\[
f_\epsilon(x^*_\epsilon) \geq f(x^*_\epsilon).
\]  
(22)

From the fact that \( x^* \) is a global maximizer of problem (6), we know

\[
f(x^*) \geq f(x^*_\epsilon).
\]  
(23)

Combining (21), (22) and (23), yields

\[
f_\epsilon(x^*_\epsilon) \geq f(x^*) \geq f_\epsilon(x^*_\epsilon) \geq f_\epsilon(x^*) - \rho \max \left( g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \right).
\]  
(24)

Thus,

\[
0 \leq f(x^*) - f(x^*_\epsilon) \leq \rho \max \left( g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \right).
\]  
(25)

Since \( g_p(\cdot) \) is concave and monotone increasing on \( [0, +\infty) \), it is easy to show that \( g_p(\epsilon) \geq g_p'(\epsilon) \epsilon \geq 0 \), for any \( \epsilon > 0 \). Hence

\[
g_p(\epsilon) \geq g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \geq 0.
\]  
(26)

Since \( g_p(\cdot) \) is continuous and monotone increasing on \( [0, +\infty) \) and \( g_p(0) = 0 \), we have \( \lim_{\epsilon \downarrow 0} g_p(\epsilon) = 0 \). Together with (26), we can conclude that

\[
\lim_{\epsilon \downarrow 0} \left( g_p(\epsilon) - \frac{g_p'(\epsilon)}{2} \epsilon \right) = 0.
\]  
(27)

Since \( \rho \) and \( n \) are constants, the proof is complete.

**D. Iteratively Reweighted Quadratic Minorization**

With the quadratic reweighted function and the smoothing technique used to deal with the singularity issue, we are now ready to state the algorithm for the approximate SGEP (6).
First, we approximate the non-differentiable surrogate functions $g_p(x_i)$ by smooth functions $g_p^\alpha(x_i)$ and obtain the smoothed problem \([20]\). Then at iteration $k$, we majorize each smoothed surrogate function $g_p^\alpha(x_i)$ at $x_i(k)$ by a quadratic function $u(x_i, x_i(k)) = w_i(k) x_i^2 + c_i(k)$ and solve the resulting minimized problem

$$\begin{align*}
\text{maximize} & \quad x^T (A - \rho \text{Diag}(w(k))) x \\
\text{subject to} & \quad x^T B x = 1,
\end{align*}$$

(28)

which is to find the leading generalized eigenvector of the matrix pair $(A - \rho \text{Diag}(w(k)), B)$, where $w(k) = [w_1(k), \ldots, w_n(k)]^T$ and $w_i(k), i = 1, \ldots, n$ are given in Table I. The method is summarized in Algorithm 1 and we will refer to it as IRQM (Iterative Reweighted Quadratic Minimization), since it is based on iteratively minimizing the penalty function with reweighted quadratic function.

**Algorithm 1** IRQM - Iteratively Reweighted Quadratic Minimization or for the sparse generalized eigenvalue problem \([6]\).

**Require:** $A \in \mathbb{S}_+^n$, $B \in \mathbb{S}_+^{n+}, \rho > 0, \epsilon > 0$  
1: Set $k = 0$, choose $x(0) \in \{x : x^T B x = 1\}$  
2: repeat  
3: Compute $w(k)$ according to Table I.  
4: $x(k+1) \leftarrow$ leading generalized eigenvector of the matrix pair $(A - \rho \text{Diag}(w(k)), B)$  
5: $k \leftarrow k + 1$  
6: until convergence  
7: return $x(k)$

At every iteration of the proposed IRQM algorithm, we need to find the generalized eigenvector of the matrix pair $(A - \rho \text{Diag}(w(k)), B)$ corresponding to the largest generalized eigenvalue. Since $B \in \mathbb{S}_+^{n+}$, a standard approach for this problem is to transform it to a standard eigenvalue problem via the Cholesky decomposition of $B$. Then standard algorithms, such as power iterations (applied to a shifted matrix) and Lanczos method can be used. The drawback of this approach is that a matrix factorization is needed, making it less attractive when this factorization is expensive. Besides, as some $w_i(k)$ become very large, the problem is highly ill-conditioned and standard iterative algorithms may suffer from extremely slow convergence.

To overcome these difficulties, we propose to use a preconditioned steepest ascent method, which is matrix factorization free and employs preconditioning to deal with the ill-conditioning problem. Let us derive the steepest ascent method without preconditioning first. The key step is to reformulate the leading generalized eigenvalue problem as maximizing the Rayleigh quotient

$$R(x) = x^T (A - \rho \text{Diag}(w(k))) x$$

(29)

over the domain $x \neq 0$. Let $x^{(l)}$ be the current iterate, the gradient of $R(x)$ at $x^{(l)}$ is

$$\frac{2}{x^{(l)T} B x^{(l)}} \left( (A - \rho \text{Diag}(w(k))) x^{(l)} - R(x^{(l)}) B x^{(l)} \right),$$

which is an ascent direction of $R(x)$ at $x^{(l)}$. Let $x^{(l)} = (A - \rho \text{Diag}(w(k))) x^{(l)} - R(x^{(l)}) B x^{(l)}$ the steepest ascent method search along the line $x^{(l)} + \tau r^{(l)}$, $\tau \geq 0$ emanating from $x^{(l)}$ for a $\tau$ that maximizes the Rayleigh quotient $R(x^{(l)} + \tau r^{(l)})$. Notice that the Rayleigh quotient $R(x^{(l)} + \tau r^{(l)})$ is a ratio of two quadratic functions in $\tau$. Setting the gradient of $R(x^{(l)} + \tau r^{(l)})$ with respect to $\tau$ equal to 0, we will get a quadratic equation and one root of the quadratic equation gives the steepest ascent. It is worth noting that the coefficients of the quadratic equation can be computed by matrix-vector multiplication and inner product only, thus very efficient.

Though the per-iteration computational complexity of this steepest ascent method is very low, it may converge very slow, especially when some $w_i(k)$ become very large. To accelerate the convergence, we introduce a preconditioner here. Preconditioning is an important technique in iterative methods for solving large system of linear equations, for example the widely used preconditioned conjugate gradient method. It can be used also for eigenvalue problems. In our steepest ascent method, to introduce a positive definite preconditioner $P$, we simply multiply the residual $r^{(l)}$ by $P$. The steepest ascent method with preconditioning for the leading generalized eigenvalue problem \([28]\) is summarized in Algorithm 2. To use the algorithm in practice, the preconditioner $P$ remains to be chosen. For the particular problem of interest, we choose a diagonal $P$ as follows

$$P = \begin{cases} 
\text{Diag} \left( \rho w^{(k)} + |\text{diag}(A)| \right)^{-1}, & \frac{\rho \|w^{(k)}\|_2}{\|\text{diag}(A)\|_2} > 10^2 \\
I_n, & \text{otherwise}
\end{cases}$$

| Surrogate function $g_p(x_i)$ | Smooth approximation $g_p^\alpha(x_i)$ | $u(x_i)$ |
|-----------------------------|---------------------------------|--------|
| $|x|_p, 0 < p \leq 1$     | $\begin{cases} 
\frac{\rho}{2} x_i^{p-2} x_i^2, & |x_i| \leq \epsilon \\
|x_i|^p - (1 - \frac{\rho}{2}) x_i^p, & |x_i| > \epsilon 
\end{cases}$ | $\begin{cases} 
\frac{\rho}{2} x_i^{p-2} x_i^2, & |x_i| \leq \epsilon \\
\frac{1}{2} x_i^{p-2} |x_i|^p - |x_i|, & |x_i| > \epsilon 
\end{cases}$ |
| $\log(1 + |x|_p) / \log(1 + 1/p), p > 0$ | $\begin{cases} 
\frac{1}{2} x_i^{p-2} x_i^2, & |x_i| \leq \epsilon \\
\frac{1}{\log(1 + 1/p) - \log(1 + |x|_p/p)} x_i^{p-2} x_i^2, & |x_i| > \epsilon 
\end{cases}$ | $\begin{cases} 
\frac{1}{2} x_i^{p-2} x_i^2, & |x_i| \leq \epsilon \\
\frac{1}{\log(1 + 1/p) - \log(1 + |x|_p/p)} x_i^{p-2} x_i^2, & |x_i| > \epsilon 
\end{cases}$ |
| $1 - e^{-|x|_p}, p > 0$ | $\begin{cases} 
c^{-e/p} x_i^2, & |x_i| \leq \epsilon \\
(1 - |x|_p) e^{-e/p}, & |x_i| > \epsilon 
\end{cases}$ | $\begin{cases} 
c^{-e/p} x_i^2, & |x_i| \leq \epsilon \\
(1 - |x|_p) e^{-e/p}, & |x_i| > \epsilon 
\end{cases}$ |

Table 1: Smooth approximation $g_p^\alpha(x_i)$ of the surrogate functions $g_p(x_i)$ and the quadratic majorization functions $u(x_i, x_i^{(k)}) = w_i^{(k)} x_i^2 + c_i^{(k)}$ at $x_i^{(k)}$.
In other words, we apply a preconditioner only when some elements of the preconditioner $P$ become relatively large. Note that this preconditioner $P$ we choose here is positive definite, thus the direction $Pr(l)$ is still an ascent direction and the algorithm is still monotonically increasing. For more details regarding preconditioned eigensolvers, the readers can refer to the book [23].

Algorithm 2 Preconditioned steepest ascent method for problem [23].

Require: $A \in S^n_+$, $B \in S^n_{++}$, $w^{(k)}$, $\rho > 0$
1: Set $l = 0$, choose $x^{(l)} \in \{x: x^T B x = 1\}$
2: Let $A = A - \rho \text{Diag}(w^{(k)})$
3: repeat
4: $R(x^{(l)}) = x^{(l)T} A x^{(l)} / x^{(l)T} B x^{(l)}$
5: $r^{(l)} = Ax^{(l)} - R(x^{(l)})B x^{(l)}$
6: $r^{(l)} = Pr(l)$
7: $x^{(l+1)} = x^{(l)} + \tau r^{(l)}$, with $\tau$ chosen to maximize $R(x^{(l)} + \tau r^{(l)})$
8: $x^{(l+1)} = x^{(l)} + \tau r^{(l)}$
9: $l = l + 1$
10: until convergence
11: return $x^{(l)}$

E. Sparse GEP with Special Structure

Until now we have considered the sparse GEP in the general case with $A \in S^n_+$, $B \in S^n_{++}$ and derived an iterative algorithm IRQM. If we assume more properties or some special structure for $A$ and $B$, then we may derive simpler and more efficient algorithms. In the following, we will consider the case where $A \in S^n_+$ and $B = \text{Diag}(b)$, $b \in R^n_{++}$. Notice that although this is a special case of the general sparse GEP, it still includes the sparse PCA problem as a special case where $B = I_n$

We first present two results that will be used when deriving fast algorithms for this special case.

Proposition 5. Given $a \in R^n$, $w, b \in R^n_{++}$, $\rho > 0$, let $I_{min} = \arg \min \{\rho w_i/b_i : i \in \{1, \ldots, n\}\}$, $\mu_{min} = -\min \{\rho w_i/b_i : i \in \{1, \ldots, n\}\}$ and $s = \sum_{i \notin I_{min}} \frac{b_i a_i^2}{(\mu_{min} b_i + \rho w_i)^2}$. Then the problem

$$\max \{2a^T x - \rho x^T \text{Diag}(w)x\} \text{ subject to } x^T \text{Diag}(b)x = 1$$

admits the following solution:

- If $\exists i \in I_{min}$, such that $a_i^2 > 0$ or $s > 1$, then

$$x_i^* = \frac{a_i}{\mu b_i + \rho w_i}, \quad i = 1, \ldots, n,$$

where $\mu > \mu_{min}$ is given by the solution of the scalar equation

$$\sum_{i=1}^n \frac{b_i a_i^2}{(\mu b_i + \rho w_i)^2} = 1.$$  

- Otherwise,

$$x_i^* = \begin{cases} a_i/(\mu_{min} b_i + \rho w_i), & i \notin I_{min} \\ \sqrt{(1-s)/b_i}, & i = \max \{i : i \in I_{min}\} \\ 0, & \text{otherwise.} \end{cases}$$  

Proof: First notice that the problem is a nonconvex QCQP but with only one constraint, thus the strong duality holds [24, 25]. The optimality conditions for this problem are

$$\mu \text{Diag}(b) + \rho \text{Diag}(w) x = a \quad (34)$$
$$x^T \text{Diag}(b)x = 1 \quad (35)$$
$$\mu \text{Diag}(b) + \rho \text{Diag}(w) \succeq 0. \quad (36)$$

Let us define

$$I_{min} = \arg \min \{\rho w_i/b_i : i \in \{1, \ldots, n\}\} \quad (37)$$

and

$$\mu_{min} = -\min \{\rho w_i/b_i : i \in \{1, \ldots, n\}\}. \quad (38)$$

Then the third optimality condition is just $\mu \geq \mu_{min}$, since $w_i > 0$, $\rho > 0$, $b_i > 0$. Let us consider the optimality condition in two different cases:

1) $\mu > \mu_{min}$. In this case, $\mu \text{Diag}(b) + \rho \text{Diag}(w) > 0$, from the first optimality condition we get

$$x = (\text{Diag}(\mu b + \rho w))^{-1} a.$$  

Substituting it into the second optimality condition yields

$$\sum_{i \notin I_{min}} \frac{b_i a_i^2}{(\mu_{min} b_i + \rho w_i)^2} + \sum_{i \in I_{min}} \frac{b_i a_i^2}{(\mu b_i + \rho w_i)^2} = 1, \quad (40)$$

and it is easy to see that the left hand side is monotonically decreasing for $\mu \in (\mu_{min}, +\infty)$. If $\exists i \in I_{min}$, such that $a_i^2 > 0$, then the left hand side of (40) tends to $+\infty$ as $\mu \to \mu_{min}$. Notice that the left hand side goes to 0 as $\mu \to +\infty$, thus we are guaranteed to find a $\mu \in (\mu_{min}, +\infty)$ satisfying equation (40). In practice, we may use bisection method to find the value of $\mu$. If $a_i^2 = 0$, $\forall i \notin I_{min}$, then there still exists a $\mu > \mu_{min}$ that satisfies equation (40) if and only if

$$\sum_{i \notin I_{min}} \frac{b_i a_i^2}{(\mu_{min} b_i + \rho w_i)^2} > 1. \quad (41)$$

If (41) does not hold, it implies $\mu = \mu_{min}$.

2) $\mu = \mu_{min}$. In this case, we cannot compute $x$ via equation (39) anymore. Then to obtain $x$, we first notice from (34) that

$$x_i = \frac{a_i}{\mu_{min} b_i + \rho w_i}, \quad \forall i \notin I_{min}. \quad (42)$$

Then, according to equation (35), for $x_i$, $i \notin I_{min}$, they just need to satisfy the following equation

$$\sum_{i \in I_{min}} \frac{b_i x_i^2}{(\mu_{min} b_i + \rho w_i)^2} = 1 - \sum_{i \notin I_{min}} \frac{b_i a_i^2}{(\mu_{min} b_i + \rho w_i)^2}. \quad (43)$$

When card($I_{min}$) > 1, (43) has infinite number of solutions and we may choose arbitrary one.
Proposition 6. Given \( a \in \mathbb{R}^n \) with \( |a_1| \geq \ldots \geq |a_n| \) and \( \rho > 0 \), then the problem

\[
\begin{align*}
\text{maximize} & \quad a^T x - \rho \|x\|_0 \\
\text{subject to} & \quad \|x\|_2 = 1
\end{align*}
\]  

admits the following solution:

- If \( |a_1| \leq \rho \), then
  \[ x_1^* = \begin{cases} 
  \text{sgn}(a_1), & i = 1 \\
  0, & \text{otherwise}
  \end{cases} \]

- Otherwise,
  \[ x_i^* = \begin{cases} 
  a_i / \sqrt{\sum_{j=1}^{s} a_j^2}, & i \leq s \\
  0, & \text{otherwise}
  \end{cases} \]

where \( s \) is the largest integer \( p \) that satisfies the following inequality

\[
\sqrt{\sum_{i=1}^{p} a_i^2} > \sqrt{\sum_{i=1}^{p-1} a_i^2} + \rho.
\]

Proof: The problem \((44)\) can be rewritten as

\[
\max_{s \in \{1, \ldots, n\}} \left\{ -\rho s + \max_x \left\{ a^T x : \|x\|_2 = 1, \|x\|_0 \leq s \right\} \right\}.
\]

The inner maximization has a closed-form solution

\[
x_i^* = \begin{cases} 
  a_i / \sqrt{\sum_{j=1}^{s} a_j^2}, & i \leq s \\
  0, & \text{otherwise}
  \end{cases}
\]

then the problem becomes

\[
\max_{s \in \{1, \ldots, n\}} \left\{ -\rho s + \sqrt{\sum_{i=1}^{s} a_i^2} \right\}.
\]

It’s easy to see that the optimal \( s \) is the largest integer \( p \) that satisfies the following inequality

\[
\sqrt{\sum_{i=1}^{p} a_i^2} > \sqrt{\sum_{i=1}^{p-1} a_i^2} + \rho.
\]

By squaring both sides of this inequality, we get

\[
a_p^2 > \rho^2 + 2\rho \sqrt{\sum_{i=1}^{p-1} a_i^2},
\]

which means \( |a_p| > \rho \) is a necessary condition for \((51)\) to be satisfied. Thus, in practice to find the largest integer \( p \) that satisfies \((51)\) we only need to check for all \( p \)'s with \( |a_p| > \rho \). If \( 0 < |a_1| \leq \rho \), it is easy to see that the solution of the problem \((44)\) is given by \((45)\).

Let us return to the problem. In this special case, the smoothed problem \((20)\) reduces to

\[
\begin{align*}
\text{maximize} & \quad x^T A x - \rho \|x\|_0 \\
\text{subject to} & \quad \|x\|_2 = 1
\end{align*}
\]

The previously derived IRQM algorithm can be used here, but in that iterative algorithm, we need to find the leading generalized eigenvector at each iteration, for which another iterative algorithm is needed. By exploiting the special structure of this case, in the following we derive a simpler algorithm that at each iteration has a closed-form solution.

Notice that, in this case, \( A \in \mathbb{S}^n_+ \), the first term \( x^T A x \) in the objective is convex and can be minorized by its tangent plane \( 2x^T A x^{(k)}(k) \). So instead of only minorizing the second term, we can minorize both terms. This suggests solving the following minorized problem at iteration \( k \):

\[
\begin{align*}
\text{maximize} & \quad 2x^T A x^{(k)} - \rho x^T \text{Diag}(w^{(k)}) x \\
\text{subject to} & \quad x^T \text{Diag}(b)x = 1,
\end{align*}
\]

where \( x^{(k)} \) is the solution at iteration \( k \) and \( w^{(k)} \) is computed according to Table 1. The problem is a nonconvex QCQP, but by letting \( a = A x^{(k)} \) and \( w = w^{(k)} \), we know from Proposition 5 that it can be solved in closed-form.

It is worth noting that although the derivation above requires \( A \) to be symmetric positive semidefinite, the approach can also deal with the case \( A \in \mathbb{S}^n \) by simply replacing \( A \) with \( A_\alpha = A + \alpha \text{Diag}(b) \), with \( \alpha > 0 \) such that \( A_\alpha \in \mathbb{S}^n_+ \). This iterative algorithm for solving problem \((53)\) is summarized in Algorithm 3.

Algorithm 3: The MM algorithm for problem \((53)\).

Require: \( A \in \mathbb{S}^n_+, b \in \mathbb{R}^n_+, \rho > 0, \epsilon > 0 \)

1: Set \( k = 0 \), choose \( x^{(0)} = \{ x : x^T \text{Diag}(b)x = 1 \} \)
2: repeat
3: \( a = A x^{(k)} \)
4: Compute \( w^{(k)} \) according to Table 1
5: Solve the following problem according to Proposition 5 and set the solution as \( x^{(k+1)} \):
6: \( k = k + 1 \)
7: until convergence
8: return \( x^{(k)} \)

In fact, in this special case, we can apply the MM scheme to solve the original problem \((1)\) directly, without approximating \( \|x\|_0 \), i.e., solving

\[
\begin{align*}
\text{maximize} & \quad x^T A x - \rho \|x\|_0 \\
\text{subject to} & \quad x^T \text{Diag}(b)x = 1.
\end{align*}
\]

First, we define a new variable \( \tilde{x} = \text{Diag}(b)^{-1} x \) and using the fact \( \|\text{Diag}(b)^{-1} x\|_0 = \|\tilde{x}\|_0 \), the problem can be rewritten as

\[
\begin{align*}
\text{maximize} & \quad \tilde{x}^T \tilde{A} \tilde{x} - \rho \|\tilde{x}\|_0 \\
\text{subject to} & \quad \tilde{x}^T \tilde{x} = 1,
\end{align*}
\]

where \( \tilde{A} = \text{Diag}(b)^{-1} A \text{Diag}(b)^{-1} \).

Now the idea is to minorize only the quadratic term by its tangent plane, while keeping the \( \ell_0 \)-norm. Given \( \tilde{x}^{(k)} \) at iteration \( k \), linearizing the quadratic term yields

\[
\begin{align*}
\text{maximize} & \quad 2\tilde{x}^T \tilde{A} \tilde{x}^{(k)} - \rho \|\tilde{x}\|_0 \\
\text{subject to} & \quad \|\tilde{x}\|_2 = 1,
\end{align*}
\]

which has a closed-form solution. To see this, we first define \( a = 2\tilde{A} \tilde{x}^{(k)} \) and sort the entries of vector \( a \) according to the absolute value (only needed for entries with \( |a_i| > \rho \)) in descending order, then Proposition 5 can be readily applied to obtain the solution. Finally, we need to reorder the solution back to the original ordering. This algorithm for solving problem \((53)\) is summarized in Algorithm 4.
Algorithm 4 The MM algorithm for problem (55).

**Require:** \( A \in S^n_+, \ b \in \mathbb{R}^n_+, \ \rho > 0 \)

1. Set \( k = 0 \), choose \( x^{(0)} \in \{ x : x^T x = 1 \} \)
2. Let \( \hat{A} = \text{Diag}(b) - \frac{\rho}{2} \text{Diag}(b) \cdot \frac{1}{2} \)
3. \textbf{repeat}
4. \( a = 2 \hat{A} x^{(k)} \)
5. Sort \( a \) with the absolute value in descending order.
6. Solve the following problem according to Proposition 6
\[
\arg \max_{x} \{ a^T x - \rho \| x \|_0 : \| \hat{x} \|_2 = 1 \}
\]
7. Reorder \( x^{(k+1)} \)
8. \( k = k + 1 \)
9. \textbf{until} convergence
10. \textbf{return} \( x = \text{Diag}(b) - \frac{1}{2} \hat{x}^{(k)} \)

IV. Convergence Analysis

The algorithms proposed in this paper are all based on the minorization-maximization scheme, thus according to subsection III-A, we know that the sequence of objective values evaluated at \( \{ x^{(k)} \} \) generated by the algorithms is non-decreasing. Since the constraint sets in our problems are compact, the sequence of objective values is bounded. Thus, the sequence of objective values is guaranteed to converge to a finite value. The monotonicity makes MM algorithms very stable. In this section, we will analyze the convergence property of the sequence \( \{ x^{(k)} \} \) generated by the algorithms.

Let us consider the IRQM algorithm in Algorithm 1 in which the minorization-maximization scheme is applied to the smoothed problem (20). In the problem, the objective is neither convex nor concave and the constraint set is also nonconvex. But as we shall see later, after introducing a technical assumption on the surrogate function \( g_p(x) \), the problem is equivalent to a problem which maximizes a convex function over a convex set and we will prove that the sequence generated by the IRQM algorithm converges to the stationary point of the equivalent problem. First, let us give the assumption and present some results that will be useful later.

**Assumption 1.** The surrogate function \( g_p(x) \) is twice differentiable on \((0, +\infty)\) and its gradient \( g'_p(x) \) is convex on \((0, +\infty)\).

It is easy to verify that the three surrogate functions listed in Table 1 all satisfy this assumption. With this assumption, the first result shows that the smooth approximation \( g_p(x) \) we have constructed is Lipschitz continuously differentiable.

**Lemma 7.** Let \( g_p(\cdot) \) be a continuous even function defined on \( \mathbb{R} \), differentiable everywhere except at zero, concave and monotone increasing on \((0, +\infty)\) with \( g_p(0) = 0 \). Let Assumption 7 be satisfied. Then the smooth approximation \( g_p'(x) \) defined by (18) is Lipschitz continuously differentiable with Lipschitz constant \( L = \max \{ \frac{g_p'(x)}{x} : |g_p''(e)| \} \).

**Proof:** See Appendix A

Next, we recall a useful property of Lipschitz continuously differentiable functions [26].

**Proposition 8.** If \( f : \mathbb{R}^n \to \mathbb{R} \) is Lipschitz continuously differentiable on a convex set \( C \) with some Lipschitz constant \( L \), then \( \varphi(x) = f(x) + \frac{\rho}{2} x^T x \) is a convex function on \( C \) for every \( \alpha \geq L \).

The next result then follows, showing that the smoothed problem (20) is equivalent to a problem in the form of maximizing a convex function over a compact set.

**Lemma 9.** There exists \( \alpha > 0 \) such that \( x^T (A + \alpha B) x - \rho \sum_{i=1}^n g_p'(x_i) \) is convex and the problem
\[
\begin{align*}
\max_{x} & \quad x^T (A + \alpha B) x - \rho \sum_{i=1}^n g_p'(x_i) \\
\text{subject to} & \quad x^T B x = 1
\end{align*}
\]

is equivalent to the problem (20) in the sense that they admit the same set of optimal solutions.

**Proof:** From Lemma 7 it is easy to see that \( x^T A x - \rho \sum_{i=1}^n g_p'(x_i) \) is Lipschitz continuously differentiable. Assume the Lipschitz constant of its gradient is \( L \), then according to Proposition 8 \( x^T (A + \frac{\alpha}{L}) x - \rho \sum_{i=1}^n g_p'(x_i) \) is convex. Since \( B \) is positive definite, \( \lambda_{\min}(B) > 0 \). By choosing \( \alpha \geq \frac{L}{2\lambda_{\min}(B)} \), we have that \( x^T (\alpha B - \frac{\alpha}{L}) x \) is convex. The sum of the two convex functions, i.e., \( x^T (A + \alpha B) x - \rho \sum_{i=1}^n g_p'(x_i) \), is convex.

Since the additional term \( \alpha x^T B x \) is just a constant \( \alpha \) over the constraint set \( x^T B x = 1 \), it is obvious that any solution of problem (55) is also a solution of problem (20) and vice versa.

Generally speaking, maximizing a convex function over a compact set remains a hard nonconvex problem. There is some consolation, however, according to the following result in convex analysis [27].

**Proposition 10.** Let \( f : \mathbb{R}^n \to \mathbb{R} \) be a convex function. Let \( S \in \mathbb{R}^n \) be an arbitrary set and \( \text{conv}(S) \) be its convex hull. Then
\[
\sup \{ f(x) | x \in \text{conv}(S) \} = \sup \{ f(x) | x \in S \},
\]
where the first supremum is attained only when the second (more restrictive) supremum is attained.

According to Proposition 10, we can further relax the constraint \( x^T B x = 1 \) in problem (55) to \( x^T B x \leq 1 \), namely, the problem
\[
\begin{align*}
\max_{x} & \quad x^T (A + \alpha B) x - \rho \sum_{i=1}^n g_p'(x_i) \\
\text{subject to} & \quad x^T B x \leq 1
\end{align*}
\]

is still equivalent to problem (20) in the sense that they admit the same set of optimal solutions.

Let us denote the objective function of problem (59) by \( f_p(x) \) and define \( B = \{ x \in \mathbb{R}^n | x^T B x \leq 1 \} \), then a point \( x^* \) is referred to as a stationary point of problem (59) if
\[
\nabla f_p(x^*)^T (x - x^*) \leq 0, \quad \forall x \in B.
\]

**Theorem 11.** Let \( \{ x^{(k)} \} \) be the sequence generated by the IRQM algorithm in Algorithm 1. Then every limit point of
the sequence \( \{x^{(k)}\} \) is a stationary point of the problem (59), which is equivalent to the problem (20).

Proof: Denote the objective function of the problem (20) by \( f_\alpha(x) \) and its quadratic minorization function at \( x^{(k)} \) by \( q(x|x^{(k)}) \), i.e., \( q(x|x^{(k)}) = x^T (A - \rho \text{Diag}(w^{(k)})) x \). Denote \( S = \{ x \in \mathbb{R}^n | x^T B x = 1 \} \) and \( B = \{ x \in \mathbb{R}^n | x^T B x \leq 1 \} \). According to the general MM framework, we have

\[
f_\alpha(x^{(k+1)}) \leq q(x^{(k+1)}|x^{(k)}) \leq q(x^{(k)}|x^{(k)}) = f_\alpha(x^{(k)}),
\]

which means \( \{f_\alpha(x^{(k)})\} \) is a non-decreasing sequence.

Assume that there exists a converging subsequence \( x^{(k_j)} \to x^\infty \), then

\[
q(x^{(k_{j+1})}|x^{(k_{j+1})}) = f_\alpha(x^{(k_{j+1})}) \geq f_\alpha(x^{(k_j)}) \geq q(x^{(k_j)}|x^{(k_j)}) \forall x \in S.
\]

Letting \( j \to +\infty \), we obtain

\[
q(x^\infty|x^\infty) \geq q(x|x^\infty), \forall x \in S.
\]

It is easy to see that we can always find \( \alpha > 0 \) such that \( q_\alpha(x|x^\infty) = q(x|x^\infty) + \alpha x^T B x \) is convex and \( x^\infty \) is still a global maximizer of \( q_\alpha(x|x^\infty) \) over \( S \). Due to Lemma 9 we can always choose \( \alpha \) large enough such that \( f_\alpha(x) = f_\alpha(x) + \alpha x^T B x \) is also convex. By Proposition 10 we have

\[
q_\alpha(x^\infty|x^\infty) \geq q_\alpha(x|x^\infty), \forall x \in B,
\]

e., \( x^\infty \) is a global maximizer of \( q_\alpha(x|x^\infty) \) over the convex set \( B \). As a necessary condition, we get

\[
\nabla q_\alpha(x^\infty|x^\infty)^T (x - x^\infty) \leq 0, \forall x \in B.
\]

Since \( \nabla f_\alpha^*(x^\infty) = \nabla q_\alpha(x^\infty|x^\infty) \) by construction, we obtain

\[
\nabla f_\alpha^*(x^\infty)^T (x - x^\infty) \leq 0, \forall x \in B,
\]

implying that \( x^\infty \) is a stationary point of the problem (59), which is equivalent to the problem (20) according to Lemma 10 (and Proposition 10).

The convergence of the Algorithm 8 can be proved similarly, since the minorization function applied can also be convexified.

V. NUMERICAL EXPERIMENTS

To compare the performance of the proposed algorithms with existing ones on the sparse generalized eigenvalue problem (SGEP) and some of its special cases, we present some experimental results in this section. All experiments were performed on a PC with a 3.20GHz i5-3470 CPU and 8GB RAM.

A. Sparse Generalized Eigenvalue Problem

In this subsection, we evaluate the proposed IRQM algorithm for the sparse generalized eigenvalue problem in terms of computational complexity and the ability to extract sparse generalized eigenvectors. The benchmark method considered here is the DC-SGEP algorithm proposed in [10], [11], which is based on D.C. (difference of convex functions) programming and minorization-maximization (to the best of our knowledge, this is the only algorithm proposed for this case). The problem that DC-SGEP solves is just (6) with the surrogate function \( g_p(x) = \log(1 + |x|/p) \log(1 + 1/p) \), but the equality constraint \( x^T B x = 1 \) is relaxed to \( x^T B x \leq 1 \). The DC-SGEP algorithm requires solving a convex quadratically constrained quadratic program (QCQP) at each iteration, which is solved by the solver Mosek [12] in our experiments. In the experiments, the stopping condition is \(|f(x^{(k+1)}) - f(x^{(k)})|/\max(1,|f(x^{(0)})|) \leq 10^{-5}\) for both algorithms. For the proposed IRQM algorithm, the smoothing parameter is set to be \( \epsilon = 10^{-8} \).

1) Computational Complexity: In this subsection, we compare the computational complexity of the proposed IRQM Algorithm 5 for SGEP with the DC-SGEP algorithm. The surrogate function \( g_p(x) = \log(1 + |x|/p) \log(1 + 1/p) \) is used for both algorithms in this experiment. The data matrices \( A \in \mathbb{R}^n \) and \( B \in \mathbb{S}_d^+ \) are generated as \( A = C + G^T \) and \( B = D^T D \), with \( C \in \mathbb{R}^{n \times n} \), \( D \in \mathbb{R}^{1 \times n \times n} \) and the entries of both \( C \) and \( D \) independent, identically distributed and following \( \mathcal{N}(0,1) \). For both algorithms, the initial point \( x^{(0)} \) is chosen randomly with each entry following \( \mathcal{N}(0,1) \) and then normalized such that \( (x^{(0)})^T B x^{(0)} = 1 \). The parameter \( p \) of the surrogate function is chosen to be 1 and the regularization parameter is \( \rho = 0.1 \).

The computational time for problems with different sizes is shown in Figure 4. The results are averaged over 100 independent trials. From Figure 4 we can see that the proposed IRQM algorithm is almost two orders of magnitude faster than the DC-SGEP algorithm. It is worth noting that the solver Mosek which is used to solve the QCQPs for the DC-SGEP algorithm is well known for its efficiency, while the IRQM algorithm is entirely implemented in Matlab. The lower computational complexity of the IRQM algorithm, compared with the DC-SGEP algorithm, attributes to both the lower per iteration computational complexity and the faster convergence. To show this, the evolution of the objective function for one trial with \( n = 100 \) is plotted in Figure 5 and we can see that the proposed IRQM algorithm takes much fewer iterations to converge. One may also notice that the two algorithms converge to the same objective value, but this does not hold in general since the problem is nonconvex.

2) Random Data with Underlying Sparse Structure: In this section, we generate random matrices \( A \in \mathbb{S}_d^n \) and \( B \in \mathbb{S}_d^{n \times n} \) such that the matrix pair \((A,B)\) has a few sparse generalized eigenvectors. To achieve this, we synthesize the data through the generalized eigenvalue decomposition \( A = V^{-T} \text{Diag}(d) V^{-1} \) and \( B = V^{-T} V^{-1} \), where the first \( k \) columns of \( V \in \mathbb{R}^{n \times n} \) are pre-specified sparse vectors and the remaining columns are generated randomly, \( d \) is the vector of the generalized eigenvectors.

Here, we choose \( n = 100 \) and \( k = 2 \), where the two sparse generalized eigenvectors are specified as follows

\[
\begin{cases}
V_{i,1} = \frac{1}{\sqrt{2}} & \text{for } i = 1, \ldots, 5, \\
V_{i,1} = 0 & \text{otherwise},
\end{cases}
\]

\[
\begin{cases}
V_{i,2} = \frac{1}{\sqrt{2}} & \text{for } i = 5, \ldots, 10, \\
V_{i,2} = 0 & \text{otherwise},
\end{cases}
\]

1Mosek, available at http://www.mosek.com/
and the generalized eigenvalues are chosen as

\[
\begin{align*}
  d_1 &= 10 \\
  d_2 &= 8 \\
  d_i &= 12, & \text{for } i = 3, 4, 5 \\
  d_i &\sim \mathcal{N}(0, 1), & \text{otherwise}.
\end{align*}
\]

We generate 200 pairs of \((A, B)\) as described above and employ the algorithms to compute the leading sparse generalized eigenvector \(x_1 \in \mathbb{R}^{100}\), which is hoped to be close to \(V_{:,1}\). The underlying sparse generalized eigenvector \(V_{:,1}\) is considered to be successfully recovered when \(\|x_1 - V_{:,1}\|_2 \leq 0.01\). For the proposed IRQM algorithm, all the three surrogate functions listed in Table 1 are considered and we call the resulting algorithms “IRQM-log”, “IRQM-Lp” and “IRQM-exp”, respectively. For all the algorithms, the initial point \(x^{(0)}\) is chosen randomly. Regarding the parameter \(p\) of the surrogate function, two values, namely 1 and 0.1, are compared. The corresponding performance along the whole path of the regularization parameter \(\rho\) is plotted in Fig. 6 and 7, respectively.

From Fig. 6 we can see that for the case \(p = 1\), the best chance of exact recovery achieved by the three IRQM algorithms are very close and all higher than that achieved by the DC-SGEP algorithm. From Fig. 7 we can see that as \(p\) becomes smaller, the best chance of exact recovery achieved by IRQM-exp, IRQM-log and DC-SGEP stay almost the same as in the case \(p = 1\) (in fact decrease a little bit), but the performance of IRQM-Lp degrades a lot. This may be explained by the fact that as \(p\) becomes smaller, the surrogate function \(|x|^p\) tends to the function \(\text{sgn}(x)|x|\) much faster than the other two surrogate functions. So when \(p = 0.1\), it is much more pointed and makes the algorithm easily get stuck at some local point. In this sense, the log-based and exp-based surrogate functions seem to be more robust.

B. Sparse Principal Component Analysis

In this section, we consider the special case of the sparse generalized eigenvalue problem in which the matrix \(B\) is the identity matrix, i.e., the sparse PCA problem, which has received most of the recent attention in the literature. In this case, the matrix \(A\) is usually a (scaled) covariance matrix. Although there exists a vast literature on sparse PCA, most popular algorithms are essentially variations of the generalized
power method (GPower) proposed in [2]. Thus we choose the GPower methods, namely GPower$r_1$ and GPower$r_6$, as the benchmarks in this section. The Matlab code of the GPower algorithms was downloaded from the authors’ website. For the proposed Algorithm [5] the surrogate function is chosen to be $g_p(x) = |x|^p$, such that the penalty function is just the $f_1$-norm, which is the same as in GPower$r_1$. We call the resulting algorithm ”MM$r_1$$p” and the Algorithm [4] is referred to as ”MM$r_6$$p” in this section.

Note that for GPower methods, direct access to the original data matrix $C$ is required. When only the covariance matrix is available, a factorization of the form $A = C^T C$ is needed (e.g., by eigenvalue decomposition or by Cholesky decomposition). If the data matrix $C$ is of size $m \times n$, then the per-iteration computational cost is $O(mn)$ for all the four algorithms under consideration.

1) Random Data Drawn from a Sparse PCA Model: In this section, we follow the procedure in [6] to generate random data with a covariance matrix having sparse eigenvectors. To achieve this, we first construct a covariance matrix through the following the procedure in [6] to generate random data with a covariance matrix having sparse eigenvectors. To achieve this, we first construct a covariance matrix through the eigendecomposition $A = V \text{Diag}(d) V^T$, where the first $k$ columns of $V \in \mathbb{R}^{m \times n}$ are pre-specified sparse orthonormal vectors. A data matrix $C \in \mathbb{R}^{m \times n}$ is then generated by drawing $m$ samples from a zero-mean normal distribution with covariance matrix $A$, that is, $C \sim \mathcal{N}(0, A)$.

Following the settings in [7], we choose $n = 500$, $k = 2$, and $m = 50$, where the two orthonormal eigenvectors are specified as follows

\begin{align*}
V_{1,1} &= \frac{1}{\sqrt{10}} \quad \text{for } i = 1, \ldots, 10, \\
V_{1,2} &= \frac{1}{\sqrt{10}} \quad \text{for } i = 11, \ldots, 20, \\
V_{1,1} &= 0 \quad \text{otherwise}, \\
V_{1,2} &= 0 \quad \text{otherwise}.
\end{align*}

The eigenvalues are fixed at $d_1 = 400$, $d_2 = 300$ and $d_i = 1$, for $i = 3, \ldots, 500$.

We randomly generate 500 data matrices $C \in \mathbb{R}^{m \times n}$ and employ the four algorithms to compute the leading sparse eigenvector $x_1 \in \mathbb{R}^{500}$, which is hoped to recover $V_{1,1}$. We consider the underlying sparse eigenvector $V_{1,1}$ is successfully recovered when $|x_1^T V_{1,1}| > 0.99$. The chance of successful recovery over a wide range of regularization parameter $\rho$ is plotted in Figure 8. The horizontal axis shows the normalized regularization parameter, that is $\rho/\max_i \|C_{i,:}\|_2$ for GPower$r_1$, and $\rho/\max_i \|C_{i,:}\|_2$ for GPower$r_6$ and MM$r_6$. For MM$r_1$ algorithm, we use $\rho/\left(2 \|C^T C\|_{\infty, 2}\right)$, where $\|\cdot\|_{\infty, 2}$ is the operator norm induced by $\|\cdot\|_\infty$ and $\|\cdot\|_2$. From the figure, we can see that the highest chance of exact recovery achieved by the four algorithms is the same and for all algorithms it is achieved over a relatively wide range of $\rho$.

2) Gene Expression Data: DNA microarrays allow measuring the expression level of thousands of genes at the same time and this opens the possibility to answer some complex biological questions. But the amount of data created in an experiment is usually large and this makes the interpretation of these data challenging. PCA has been applied as a tool in the studies of gene expression data and their interpretation [28].

Naturally, sparse PCA, which extracts principal components with only a few nonzero elements can potentially enhance the interpretation.

In this subsection, we test the performance of the algorithms on gene expression data collected in the breast cancer study by Bild et al. [29]. The data set contains 158 samples over 12625 genes, resulting in a $158 \times 12625$ data matrix. Figure 9 shows the explained variance versus cardinality for five algorithms, including the simple thresholding scheme. The proportion of explained variance is computed as $\frac{x_{SPCA}^T (C^T C) x_{SPCA}}{x_{PCA}^T (C^T C) x_{PCA}}$, where $x_{SPCA}$ is the sparse eigenvector extracted by sparse PCA algorithms, $x_{PCA}$ is the true leading eigenvector and $C$ is the data matrix. The simple thresholding scheme first computes the regular principal component $x_{PCA}$ and then keeps a required number of entries with largest absolute values. From the figure, we can see that the proportion of variance being explained increases as the cardinality increases as expected. For a fixed cardinality, the two GPower algorithms and the two proposed MM algorithms can explain almost the same amount of variance, all higher than the simple thresholding scheme, especially when the cardinality is small.
VI. Conclusions

We have developed an efficient algorithm IRQM that allows to obtain sparse generalized eigenvectors of a matrix pair. After approximating the \(\ell_0\)-norm penalty by some nonconvex surrogate functions, the minorization-maximization scheme is applied and the sparse generalized eigenvalue problem is turned into a sequence of regular generalized eigenvalue problems. The convergence to a stationary point is proved. Numerical experiments show that the proposed IRQM algorithm outperforms an existing algorithm based on D.C. programming in terms of both computational cost and support recovery. For sparse generalized eigenvalue problems with special structure (but still including sparse PCA as a special instance), two more efficient algorithms that have a closed-form solution at every iteration are derived again based on the minorization-maximization scheme. On both synthetic random data and real-life gene expression data, the two algorithms are shown experimentally to have similar performance to the state-of-the-art.

APPENDIX A

Proof of Lemma 1

Proof: From the way \(g_p(x)\) is constructed, it is continuously differentiable. It remains to show that the gradient

\[
(g_p'(x)) = \begin{cases} \frac{g_p'(x)}{g_p(x)}, & |x| \leq \epsilon \\ \frac{g_p(x)}{g_p'(x)}, & x > \epsilon \\ \end{cases}
\]

is Lipschitz continuous. From the fact that \(g_p(x)\) is concave and monotone increasing on \((0, +\infty)\), we know that \(g_p'(x)\) is non-increasing on \((0, +\infty)\) and \(g_p'(x) > 0\). Since \(g_p'(x)\) is an even function, \(g_p'(x)\) is odd. Thus, \(g_p'(x)\) is non-increasing on \((-\infty, -\epsilon)\), linearly increasing on \([-\epsilon, \epsilon]\) and non-increasing on \((\epsilon, +\infty)\). In addition, \(g_p'(x)\) \(\leq 0\) when \(x < 0\) and \(g_p'(x) \geq 0\) when \(x > 0\). With \(g_p'(x)\) having these properties, to show the Lipschitz continuity of \(g_p'(x)\), it is sufficient to show that \(g_p'(x)\) is Lipschitz continuous on \([-\epsilon, \epsilon]\) and \((\epsilon, +\infty)\) respectively.

On \([-\epsilon, \epsilon]\), \(g_p'(x) = \frac{g_p(x)}{g_p'(x)}\), which is Lipschitz continuous with Lipschitz constant \(\frac{1}{\epsilon}\).

On \((\epsilon, +\infty)\), \(g_p'(x) = g_p'(x)\), from Assumption II we know that \(g_p'(x)\) is convex and differentiable on \((0, +\infty)\). Since \(g_p'(x)\) is also non-increasing, we can conclude that \(g_p'(x) \leq 0\) and is non-decreasing on \((0, +\infty)\). Thus, on \((\epsilon, +\infty)\), \(g_p'(x)\) is bounded by \(g_p'(\epsilon)\) and the Lipschitz continuity of \(g_p'(x)\) on \((\epsilon, +\infty)\) follows.
