Abstract

While oxygen-17 NMR is increasingly being used for elucidating the structure and reactivity of complex molecular and materials systems, much effort is still required for it to become a routine analytical technique. One of the main difficulties for its development comes from the very low natural abundance of oxygen-17 (0.04%), which implies that isotopic labeling is generally needed prior to NMR analyses. However, $^{17}$O-enrichment protocols are often unattractive in terms of cost, safety, and/or practicality, even for compounds as simple as metal oxides. Here, we demonstrate how mechanochemistry can be used in a highly efficient way for the direct $^{17}$O-isotopic labeling of a variety of s-, p- and d-block oxides which are of major interest for the preparation of functional ceramics and glasses: Li$_2$O, CaO, Al$_2$O$_3$, SiO$_2$, TiO$_2$, and ZrO$_2$. For each oxide, the enrichment step was performed under ambient conditions in less than 1 hour and at low cost, which makes these synthetic approaches highly appealing in comparison to the existing literature. Using high-resolution $^{17}$O solid state NMR and Dynamic Nuclear Polarization, atomic-level insight into the enrichment process is achieved, especially for titania and alumina. Indeed, it was possible to demonstrate that enriched oxygen sites are present not only at the surface, but also within the oxide particles. Moreover, information on the actual reactions occurring during the milling step could be obtained by $^{17}$O NMR, both in terms of their kinetics and the nature of the reactive species. Finally, it was demonstrated how high resolution $^{17}$O NMR can be used for studying the reactivity at the interfaces between different oxide particles during ball-milling, especially in cases when X-ray diffraction techniques are uninformative. More generally, such investigations will be useful not only for producing $^{17}$O-enriched precursors efficiently, but also for understanding better mechanisms of mechanochemical processes themselves.
Introduction

Oxygen, as an element, is present in the majority of natural and synthetic materials. It is thus essential to have access to information about the local binding environment around this element to be able to rationalize structure - properties relationships in a variety of systems. Oxygen-17 NMR spectroscopy is one of the most promising spectroscopic techniques for this. Indeed, thanks to the very wide range of variation of $^{17}$O NMR parameters, detailed insight into the bulk and surface structure of a variety of materials can be obtained. For example, recent studies have used $^{17}$O NMR to elucidate the structure of porous materials like zeolites and metal organic frameworks, of mixed metal oxides used as electrode materials, or of nanoparticle surfaces.

Natural abundance $^{17}$O NMR unfortunately suffers from a very poor absolute signal sensitivity, due to the very low abundance of the NMR-active isotope (only 0.04%). This implies that enriching the compounds of interest in $^{17}$O is generally necessary to be able to perform high-resolution $^{17}$O NMR studies. Until recently, this has actually hampered the large-scale development of $^{17}$O NMR spectroscopy, due to the lack of cost-efficient and user-friendly enrichment protocols. Indeed, some of the early labeling schemes employed excessive amounts of expensive $^{17}$O-enriched precursors (H$_2$-$^{17}$O or $^{17}$O$_2$), and/or were experimentally constraining, due to the need to operate under inert atmosphere or at high temperatures, or because of the excessive experimental times (lasting hours or days). In the case of oxides, among the different labeling procedures proposed, those based on sol-gel chemistry have found some success for the preparation of $^{17}$O-enriched phases. However, they rely on the availability of the metal alkoxide precursors, and also require optimizing not only the hydrolysis and condensation steps, but also the drying step, in order to remove the alcohol by-product from the reaction mixture and produce a dry gel which can be then converted into the metal oxide of interest. More recently, affordable and practical $^{17}$O-enrichment protocols have been proposed, either for the direct labeling of the inorganic or hybrid materials of interest, or for the labeling of the precursors which can then be used for preparing these materials. In both cases, mechanochemistry techniques like ball-milling (BM) have been shown to be particularly attractive.

In ball-milling, mechanical forces are applied to solid particles, in order to mix them efficiently, alter their size and shape, and make them react at their interfaces. The addition of small amounts of liquid during the milling process (typically in the order of 0.1 μL/mg of sample) can have a significant impact on the course of the reactions, such as accelerating their speed. This general approach, which is referred to as “liquid assisted grinding” (LAG), served as a basis of the development of new $^{17}$O-enrichment schemes. Indeed, we showed that using $^{17}$O-enriched water as a liquid-grinding assistant, it was possible to enrich in oxygen-17 a variety of organic and inorganic compounds of synthetic interest, including metal hydroxides like Mg(OH)$_2$, Ca(OH)$_2$ and Al(OH)$_3$. These were then converted into the corresponding metal oxides by heat-treatment under inert atmosphere, leading to the formation of $^{17}$O-labeled MgO, CaO and Al$_2$O$_3$ (Scheme 1).
The possibility to easily produce $^{17}$O-enriched oxides is highly attractive, as these can then be engaged in a variety of reactions using previously established synthetic protocols, to prepare enriched ceramics, glasses, or hybrid organic-inorganic materials. However, in order to further broaden the scope of oxides which can be enriched in $^{17}$O using mechanochemistry, it appeared to us necessary to look into synthetic approaches which would not require starting from a hydroxide. Indeed, in contrast to Mg(OH)$_2$, Ca(OH)$_2$ and Al(OH)$_3$, a well-defined and stable form of the starting hydroxide may not be readily available, as is the case for titania and silica. Moreover, the initial labeling step of the hydroxide by LAG proceeds by equilibration in the presence of $^{17}$O-enriched water (scheme 1), which is not optimal in terms of enrichment yield, because the by-product formed after full isotopic scrambling will be partially-enriched H$_2$*O (with the same $^{17}$O-labeling level as the final labeled hydroxide). Using oxides as precursors instead of the hydroxides should allow both these issues to be addressed at the same time. Preliminary evidence that oxides could potentially be directly enriched in $^{17}$O using LAG was provided in a recent study, in which $^{17}$O-labeled alkali transition metal oxides like Li$_2$MO$_3$ (M = Mn, Ru) were synthesized by performing an initial LAG step on non-enriched oxide precursors in the presence of $^{17}$O-enriched water, followed by a heat-treatment at high temperature. However, no detail regarding the mechanisms by which the isotopic labeling was occurring was proposed, making it difficult to determine at what moment of the reaction the enrichment had taken place, and how to adapt this strategy to other materials systems in order to achieve optimal labeling for high resolution $^{17}$O NMR.

In this article, we study the reactivity of a selection of oxides under LAG using $^{17}$O-labeled water, with the overall goal of producing $^{17}$O-enriched compounds of synthetic interest for the elaboration of advanced functional materials. First, an improved strategy for preparing Ca*O will be described, calcium oxide being of interest for the elaboration of bioceramics and bioglasses. Its extension to the synthesis of Li$_2$*O is also presented, this precursor being important for preparing lithium-based batteries and ion-conducting glasses. Then, the direct labeling of four widely-used oxides of different composition and crystallinity (silica, alumina, titania and zirconia) will be discussed, providing insight into the isotopic enrichment process using high-resolution $^{17}$O NMR and DNP (Dynamic Nuclear Polarization) analyses. Besides the interest for direct and efficient $^{17}$O-labeling, it will be shown how our approach offers new opportunities for understanding mechanochemical processes at the atomic level.

Scheme 1. Strategy previously proposed for the $^{17}$O-labeling of Mg-, Ca- and Al- oxides, starting from their hydroxides.\textsuperscript{18}
Results and discussion

1/ Improved LAG approach for the $^{17}$O-labeling of s-block metal oxides

We first focused on improving the labeling strategy we had previously proposed for enriching calcium oxide. More specifically, in order to avoid the initial equilibration step (scheme 1) and to achieve a better enrichment level of the intermediate hydroxide, we started from the non-labeled oxide CaO, and hydrolyzed it by mechanochemistry to produce Ca(*OH)$_2$ (scheme 2). The idea here is that all the $^{17}$O label introduced as H$_2^*$O during the LAG step reacts with CaO to form the $^{17}$O-enriched hydroxide.

The BM conditions required to perform the hydrolysis step were initially tested using non-labeled water, by analyzing the reaction medium by powder X-ray diffraction (PXRD). It was found that after 1 hour milling of CaO at 25 Hz in the presence of 1 equivalent of water, complete conversion into the hydroxide phase occurred. Using these synthetic conditions with $^{17}$O-enriched water, $^{17}$O-labeled Ca(*OH)$_2$ was then obtained, as shown by PXRD (Figure 1a) and $^{17}$O Magic Angle Spinning (MAS) solid state NMR (Figure 1b, top). This phase could then be transformed into enriched Ca*O by heat treatment under an inert atmosphere (Figure 1b, bottom).

**Scheme 2.** Alternative strategy proposed here for the $^{17}$O-labeling of Ca oxide.

**Figure 1.** a/ PXRD analyses before and after LAG: CaO precursor obtained after heat-treatment of commercial Ca(OH)$_2$ (top), and enriched phase recovered after LAG in the presence of H$_2^{*}$O (bottom). “●” and “○” symbols correspond to the diffraction peaks expected for CaO (ICSD # 163628) and Ca(OH)$_2$ (ICSD #15471), respectively; b/ $^{17}$O solid state NMR spectra of $^{17}$O-enriched Ca(*OH)$_2$ (prepared by LAG of CaO using H$_2^{*}$O) and Ca*O (obtained after heat-treatment of Ca(*OH)$_2$). These $^{17}$O MAS NMR spectra are in agreement with previous measurements at this magnetic field.
Based on the above, it is clear that direct conversion of oxides like CaO into their hydroxides can be achieved by BM in the presence of stoichiometric amounts of $^{17}$O-enriched water, which is an improvement for the production of labeled hydroxides like Ca(\(^{17}\)OH)$_2$. Using a similar approach, the labeling of other s-block oxides like Li$_2$O could be achieved, which provide attractive alternatives in comparison to existing protocols, as discussed in supporting information S1. As detailed below, the extension of this type of approach to oxides of the p- and d- blocks was then studied, in order to expand the scope of precursors which could be enriched by this technique.

2/ $^{17}$O-labeling of p and d-block oxides using LAG

2a/ Enrichment of SiO$_3$, Al$_2$O$_3$, TiO$_2$ and ZrO$_2$: structural analyses after 1 hour LAG

Silica, alumina, titania, and zirconia were selected for the $^{17}$O labeling tests on p- and d-block oxides, due to their numerous usages for the preparation of functional materials. For each of these phases, the starting materials were commercially available porous samples with relatively high surface areas (all above 80 m$^2$/g), as this was expected to favor surface-reactions with the enriched water during BM. Based on scanning electron microscopy (SEM) and PXRD analyses, each precursor was initially composed of agglomerated nanoparticles of ~10 to 20 nm diameter, but with different crystallinity. Indeed, while the silica precursor was fully amorphous, the three others gave diffraction peaks in XRD, which could be assigned to the anatase phase for titania, to the monoclinic polymorph for zirconia, and to a mixture of γ and δ polymorphs for alumina (see Figure 2, inserts).

Each compound was milled in presence of stoichiometric amounts of $^{17}$O-enriched water, for durations up to 1 hour. The initial LAG conditions were set such that 1 equivalent of “MO$_x$” (y = 2 for M = Si, Ti, Zr, and y = 3/2 for M = Al) was reacted with 1 equivalent of H$_2$*O, as a means to minimize losses of H$_2$*O, if the BM hydrolysis reaction were to be incomplete. Milled samples were characterized by PXRD, nitrogen adsorption volumetry, SEM, energy dispersive X-ray spectroscopy (EDXS), and $^{17}$O MAS NMR (see Figure 2 and Figures S2 to S5).

After 1 hour of LAG, no new phase was observed by PXRD, and the diffractograms of all phases were essentially the same as the ones recorded before milling (Figure 2, inserts). In SEM, the presence of agglomerated nanoparticles could still be observed, without any significant change in particle size, except in the case of silica, for which nanoparticles appeared to have merged into forming larger entities. More striking differences were found in the nitrogen adsorption-desorption isotherms of all oxides before and after milling (Figures S2 to S5), due to changes in surface area and/or pore geometry. In the case of silica, a decrease in porosity was observed (the surface area being reduced by a factor of ~ 3), while in the case of alumina, the main change concerned the pore geometry (as the surface area remained essentially the same as before milling). For titania and zirconia, the differences in the isotherms revealed that both a reduction in surface area and a change in pore geometry had occurred during the milling. In order to understand the origin of the changes in texture of the different oxides, high-resolution NMR experiments were performed.
All four materials were analyzed by $^{17}$O solid state NMR (Figure 2). The spectra obtained show that in all cases the labeling was successful. Indeed, for each oxide, $^{17}$O NMR resonances attesting of the formation of a significant proportion of $^{*}$OM$_x$ environments (M = Si, Al, Ti, Zr) were observed. In the case of silica, the observed quadrupolar lineshape is consistent with enriched siloxanes (Si-$^{*}$O-Si), as shown by the fit of the $^{17}$O MAS spectrum (Figure S7).\textsuperscript{1, 24-25} Concerning alumina, two broad resonances are observed, the high-frequency contribution (centered at ~60 ppm at 14.1T) coming from various $^{*}$Al$_x$ environments ($x = 3, 4$),\textsuperscript{12, 25-26} while the other originates from $^{*}$OH groups, as further discussed below. In the case of titania, the main $^{17}$O resonance is centered at ~560 ppm, which corresponds to the $^{*}$Ti$_3$ environments of anatase.\textsuperscript{27-28} Regarding zirconia, two sharp resonances are observed, which are centered at 325 and 403 ppm, and correspond to the $^{*}$OZr$_3$ and $^{*}$OZr$_4$ environments of the monoclinic form.\textsuperscript{14, 27, 29} For the latter two phases, it is particularly noteworthy that the main $^{17}$O NMR resonances detected are those of crystalline environments of titania (anatase form) and zirconia.
(monoclinic form). Hence, although XRD had not revealed any strong changes during the LAG step, $^{17}$O NMR shows that a significant restructuring of the four oxides actually occurs, which leads to the breaking/formation of multiple M-O bonds, and eventually results in a significant proportion of enriched $^{*}$OM$_x$ core-like environments.

The $^{17}$O solid state NMR data also reveals that the overall $^{17}$O-enrichment level is high (see Figure S6b for comparison with natural-abundance data). More quantitative analyses were carried out on the silica and titania samples using surface ion mass spectrometry (SIMS), in order to determine the absolute enrichment after the LAG step. Measurements were performed on $^{18}$O-enriched samples, which were prepared using a similar procedure as above, but with 97% $^{18}$O-labeled water to achieve better quantification by SIMS. Under these conditions, given that 1 equivalent of H$_2$$^{*}$O is reacted with 1 equivalent of MO$_2$ (M = Si, Ti), the maximum enrichment was expected to be $\sim$ 32% (i.e. $\sim$ 97/3) in the case of complete isotopic scrambling of the oxygen sites during the H$_2^{18}$O-LAG. After 1 hour LAG (followed by drying at room temperature under vacuum), the $^{18}$O-enrichments determined by SIMS were of 27% for silica and 15% for titania. This demonstrates that the isotopic scrambling was indeed nearly complete for silica under the milling conditions used here, but that a higher enrichment level is potentially achievable for titania. From a more general perspective, considering that the natural abundance of $^{17}$O is only 0.04%, these analyses confirm that high enrichment levels of oxides can be easily reached by LAG in just 1 hour, using stoichiometric amounts of enriched H$_2$$^{*}$O.

**2b/ Insight into the labeling mechanisms: NMR analyses after different LAG times**

Given that the source of $^{17}$O is enriched water, it is reasonable to propose that part of the labeled $^{*}$OM$_x$ sites have formed by condensation reactions involving intermediate M-$^{*}$OH species (M = Si, Al, Ti, Zr). Additional multinuclear NMR analyses at different milling times were thus performed on each of the oxides to gain more insight into the enrichment mechanisms. The most complete studies were carried out on alumina and titania, as described below.

**Alumina**

Quantitative $^{17}$O NMR analyses were performed on alumina phases recovered after different LAG times (between 5 minutes and 1 hour). In all cases, two main resonances were observed at 14.1T, which were centered at $\sim$ 9 and 60 ppm. As mentioned above, the higher frequency signal corresponds to $^{*}$OAl$_x$ environments, and its intensity was found to gradually increase with the milling time (see Figures 3a-b). This is all the more interesting that no significant changes could be observed for these samples in the X-ray diffraction patterns, nor in the $^{27}$Al MAS and $^{27}$Al{$^{1}$H} CPMAS NMR spectra (aside from the appearance of a very weak Al$^{IV}$ signal after 1h BM, as shown in Figure S8). These observations confirm that $^{17}$O NMR can provide unique insight into both structural and kinetic aspects of the bonding-rearrangements occurring at the atomic level during ball-milling for this system.
The broad low frequency signal (centered at ~9 ppm) is consistent with labeled *OH groups. Given that both Al₃-OH species and H₂O molecules can potentially be found in this chemical shift range at 14.1 T, additional characterizations were performed at ultra-high magnetic field (35.2 T), to reduce the effect of second-order quadrupolar broadening and discriminate better the *OH and H₂*O species. When comparing the 1D MAS spectrum at 35.2T to data reported in the literature, it appears that few ¹⁷O-enriched water molecules are likely to be present, meaning that the majority of enriched *OH groups correspond to Al₃-*OH species (Figure 3c). In order to achieve higher resolution, complementary analyses were performed, using the ¹⁷O multiple quantum MAS (MQMAS) sequence. This allowed the Al₃-*OH sites to be more clearly separated from the *OAl₃ ones (Figure 3d, dashed circles). Moreover, it revealed a significant distribution in the ¹⁷O chemical shifts for both types of sites, which each span more than 30 ppm. This means that there are several different local environments for the enriched oxygen sites, possibly because of variations in the H-bond network around them, and/or in the number and type of Al³⁺ cations to which they are bound. To analyze this in more detail, additional high-resolution ¹H-¹⁷O and ²⁷Al-¹⁷O heteronuclear correlation experiments were carried out.

The different types of protons present around the enriched oxygen sites were studied using fast MAS $^1$H($^{17}$O) HMQC (Heteronuclear Multiple Quantum Coherence) experiments at high magnetic field (20.0 T), looking at through-bond connectivities (J-HMQC), as well as through-space proximities (D-HMQC). The main crosspeak observed on the 2D J-HMQC spectrum correlates the low frequency $^{17}$O resonance ($\text{Al}_{x}$$^\circ$OH) to a $^1$H resonance centered at ~ 3.8 ppm (Figure 4a). This $^1$H chemical shift is consistent with a surface OH group acting as hydrogen-bond donor (denoted here $\mu$-OH$_{HBD}$).$^{34}$ The significant linewidth of the $^1$H resonance points to a distribution in $\mu$-OH$_{HBD}$…O bond distances and angles.$^{34,35}$ Complementary 2D D-HMQC experiments were carried out to further characterize these hydroxyl environments (Figure 4b). At short recoupling time ($\tau_{rec} = 100 \mu$s), the D-HMQC spectrum provides similar conclusions as the J-HMQC experiment, given that only correlations to the closest H atoms appear in these conditions, i.e. with hydrogen atoms which are directly bound to $^{17}$O. In contrast, at longer recoupling times ($\tau_{rec} = 300 \mu$s), an additional correlation is observed with $^\circ$OAl$_x$ resonances. This points to the close proximity of some of the $\mu$-OH$_{HBD}$ protons to $^\circ$OAl$_x$ sites, possibly due to $\mu$-OH$_{HBD}$…$^\circ$OAl$_x$ hydrogen bonds. It is worth noting that recent computational studies of $\gamma$-alumina surfaces suggest that $\mu$-OH$_{HBD}$…OAl$_x$ hydrogen bonds can indeed be present at the surface.$^{34}$ The diversity of H-bonding environments of surface hydroxyls can thus account, at least in part, for the distribution in oxygen environments around the Al$_x$$^\circ$OH and $^\circ$OAl$_x$ moieties mentioned above (Figure 3d).
Figure 4. a/ $^1$H($^{17}$O) J-HMQC NMR spectrum recorded at 20.0 T and 60 kHz MAS on an Al$_2$O$_3$ phase enriched in $^{17}$O by LAG after 15 minutes grinding, followed by drying the sample at room temperature; the projection corresponds to the DFS-1 pulse signal for this phase; b/ $^1$H($^{17}$O) D-HMQC NMR spectra recorded at 20.0 T and 60 kHz MAS on the same phase, using 2 different recoupling times (100 and 300 μs); c/ $^{27}$Al($^{17}$O) J-HMQC spectrum recorded at 20.0 T for an Al$_2$O$_3$ phase enriched in $^{17}$O by LAG (15 min BM), after drying under vacuum at room temperature (the total acquisition time was ~50 h for this spectrum). Projections correspond to Hahn-echo spectra recorded for the sample at this magnetic field; d/ $^1$H NMR spectra recorded at 20.0 T and 60 kHz MAS, using echo delays of 2 (black) and 50 (brown) rotor periods (see Figure S10 in Supporting Information for comparison to the background $^1$H NMR spectrum). $^1$H resonances are assigned based on recent literature (HBD = hydrogen bond donor).  

To go one step further, a $^{27}$Al($^{17}$O) J-HMQC experiment was performed, to see which of the hexacoordinate (Al$^{VI}$) and tetracoordinate (Al$^{IV}$) sites of alumina were linked to $^\ast$OAl$\alpha$ and Al$\gamma$-$^\ast$OH moieties (Figure 4c). Three crosspeaks are observed on the 2D spectrum, which provide direct evidence of the presence of Al$^{VI}$-$^\ast$OH, Al$^{VI}$-$^\ast$O and Al$^{IV}$-$^\ast$O bonds. Considering the $^\ast$OAl$\alpha$ sites, this spectrum
clearly shows that part of the chemical shift distribution observed in Figure 3d can come not only from
the number but also from the type of aluminum atoms attached to the oxygen (Al\textsuperscript{IV} and/or Al\textsuperscript{V}).

The lack of Al\textsuperscript{IV}-*OH correlations in Figure 4c may seem surprising when considering the \(^1\text{H}\) MAS NMR data (see Figures 4d and S10). Indeed, the 1D \(^1\text{H}\) NMR spectrum (which was recorded using
two different echo delays to achieve better resolution) shows sharp resonances, notably at \textasciitilde{} -0.2, 0.7
and 1.1 ppm. Based on the literature, these could correspond to terminal (\(\mu^1\)-OH) and bridging (\(\mu^2\)-OH)
sites,\textsuperscript{34,36} located at the surfaces and edges of alumina particles. In particular, the signal at \textasciitilde{} -0.2 ppm has
recently been attributed to \(\mu^1\)-OH species present at the edges,\textsuperscript{34} which are likely to be linked to
tetrahedral Al\textsuperscript{IV} sites.\textsuperscript{36} This would imply that while Al\textsuperscript{IV}-OH species appear to be present in the sample,
you could not be detected in \(^{17}\text{O}\) NMR. Several explanations can be proposed to this. First, this
observation could be consistent with the known difference in reactivity of the different surface
hydroxyls.\textsuperscript{34,37} Indeed, it is possible that upon exposure of the sample to air and hence ambient humidity
(when recovering the sample after the LAG step or during the packing/unpacking of NMR rotors), some
of the enriched Al-*OH groups back exchange with non-labeled hydroxyls. The fact that the samples
are still porous after LAG would indeed be in favor of surface exchanges of reactive OH groups, which
would be more likely to occur for the hydroxyls which are more reactive and/or less tightly bound, as
would be the case for \(\mu^1\)-OH and \(\mu^2\)-OH groups with \(^1\text{H}\) resonances below 3 ppm, which are not involved
in strong H-bonds.\textsuperscript{34} This exchange would also be consistent with the fact that on the \(^1\text{H}\{^{17}\text{O}\}\) J-HMQC
data, only the \(^1\text{H}\) resonances of the hydrogen-bonded \(\mu\)-OH groups at \textasciitilde{} 3.8 ppm correlate to the Al\textsuperscript{IV}-
*OH resonance, but not those at \textasciitilde{} -0.2, 0.7 and 1.1 ppm (due to their back-exchange). Second, from a
purely NMR perspective, it is also possible that the small proportion of \(\mu^1\)-OH and \(\mu^2\)-OH resonances
(shown by \(^1\text{H}\) NMR), combined to a potentially smaller values of \(J\) couplings, renders them “invisible”
in the \(^{27}\text{Al}\{^{17}\text{O}\}\) 2D experiment (Figure 4c). All the above reasons could explain (at least in part), why
no cross-peak correlating Al\textsuperscript{IV} sites to OH groups could be observed on the \(^{27}\text{Al}\{^{17}\text{O}\}\) J-HMQC
spectrum.

The observation of the progressive formation of *OAl\textsubscript{x} sites (Figure 3b), and the potential back-exchange of some of the enriched hydroxyls, prompted us to use \(^{17}\text{O}\) DNP SENS (surface enhanced
NMR spectroscopy)\textsuperscript{38-39} to examine the nature of the oxygen environments present at the surface of the
alumina particles. DNP analyses were performed on a sample recovered after 15 minutes milling, after
impregnation by a biradical solution of TEKPol in deuterated tetrachloroethane. Two types of NMR
sequences were used, as a means to polarize differently the surface atoms oxygen during microwave
irradiation: (i) direct-excitation \(^{17}\text{O}\) NMR (preceded by a double-frequency sweep enhancement), in
order to polarize the surface oxygen sites directly from the radical, and (ii) \(^{17}\text{O}\{^{1}\text{H}\}\) CPMAS, where \(^{17}\text{O}\) sites are detected based on their relative proximity to the protons polarized by the biradical (by varying
the contact time used). In both situations, the \(^{17}\text{O}\) NMR signals of *OAl\textsubscript{x} and *OH groups were found
to be enhanced upon microwave irradiation (Figure 5), suggesting that both of these \(^{17}\text{O}\) environments
are present at the surface of the alumina particles. In particular, under \(^{17}\text{O}\{^{1}\text{H}\}\) DNP CPMAS conditions
Figure 5, both sites were enhanced by a factor ~ 4, meaning that protons located at the surface of the particles after LAG can transfer their polarization to neighboring Al-•OH (at short contact time) and *OAlx sites (at longer contact time). Although these DNP-SENS experiments did not allow any absolute quantification of the relative labeling of the bulk or surface of the material, they clearly suggest that some enriched oxygen sites are still present at the surface of the particles, despite possible partial 17O/16O back-exchanges upon exposure of the sample to ambient atmosphere.

In summary, although the overall structure of alumina appears to be maintained during the LAG step (according to X-ray diffraction and 27Al NMR), part of this phase actually undergoes several reactions in the presence of H2•O, leading to a change in texture of the material, and to the formation of Alx-•OH and *OAlx species. The fact that *OAlx environments were detected after only 5 minutes of milling underscores that the condensation of Alx-•OH groups proceeds very quickly under the reaction conditions used here. For both Alx-•OH and *OAlx species, high resolution NMR experiments were able to shed light on the diversity of oxygen local environments, due to the presence of hydrogen bonds and differences in the nature and number of Al-sites to which they are bound. Moreover, 17O DNP-SENS experiments were performed, suggesting that some of the enriched Alx-•OH and *OAlx sites are located at the surface of the particles.

Figure 5. 17O DNP experiments carried out at 14.1T on an Al2O3 phase enriched in 17O by 15 minutes LAG (followed by drying the sample at room temperature), and impregnation by TEKPol/D2-TCE: (i) Direct-excitation 17O DNP NMR spectra (with a DFS enhancement), and (ii) 1H{17O} CPMAS DNP NMR spectra recorded at 50 μs and 5 ms contact times (CT). Spectra recorded without (brown) and with (blue) microwave irradiation are compared (μw on / μw off). DNP acquisition conditions and enhancements are discussed in Supporting Information (S11), and comparisons to 17O NMR data recorded at room temperature are reported in Figure S12.
**Titania**

Enriched titania phases were studied by $^{17}$O MAS NMR after different LAG times (1 min, 15 min and 1 hour). NMR spectra were recorded both on “fresh” samples, which were analyzed by NMR directly after milling, and on samples which had undergone an additional drying step at room temperature. In all cases, signals belonging to $^\text{83}\text{OTi}_3$ environments were observed around 550 ppm. The resonance characteristic of crystalline anatase was found to increase with the milling time (signal at 560 ppm, Figure 6a). Weaker underlying resonances, which span between 500 and 600 ppm (Figure 6b), were also observed at all milling times, and can be ascribed to more distorted/disordered $^\text{83}\text{OTi}_3$ environments and surface defects.$^{9,28,40}$

In the case of the “fresh” phases, residual $^{17}$O labeled water was detected at ~0 ppm. Its relative proportion was found to decrease as the milling time increased (Figure 6a). However, no clear evidence of Ti-$^\text{17}$OH groups was observed. Based on the literature, Ti-$^\text{17}$OH resonances were expected to be centered just above 200 ppm.$^{9,40-41}$ Complementary $^{17}$O DNP SENS analyses were thus carried out to try to detect more clearly the surface species (Figures 6c-d), and bring direct evidence of Ti-$^\text{17}$OH groups (if any). First, it is worth noting that at low temperatures such as those used for DNP analyses (~100 K), a very weak signal could be detected at ~200 ppm, suggesting the presence of a small number of Ti-$^\text{17}$OH species. Dynamics within the Ti-$^\text{17}$OH moieties at room temperature may explain why they could not be detected by conventional NMR. This signal could then be enhanced by direct excitation $^{17}$O-DNP (Figure 6c), and even more so using DNP $^{17}$O$^\text{1H}$ CPMAS experiments at very short contact times (Figure 6d). Indeed, the main signal observed by DNP $^{17}$O$^\text{1H}$ CPMAS for 50 μs contact time was centered at ~200 ppm.

Based on previous experimental and computational studies reported in the literature, the extent of water dissociation on anatase surfaces is known to be highly dependent on several parameters, including the nature of the surface exposed and the extent of surface defects.$^{42-43}$ Hence, it is possible that the formation of Ti-$^\text{17}$OH groups by dissociation of H$_2^\text{17}$O on anatase requires the creation of reactive surfaces by mechanochemistry. Moreover, given that very few Ti-$^\text{17}$OH species could be detected at the surface of the materials (even for “fresh” phases), it is possible that these recondense quickly to form $^\text{83}\text{OTi}_x$ sites under the reaction conditions used here. Overall, this would explain the evolution of the reaction medium shown in Figure 6a.
DNP SENS analyses were able to provide additional information regarding the other enriched oxygen sites which were present close to the surface, aside from the Ti-*OH moieties. First, when analyzing the results of the DNP experiments performed with direct $^{17}$O acquisition (Figure 6c), it is clear that bulk-like $^{*}\text{OT}_3$ environments are also present close to the surface of the particles. Second, by increasing the contact time in the DNP $^{17}$O{H} CPMAS experiment, it was possible to observe weak resonances in the $^{*}\text{OT}_3$ region (Figure 6d, CT = 3 ms). These correspond to oxygen species which are spatially close to protons (but not directly bound to them) and appear to contribute to the “underlying” disordered/distorted Ti*O$_3$ resonances detected in Figure 6b. Such detailed information on the different...
oxygen environments is expected to be of high interest for proposing realistic models of the anatase surface recovered after the milling step, by combining computational modeling to ab-initio calculations of $^{17}$O NMR parameters, and comparing results to experimental $^{17}$O NMR data, as previously proposed for other studies on titania surfaces.9, 44

To sum up, although the overall structure of anatase appears to be maintained according to X-ray diffraction, the texture of the material is affected by the milling process, and $^{17}$O NMR further shows that this phase reacts with labeled water to form enriched anatase-like $^\ast$OTi$_3$ environments after only 1 minute of milling. However, in contrast to alumina, only a very small number of labeled $^\ast$OH species were observed in the 1D $^{17}$O MAS NMR spectra (even when analyzing freshly recovered samples), and these could only be clearly detected using DNP-SENS analyses.

**Silica and zirconia**

Preliminary investigations were also performed at different milling times on silica and zirconia. For the former (Figure 7a), characterizations after only 1 minute milling suggested the presence of both silanols (Si-$^\ast$OH) and siloxanes (Si-$^\ast$O-Si). The significant proportion of siloxane bridges after 1 minute of milling is particularly noteworthy, because it demonstrates that the condensation reactions of intermediate Si-$^\ast$OH groups proceeds quickly under the reaction conditions used here. In contrast, in the case of zirconia, it was found that the $^{17}$O-enrichment using LAG is much more challenging to achieve. Indeed, the two resonances characteristic of the monoclinic form were barely visible after 15 minutes milling (Figure 7b). Moreover, no direct evidence of Zr-$^\ast$OH groups could be detected by conventional $^{17}$O NMR (these being expected around ~ 100 ppm).10 The underlying resonances observed as a shoulder around 400 ppm after 1 hour of milling may be due to more disordered $^\ast$OZrx environments. Further investigations are currently in progress on these phases, both from the synthesis and NMR/DNP points of view, in order to better characterize and control the nature of enriched $^\ast$OMx and M-$^\ast$OH groups at different milling times, and to establish the optimal conditions for isotopic labeling.
17

Figure 7. a/ $^{17}$O MAS NMR analysis performed at 20.0T and 60 kHz MAS on a SiO$_2$ phase enriched in $^{17}$O by LAG (1 min BM), after drying under vacuum at room temperature. The fit (dashed red line) was performed considering siloxanes (green) and silanols (purple). The silanol resonances could be more clearly resolved using $^{17}$O{$_1$H} CPMAS analyses at short contact times (see Supporting Information, Figure S13), and their NMR signature is consistent with previous reports.\textsuperscript{24, 45} b/ $^{17}$O MAS NMR analyses performed at 14.1T and 20 kHz MAS on a ZrO$_2$ phase enriched in $^{17}$O by LAG, after 15 min (black) and 1h (blue) milling. The “m” symbols indicate the two main resonances of monoclinic zirconia. * symbols correspond to spinning sidebands, and the ◊ symbol to the zirconia rotor background signal (see Figure S6).

3/ $^{17}$O-labeling of mixtures of oxides: from liquid to solid oxygen-transfer reactions

Having demonstrated that it is possible to perform the direct $^{17}$O-enrichment of simple oxides using LAG, the obvious next step was to see how mechanochemistry can be used to synthesize $^{17}$O-labeled mixed oxides. Two mechanochemical approaches were considered to introduce the $^{17}$O-label (Figure 8a): (i) milling the non-labeled oxide precursors together with H$_2$*O, or (ii) pre-enriching separately oxide precursors, before ‘dry’-milling them together. While the former strategy was recently used for enriching the lithium-ion battery electrode materials like Li$_2$RuO$_3$,\textsuperscript{7} no $^{17}$O NMR analysis of the milling medium just after the LAG step was reported. Moreover, comparing the two strategies may actually shed light on how oxides react with each other in the solid state during mechanochemical reactions.

These two approaches were tested on a TiO$_2$/SiO$_2$ mixture, using the same oxide sources as mentioned previously (mesoporous anatase and amorphous silica), with the aim of comparing the media recovered just after the milling step, \textit{i.e.} before any further heat treatment. On one hand, equimolar quantities of TiO$_2$ and SiO$_2$ were milled together by LAG using H$_2$*O. On the other hand, a pre-enriched Ti*O$_2$ phase was dry-milled in presence of an equimolar quantity of non-labeled SiO$_2$. Both media were compared after 3 minutes BM. Although the XRD patterns were found to be the same (Figure 8b), their solid-state NMR spectra were completely different (Figure 8c).

In the LAG case, the $^{17}$O signatures of enriched titania and silica were both visible, but with a significant discrepancy in their relative enrichment, the vast majority of the isotopic label having entered the silica phase (Figure 8c, black curve). Interestingly, in addition to the *OTi$_3$ and siloxane resonances, it is worth noting that a broad signal is also observed between ~ 450 and 100 ppm, \textit{i.e.} in a zone which covers the range expected for *OTi$_4$, Si-*O-Ti and Ti-*OH groups.\textsuperscript{46-47} The more distinct contribution
around ~200 ppm could be indicative of the formation of a small number of Ti-*OH groups under these synthetic conditions.

In the Ti*O$_2$/SiO$_2$ “dry-milling” case, although the *OTi$_3$ anatase signal is still predominant, a broad signal is also detected between ~450 and 100 ppm, as well as a new resonance around ~30 ppm (Figure 8c, red curve). The latter resonance can be assigned to enriched Si-*O-Si bridges (see Figure S14 in supporting information, for an expansion into the siloxane region). Given that the silica precursor was initially non-labeled, this clearly points to the fact that the reactions occurring at the interface of Ti*O$_2$ and SiO$_2$ during the ball-milling eventually result in bonding rearrangements around the oxygen atoms, which lead to the enrichment of the silica phase. More importantly, such an “oxygen transfer” between the two oxides starts to occur after just 3 minutes, meaning that very short milling times are sufficient to mix the reagents intimately, so that they can start reacting at their interface.

**Figure 8.** a/ Schematic representation of the two synthetic approaches tested for enriching mixtures of SiO$_2$ and TiO$_2$ in $^{17}$O using mechanochemistry (shades of red are used to reflect the average relative $^{17}$O-labeling of the oxides after milling); b/ and c/ Characterizations of $^{17}$O-enriched SiO$_2$/TiO$_2$ mixtures using PXRD and $^{17}$O MAS solid state NMR at 20T. Top: Dry-milling of non-labeled SiO$_2$ with enriched Ti*O$_2$ for 3 minutes (blue curves). Bottom: LAG of a mixture of TiO$_2$ and SiO$_2$ for 3 minutes in presence of H$_2$*O (black curves). “∆” symbols correspond to the diffraction peaks of anatase in PXRD (ICSD #7206075), and “*” symbols correspond to spinning sidebands in $^{17}$O NMR. The shaded regions on the $^{17}$O MAS NMR spectra correspond to the chemical shifts expected for OTi$_x$ (light blue) and siloxane (light grey) environments. An expansion of the $^{17}$O NMR spectra in the siloxane region can be found in Figure S14.
The comparison of the two $^{17}$O-labeling approaches points to the major advantages of $^{17}$O NMR for studying the reactivity of inorganic oxides in BM and helps understand better the differences in reactivity of oxides during ball-milling. On one hand, it allows identifying the different oxygen environments present, thereby revealing oxygen bonding rearrangements which occur at the interfaces between the oxides. On the other hand, it can also bring clear evidence of discrepancies in oxygen isotopic distribution within samples. Moreover, the $\text{H}_2^{17}$O-LAG approach used here could more generally help shed light on differences in reactivity of liquid grinding assistants like water with respect to the different components of a mixture, a feature which has not been looked into so far.

4/ Discussion

New $^{17}$O-enrichment approaches for oxides

The enrichment strategies described above significantly broaden the scope of approaches available for producing $^{17}$O-enriched s-, p- and d- block oxides, and offer synthetic alternatives which are highly efficient, both in terms of cost and practicality. One of the reasons to this comes from the nature of the precursors involved: oxides and $^{17}$O-enriched water. Oxides are indeed very interesting starting materials because they are either directly commercially available (as for TiO$_2$, SiO$_2$, Al$_2$O$_3$ and ZrO$_2$), or because they can be easily produced by heat treatment of hydroxides (as illustrated here for CaO and Li$_2$O) or even carbonates. Moreover, being able to perform the $^{17}$O-labeling on commercially available sources of titania, silica, alumina and zirconia, which can be stored and handled under ambient conditions for several months, is a key advantage in comparison to other procedures used so far for enriching these phases, in which more sensitive alkoxide or chloride precursors had been used. Indeed, no safety hazard was involved here in the LAG step, which could be easily scaled up to produce gram quantities of labeled material, which contrasts with syntheses involving highly reactive and toxic reagents such as SiCl$_4$ and TiCl$_4$. Although the maximum $^{17}$O-enrichment is meant to be higher in the latter case (as the only source of oxygen is $^{17}$O-enriched water), the $^{17}$O content of the phases recovered after LAG was nevertheless sufficient for performing a wide range of high-resolution NMR experiments, as shown in the case of the 2D $^1$H-$^{17}$O and $^{27}$Al-$^{17}$O MAS NMR experiments performed on alumina (Figures 4a-c). Moreover, it is possible that further optimizations of the LAG step could lead to higher enrichments than those achieved so far, by increasing the amount of H$_2$O added, varying the texture/porosity of the oxide precursor used, and/or optimizing the ball-milling conditions.

Using stoichiometric amounts of $^{17}$O-enriched water for the labeling-step is also much less hazardous and constraining than having to manipulate $^{17}$O-enriched O$_2$ gas at high temperatures, as had been described in previous $^{17}$O-enrichment protocols for oxides. Indeed, the labeling reactions were performed here under ambient temperature and pressure, and proceeded extremely quickly (less than 1 hour of milling). Moreover, in terms of cost, all syntheses were relatively cheap, amounting to less than ~ 40 euros for enriching ~ 50 mg of compound (when using 90% $^{17}$O-enriched water in the syntheses). Overall, this implies that these protocols are expected to be accessible to both research and
teaching laboratories, and to contribute to the development of advanced spectroscopic studies on various oxides (or oxide mixtures), which would require oxygen-17 (or oxygen-18) labeling.

Another very attractive feature of the protocols developed here is that the 17O-enriched phases recovered after LAG can be used in multiple ways. First, they can be converted into related oxide phases by performing additional heat-treatments under inert conditions, as illustrated in Figure S15 for alumina and titania. Alternatively, they can directly serve as precursors for the synthesis of more complex mixed metal oxides, as illustrated in the previous section for the dry milling of Ti*O2 with SiO2. Last but not least, given that one of the unique properties of the enriched p- and d- block oxides produced here is that they are still mesoporous after LAG, with some of the surface sites enriched in 17O (as suggested by DNP), they could be used as model systems for studying the surface reactivity of oxides by high-resolution 17O NMR. In particular, considering the wide range of applications of transitional aluminas like γ- and δ- Al2O3 in heterogeneous catalysis, the 17O-labeled alumina phases prepared by LAG could be of high interest to gain new insight into the surface reactivity of catalytic materials using high-resolution 17O NMR and DNP.

**Atomic-level insight into reactions occurring during ball-milling**

Beyond the production of 17O-enriched materials, our results also show how high-resolution 17O NMR and DNP can help gain atomic-level information into LAG processes, and more generally reaction mechanisms in ball-milling. Mechanochemical reactions are indeed far from trivial, as they involve both physical steps (mixing of reagents, particle size reduction, creation of reactive surfaces, diffusion of atoms/molecules at the interfaces…) and chemical steps (chemical reactions), both of which are important for the system to evolve towards a given product.53-54 Despite numerous investigations, some of which include in situ measurements and/or innovative designs of the milling equipment,54-59 many blind spots remain regarding both the physics and chemistry of mechanochemical reactions. This is even more true when common techniques like X-ray diffraction are not informative, as observed here for the four p- and d- block oxides, as well as for the mixed SiO2/TiO2 system.

In the case of titania, alumina, and silica, 17O NMR and DNP measurements at different milling times were able to provide clear evidence of the presence of intermediate M- *OH species, which can then condense to form *OMx sites. One important point arising from these analyses was that the quantity of M- *OH sites detected differed significantly from one oxide to the other. In particular, at the shortest milling times, while Al- *OH and Si- *OH groups could be clearly observed, this was not the case for Ti- *OH species, for which DNP analyses were needed to bring evidence of their presence. Given that several parameters can influence the formation of M- *OH groups (initial degree of covalency or ionicity of the M-O bonds within the oxide, texture and surface area of the material, and reactivity under the ball-milling conditions used), further investigations will be needed to determine the mechanism(s) by which enriched M- *OH groups form for each phase, i.e. whether it is by surface hydrolysis, dissociative adsorption of water, or exchange of labile M-OH groups initially present at the surface. From a more
practical perspective, the differences in reactivity shown here demonstrate that milling conditions need to be optimized case by case for each oxide, in order to find how to achieve the highest $^{17}\text{O}$-enrichment possible.

Concerning alumina, solid state NMR analyses also enabled to shed light on additional features of ball-milling reactions. First, as shown in Figure 3b, it is interesting to note that no “induction time” in the formation of $^{*}\text{OAl}_x$ species could be detected within the time scale investigated. Induction periods in ball-milling are generally made evident using X-ray diffraction techniques, but such analyses would have led to an erroneous conclusion here, given that no change was observed in PXRD. Moreover, it is interesting to note that while an increase in the relative number of $^{*}\text{OAl}_x$ environments with time was observed, it progressively slowed down after the first 15 minutes. Given that Al-$^{*}\text{OH}$ and $^{*}\text{OAl}_x$ environments very easily formed during the milling (as they were detected after only 5 minutes of reaction), this suggests that other rate-limiting steps takeover after 15 minutes. It is possible that the enrichment of $^{*}\text{OAl}_x$ sites then proceeds by other mechanisms, involving the gradual rearrangement of oxygen bonding environments within the intermediate oxy-hydroxy phase. Alternatively, changes in the texture and rheological properties of the medium (due to the progressive consumption of enriched water and/or modification of the mesoporosity of the material) may render the milling process less efficient in creating new reactive surfaces, thereby slowing down the speed of enrichment. To go one step further, additional high-resolution $^{17}\text{O}$ NMR and DNP analyses will be needed to study the relative binding of oxygen atoms to Al$^{IV}$ and Al$^{VI}$ sites as a function of milling time, and the reactivity of the different surface $^{*}\text{OH}$ groups created by LAG. This should, in return, help rationalize the enrichment process at the atomic level, and better control the nature and proportion between the enriched sites.

Finally, the studies on the mixed SiO$_2$/TiO$_2$ system show how $^{17}\text{O}$ NMR can be used for looking at reactions occurring at the interfaces between different oxides during ball-milling. Indeed, the $^{17}\text{O}$ NMR characterization performed on the {SiO$_2$ + Ti$^{*}\text{O}_2$} system demonstrate that after only 3 minutes of reaction, a variety of $^{17}\text{O}$-enriched oxygen environments are present, which include enriched oxygen atoms within the silica phase. Being able to provide such atomic-level insight at the very early stages of the reaction is important to evaluate the efficiency of a given milling process to mix different solid particles (whether they are crystalline or amorphous, as is the case here), and to create contacts between them which will allow solid/solid reactions to occur. More generally, such analyses will certainly help understand better what chemical reactions occur during ball-milling when disordered or amorphous phases are involved, such reactions being intrinsically very complex to study.

**Conclusion**

In this manuscript, we have shown how the $^{17}\text{O}$-labeling of oxides using mechanochemistry can be used for two main purposes: *(i)* preparing $^{17}\text{O}$-enriched oxides, and *(ii)* understanding reaction mechanisms occurring during ball-milling. Concerning the first point, liquid assisted grinding in presence of $^{17}\text{O}$-enriched water was shown to be a highly attractive enrichment strategy for the fast and
straightforward labeling of simple oxides of the s, p and d blocks, starting from the non-labeled oxide precursors. Regarding the second point, it was demonstrated how thanks to mechanochemistry-mediated isotopic labeling, it becomes possible to address questions regarding the physical and chemical processes occurring at the atomic level during ball-milling, by performing advanced $^{17}$O solid state NMR analyses, including ultra-high-field NMR, DNP and fast-MAS measurements. In this context, one of the highlights of this work is to shed light on what chemical reactions start occurring at the interfaces between different oxide particles in the first few minutes of milling. Given that milling together inorganic precursors is frequently one of the first steps in the synthesis of functional mixed-metal oxides, performing similar high-resolution $^{17}$O NMR analyses on different mixtures of enriched oxide precursors and under different milling conditions could not only help optimize the milling process, but also help identify intermediate phases, which could in turn serve for the preparation of novel materials.

This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation program (grant agreement No 772204; 2017 ERC-COG, MISOTOP project). A portion of this work was performed at the National High Magnetic Field Laboratory, which is supported by the National Science Foundation Cooperative Agreement No. DMR-1644779, the State of Florida and the United States Department of Energy. The MAS-DNP system at the NHMFL is funded in part by NIH S10 OD018519 and P41 GM122698. Financial support from the IR-RMN-THC Fr3050 CNRS for conducting part of the high-field NMR experiments is gratefully acknowledged. The UK 850 MHz solid-state NMR Facility used in this research was funded by EPSRC and BBSRC, as well as the University of Warwick including via part funding through Birmingham Science City Advanced Materials Projects 1 and 2 supported by Advantage West Midlands (AWM) and the European Regional Development Fund (ERDF). Dr Franck Fayon (CEMHTI, CNRS) and Dr Dinu Iuga (University of Warwick) are acknowledged for discussions, and Anastasia Kuznetsova for the BM-enrichment of some of the alumina phases studied here.

Author contributions

C.-H. C., E. G., R. B., B. R., T.-X. M. and D.L. participated to the synthesis and characterization of the enriched-materials. C.-H. C., Ph. G., B. A. and D. L. performed SSNMR analyses at 14.1T. F. M.-V. carried out all DNP experiments. K. C., Z. G., P. F., C. B., M. E. S., B. A. and D. L. participated to the ultra-high field NMR experiments. C.-H. C., T.-X. M., B. A. and D. L. designed the investigations, and D. L. coordinated the project. All co-authors participated in the writing of the manuscript.
Experimental section

Synthesis of $^{17}$O-labeled phases

**Reagents and milling equipment.** Calcium hydroxide (Ca(OH)$_2$, Sigma-Aldrich, ≥ 96%) and lithium hydroxide monohydrate (LiOH·H$_2$O, Prolabo Normapur, Analytical Reagent, ≥ 99.0%) were used as received, and served as precursors for the synthesis of CaO and Li$_2$O. Silica (SiO$_2$, Aerosil 200, Degussa, 180 m$^2$/g), alumina (Al$_2$O$_3$, “aluminoxid C”, Degussa, mixture of γ- and δ- forms, 100 m$^2$/g), titania (TiO$_2$, St-Gobain Norpro, anatase phase, 150 m$^2$/g), and zirconia (ZrO$_2$, St-Gobain Norpro, monoclinic form, 85 m$^2$/g) were dried under vacuum for 3 to 4 hours at room temperature prior to use. $^{17}$O-labeled water (with 40% or 90% $^{17}$O-enrichment) was purchased from CortecNet. $^{18}$O-labeled water (with 97% $^{18}$O-enrichment) was purchased from Eurisotop. For DNP experiments, TEKPol$^{63}$ was purchased from Cortecnet.

All milling treatments were carried out at ~ 22°C (± 3 °C) in a Retsch Mixer Mill 400 apparatus, using 10 mL stainless steel grinding jars with screw top or push-fit lids. Unless otherwise noted, the protocols were first tested in triplicate using non-labeled water, before performing the experiments with $^{17}$O (or $^{18}$O) -enriched H$_2$O.

**Synthesis of Ca($^{18}$OH)$_2$ and Ca$^{18}$O.** Non-labeled Ca(OH)$_2$ was first heat-treated to 950°C in a tubular furnace under Ar atmosphere (heating rate: 10°C / min; dwell-time at 950°C: 4 h) to produce CaO. The freshly prepared CaO phase (50 mg, 0.9 mmol, 1 eq) was introduced in the grinding jar together with 16μL of 40%-enriched H$_2^{17}$O (0.9 mmol, 1 eq) with two stainless steel balls (10 mm diameter). The jar was closed and subjected to grinding for 1 hour in the mixer mill operated at 25Hz. The reactor was opened and the white powder, which progressively dries upon contact with air, was recovered by scraping the edges of the reactor and beads with a spatula, and characterized by XRD and $^{17}$O solid state NMR, showing the formation of Ca($^{18}$OH)$_2$. (Average yield (n = 4): 54 mg, 82%). $^{17}$O-enriched CaO was then synthesized by heat-treating the labeled hydroxide for 4 h at 950°C in a tubular furnace under Ar atmosphere, using the same conditions as above.

**LAG of SiO$_2$.** SiO$_2$ (50 mg, 0.84 mmol, 1.0 eq) was introduced in a screw top grinding jar with $^{17}$O-labeled water (15 μL, 0.83 mmol, 1.0 eq) and two stainless steel balls (10 mm diameter). The jar was closed and subjected to grinding for milling times ranging from 1 minute to 1 hour, in the mixer mill operated at 25 Hz. The reactor was opened and the sample was recovered by scraping the edges of the reactor and beads with a spatula (average mass of the crude material (n = 4): 60 mg). The recovered sample was white for short milling times, but light grey beyond 15 minutes milling (see supporting information, Figure S2, for EDXS analyses). Samples were then dried under vacuum at room temperature.

**LAG of Al$_2$O$_3$.** Al$_2$O$_3$ (50 mg, 0.49 mmol, 1.0 eq) was introduced in a grinding jar with $^{17}$O-labeled water (13 μL, 0.72 mmol, 1.5 eq) and one stainless steel ball (10 mm diameter). The jar was closed and subjected to grinding for milling times ranging from 5 minutes to 1 hour in the mixer mill operated at
25 Hz. The reactor was opened and the solid powder was recovered by scraping the edges of the reactor and beads with a spatula (average mass of the crude material (n = 4): 45 mg). The recovered sample was white for short milling times, but very light grey beyond 15 minutes milling (see supporting information, Figure S3, for EDXS analyses). Depending on the sample, further treatments were performed, either under vacuum at room temperature, or at high temperature under Ar atmosphere (heating rate: 10°C / min; dwell-time at 900°C: 4 h – see Figure S15).

**LAG of TiO<sub>2</sub>.** TiO<sub>2</sub> (50 mg, 0.63 mmol, 1.0 eq) was introduced in a grinding jar with <sup>17</sup>O-labeled water (11 μL, 0.61 mmol, 1.0 eq) and one stainless steel ball (10 mm diameter). The jar was closed and subjected to grinding for milling times ranging from 1 minute to 1 hour in the mixer mill operated at 25 Hz. The reactor was opened and the solid powder was recovered by scraping the edges of the reactor and beads with a spatula (average mass of the crude material (n = 4): 44 mg). The recovered sample was white for short milling times, but light grey/yellowish beyond 15 minutes milling (see supporting information, Figure S4, for EDXS analyses). Depending on the sample, further treatments were performed, either under vacuum at room temperature, or at high temperature under Ar atmosphere (heating rate: 10°C / min; dwell-time at 900°C: 4 h – See figure S15).

**LAG of ZrO<sub>2</sub>.** ZrO<sub>2</sub> (50 mg, 0.41 mmol, 1 eq) was introduced in a grinding jar with <sup>17</sup>O-labeled water (7 μL, 0.39 mmol, 1 eq) and one stainless steel ball (10 mm diameter). The jar was closed and subjected to grinding for milling times ranging from 15 minutes to 1 hour in the mixer mill operated at 25 Hz. The reactor was opened and the solid powder was recovered by scraping the edges of the reactor and beads with a spatula (average mass of the crude material (n = 4): 42 mg). The recovered sample was white for short milling times, but very light grey beyond 15 minutes milling (see supporting information, Figure S5, for EDXS analyses). Samples were then dried under vacuum at room temperature.

**LAG of TiO<sub>2</sub> and SiO<sub>2</sub>.** TiO<sub>2</sub> (28.3 mg, 0.35 mmol, 1 eq) and SiO<sub>2</sub> (21.5 mg, 0.35 mmol, 1 eq) were introduced in a grinding jar with <sup>17</sup>O-labeled water (13 μL, 0.72 mmol, 2 eq) and one stainless steel ball (10 mm diameter). The jar was closed and subjected to grinding for 3 minutes in the mixer mill operated at 25 Hz. The reactor was opened and the white powder was recovered by scraping the edges of the reactor and beads (m ~ 43 mg).

**BM of Ti<sup>*</sup>O<sub>2</sub> with SiO<sub>2</sub>.** Ti<sup>*</sup>O<sub>2</sub> was first synthesized as described above, by milling TiO<sub>2</sub> for 15 minutes, and then drying the sample under vacuum for 1 hour at room temperature. Then, labeled Ti<sup>*</sup>O<sub>2</sub> (28.6 mg, ~0.35 mmol, 1 eq) was introduced in a grinding jar with non-labeled SiO<sub>2</sub> (21.4 mg, 0.35 mmol, 1 eq) and one stainless steel ball (10 mm diameter). The jar was closed and subjected to grinding for 3 minutes in the mixer mill operated at 25 Hz. The reactor was opened and the solid powder was recovered by scraping the edges of the reactor and beads (m = 42 mg).
Characterization techniques

**Powder X-ray diffraction.** Powder XRD analyses were carried out on a Philips X’pert Pro MPD diffractometer using Cu Kα radiation (λ = 1.5406 Å) in Bragg-Brentano scanning mode with a 2θ angle between 10 and 70°, and a time per step ranging from 30 to 240 s, depending on the sample.

**Scanning Electron Microscopy and EDX analyses.** SEM measurements were conducted on a Hitachi S4800 instrument under an excitation voltage between 0.5 and 8.0 kV depending on each powder’s surface charging. For SEM, powdered samples were deposited on double sided conducting carbon tape and then Pt-metallized by sputtering under vacuum. EDXS analyses were carried out on a Zeiss Evo HD15 scanning electron microscope equipped with an Oxford Instruments X-MaxN SDD 50 mm² EDX detector. For EDXS, powdered samples were deposited on double sided conducting carbon tape and then metallized with carbon before analyses.

**N₂ adsorption/desorption isotherms.** N₂ volumetry analyses were performed by physisorption of N₂ using a Tristar instrument (Micromeritics, Norcross, USA). Prior to measurements, samples were degassed under vacuum overnight at 150 °C.

**Surface Ion Mass Spectrometry (SIMS).** SIMS analyses were performed on (i) SiO₂ and TiO₂ samples which had been enriched by LAG as described previously (1h BM), but using 97% ¹⁸O-labeled water, and (ii) non-labeled SiO₂ and TiO₂ phases, which served as controls. All samples were pelletized, dried under vacuum, and then sputtered by a thin layer of gold prior to analysis. Measurements were performed on the IMS4F apparatus (Cameca) of the Geosciences Platform of the University of Montpellier, equipped with a 10 keV Cs sputter gun. For each sample, average ¹⁸O/¹⁶O ratios were determined by analyzing 3 different zones of the surface, and performing 5 blocks of 10 measurements on each zone.

**¹⁷O solid state NMR – 1D experiments.** The majority of ¹⁷O solid state NMR experiments were performed on a Varian VNMRS 600 MHz (14.1 T) NMR spectrometer, using either Varian 3.2 mm HX or HXY probes, or a Phoenix 3.2 mm probe, tuned to ¹H (599.82 MHz) and ¹⁷O (81.31 MHz). Spectra were recorded under magic angle spinning (MAS) conditions, with spinning speeds ranging from 16 to 20 kHz, depending on the sample. Additional ¹⁷O MAS NMR experiments were performed on a Bruker 850 MHz (20.0 T) NMR spectrometer, using Bruker 1.3 or 3.2 mm probes, tuned to ¹H (850.23 MHz) and ¹⁷O (115.26 MHz). Finally, ultra-high magnetic field experiments were also performed on the 1.5 GHz (35.2 T) SCH-instrument in Tallahassee, using a 3.2 mm single-channel MAS probe, spinning at 18 kHz. The acquisition parameters used for each sample can be found in Table S1. ¹⁷O-enriched Ca(*OH)₂ was used to set up the DFS (double-frequency sweep) enhancement scheme and ¹⁷O[¹H] CPMAS experiments. ¹⁷O chemical shifts were referenced externally to tap water at 0.0 ppm (or to D₂O at -0.7 ppm).

**²⁷Al solid state NMR – 1D experiments.** ²⁷Al solid state NMR experiments were performed on a Varian VNMRS 600 MHz (14.1 T) NMR spectrometer, using a Varian 3.2 mm HX probe, or a Phoenix 3.2 mm probe, tuned to ¹H (599.82 MHz) and ²⁷Al (156.29 MHz). Samples were packed into low-Al background
zirconia rotors for these measurements. Single-pulse experiments were performed spinning at 18 kHz, using a $^{27}$Al excitation pulse of 0.7 μs (π/18 tip angle), a recycle delay of 6s, and acquiring a total of 512 transients. $^{27}$Al[$^1$H] CPMAS experiments were performed spinning at 18 kHz, using a $^1$H excitation pulse of 6 μs (π/2 tip angle), and a contact time of 0.5 ms. The recycle delay was set to 1s, and the number of scans acquired ranged from 8000 to 61700, depending on the sample. $^{27}$Al chemical shifts were referenced externally to a 1 M aqueous solution of Al(NO₃)₃.

$^1$H solid state NMR – 1D experiments. Fast MAS $^1$H solid state NMR spectra were recorded on a Bruker 850 MHz (20.0 T) instrument, using a Bruker 1.3 mm probe spinning at 60 kHz. A Hahn echo sequence was used, with π/2 and π pulses of 2.05 and 4.1 μs, and a rotor-synchronized echo delay corresponding to 2 or 50 rotor periods (Figure 4d). $^1$H chemical shifts were referenced to a dipeptide (Asp-Ala), used as a secondary reference, the low frequency signal being set to 1.1 ppm with respect to tetramethylsilane. Additional Hahn-echo $^1$H NMR spectra were also recorded on a Varian VNMRS 600 MHz (14.1 T) NMR spectrometer using a Phoenix 1.2 mm MAS probe, in order to evaluate potential contributions of background $^1$H signals from the rotor and caps (see Figure S10, supporting information).

$^{27}$Al[$^{17}$O] J-HMQC. A $^{27}$Al[$^{17}$O] J-HMQC MAS NMR experiment was performed on a Bruker 850 MHz (20.0 T) NMR spectrometer, using a 3.2 mm HXY probe, tuned to $^1$H (850.29 MHz), $^{27}$Al (221.56 MHz), and $^{17}$O (115.27 MHz), and spinning at 24 kHz. DFS excitation pulses were first applied on $^{27}$Al (1 ms pulse of 30 W, with a 600 to 150 kHz sweep). The π/2 and π pulses on $^{27}$Al were set to 8.3 and 16.6 μs, respectively (~10 kHz RF). The evolution delay following the π/2 pulse on $^{27}$Al was set to 2.5 ms. The π/2 pulses on $^{17}$O were set to 8.5 μs (~10 kHz RF). Spinal-64 $^1$H decoupling (100 kHz RF) was applied throughout the sequence (except during the DFS). The recycle delay was set to 1s, and a total of 10000 scans were acquired for each of the 18 increments of the 2D. $^{17}$O and $^{27}$Al chemical shifts were referenced using respectively tap water (at 0 ppm) and a 1 mol.L$^{-1}$ solution of aluminum-nitrate (at 0 ppm).

$^1$H[$^{17}$O] D- and J- HMQC. $^1$H[$^{17}$O] HMQC MAS NMR experiments were performed on a Bruker 850 MHz (20.0 T) NMR spectrometer, using a 1.3 mm HX probe, tuned to $^1$H (850.29 MHz) and $^{17}$O (115.27 MHz), and spinning at 60 kHz. The π/2 and π pulses on $^1$H were set to 2.05 and 4.1 μs, respectively. The π/2 pulses on $^{17}$O were set to 6.0 μs. For the J-HMQC experiment, the evolution delay following the π/2 pulse on $^1$H was set to 600 μs. For the D-HMQC experiment, the recoupling time τrec was set to 100 or 300 μs, during which an SR4$^2_1$ pulse was applied on $^1$H (120 kHz RF) and a WURST pulse was applied on $^{17}$O (at an offset of 120 kHz). The recycle delay was set to 0.5s. The number of scans and duration of each experiment can be found in supporting information (Table S1). $^{17}$O and $^1$H chemical shifts were referenced using respectively tap water (at 0 ppm) and a dipeptide (Asp-Ala), for which the low frequency signal was set to 1.1 ppm with respect to tetramethylsilane.

$^{17}$O MQMAS. A $^{17}$O MQMAS experiment was performed on an enriched alumina phase on the SCH-instrument in Tallahassee, using a 3.2 mm single-channel MAS probe, and spinning at 16 kHz. $^{17}$O excitation and conversion pulses were respectively set to 4 and 1.4 μs (600W power), and followed by
a 4.4 μs pulse (36W power). The recycle delay was set to 0.2s, and a total of 240 scans were acquired for each of the increments of the 2D. ¹⁷O chemical shifts were referenced externally to D₂O at −2.7 ppm (which was measured to be equivalent to tap-water at 0 ppm).

¹⁷O DNP. The MAS-DNP experiments were carried out on the 600 MHz/395 GHz setup installed at the National High Magnetic Field Laboratory in Tallahassee. The magnetic field was set at 14.094 T, the gyrotron generates a microwave power of 12 W at the probe base and a frequency of 395.166 GHz. The sample was packed in a 3.2 mm thin wall ZrO₂ rotor and spun at 13 kHz. The temperature for VT/Bearing/Drive were 91.6/98/110 K, leading to a sample temperature under microwave irradiation of ~100K, and ~94K in absence of it. The higher drive temperature allowed achieving 13 kHz spinning frequency while reducing the pressure needed. The sample was pre-spun at room temperature with a benchtop spinner (home-built) and the EPR measurement was carried out prior to the MAS-DNP experiment. Finally, 3 freeze-thaw were applied to the sample before insertion into the probe. The powder was impregnated with a 16 mM solution of TEKPol (purchased from Cortecnet) in D₂-tetrachloroethane (Cortecnet) for Al₂O₃, or tetrabromoethane (Sigma-Aldrich) for TiO₂. For the experiments, ~30 mg of powder was impregnated with ~30 μL of solution leading to tooth-pasty texture. The NMR acquisition parameters used for each spectrum are reported in Table S1, for the ¹⁷O{¹H} CPMAS and DFS-echo experiments performed with or without microwaves.
