ABSTRACT

More than about 20 central stars of planetary nebulae (CSPNs) have been observed spectropolarimetrically, yet no clear, unambiguously signal of the presence of a magnetic field in these objects has been found. We perform a statistical (Bayesian) analysis of all the available spectropolarimetric observations of CSPN to constrain the magnetic fields in these objects. Assuming that the stellar field is dipolar and that the dipole axis of the objects is oriented randomly (isotropically), we find that the dipole magnetic field strength is smaller than 400 G with 95% probability using all available observations. The analysis introduced allows integration of future observations to further constrain the parameters of the distribution, and it is general, so that it can be easily applied to other classes of magnetic objects. We propose several ways to improve the upper limits found here.

Key words: magnetic fields – methods: data analysis – methods: statistical – polarization – techniques: polarimetric

Online-only material: color figures

1. INTRODUCTION

The detection of magnetic fields in central stars of planetary nebulae (CSPNs) has been a subject of considerable interest recently. The presence of magnetic fields in CSPNs could shed some light on the magnetic field of planetary nebulae (PNs) themselves, and hence on the role of magnetic fields in the shaping of PNs (Chevalier & Luo 1994; Tweedy et al. 1995; García-Segura et al. 1999; Blackman et al. 2001a, 2001b; Balick & Frank 2002; Soker 2004, 2006; Vlemmings et al. 2006; Sabin et al. 2007). However, magnetic fields in CSPNs have proved elusive and so far, no clear, unambiguous spectropolarimetric detection of a magnetic field in a CSPN has been possible (Leone et al. 2011; Bagnulo et al. 2012; Jordan et al. 2012).

Spectropolarimetry of CSPNs is challenging because they are intrinsically faint and must be observed at relatively low spectral resolutions, which leads to cancellations attenuating the, already weak, polarimetric signals. Additionally, CSPNs present a relatively low number of spectral lines, which hampers line addition techniques that exploit the collective contribution of hundreds (or even thousands) of spectral lines to increase the signal-to-noise ratio (Semel & Li 1996; Donati et al. 1997; Martínez González et al. 2008).

Here we follow a different approach. We aim at constraining the magnetic field in CSPNs statistically, combining the overall information of all available observations to constrain the magnetism of CSPNs (in a way similar to, but more general than, the analysis of magnetic fields in RR Lyrae by Kolenberg et al. 2010 to estimate the distribution of eccentricities in the orbits of binary stars and exoplanets. However, unlike them, we carry out the full hierarchical Bayesian analysis here.)

2. MAGNETIC FIELD INFERENCE UNDER A BAYESIAN HIERARCHICAL ANALYSIS

In magnetized atmospheres, spectral lines show a characteristic circular polarization pattern dominated by the Zeeman effect. If the Zeeman splitting is sufficiently small so that it does not dominate the broadening of the spectral lines, and assuming that the magnetic field is roughly constant along the line of sight (LOS) and has a dipolar topology in the stellar surface, this circular polarization flux pattern $F_V$ can be simply modeled as (see Landi Degl’Innocenti 1992; Martínez González et al. 2012)

$$F_V(\lambda) = −αB_1 \frac{dF_I(\lambda)}{d\lambda},$$

where $F_I$ is the intensity flux and $B_1 = B_\parallel \cos \theta_d$, with $B_\parallel$ being the magnetic field strength in the pole and $\theta_d$ the inclination of the dipole axis with respect to the LOS. Additionally, $α = 1.17 \times 10^{-13} \lambda_0^{2} g_{\text{eff}}$ in the absence of limb darkening (see Martínez González et al. 2012, for the general expression), $\lambda_0$ is the central wavelength of the spectral line (in Å), and $g_{\text{eff}}$ is the effective Landé factor of the transition (Landi Degl’Innocenti 1982). For a general discussion about the weak-field approximation in stellar magnetism, we refer to Martínez González et al. (2012). From the observational point of view, $F_V/F_I$ is easier to measure because it is less prone to errors (e.g., Bagnulo et al. 2009). Consequently, we work instead with

$$\frac{F_V(\lambda)}{F_I(\lambda)} = −αB_\parallel \frac{1}{F_I(\lambda)} \frac{dF_I(\lambda)}{d\lambda}.$$  

Although all subsequent formalism is presented in terms of $F_V(\lambda)/F_I(\lambda)$ to simplify the notation, they are still valid provided one substitutes $F_V(\lambda)$ for $F_V(\lambda)/F_I(\lambda)$ and $dF_I(\lambda)/d\lambda$ for $(dF_I(\lambda)/d\lambda)/F_I(\lambda)$.
A number of different methods have been devised to infer the magnetic field $B_1$ of an object from a set of observations $D = \{F_1(\lambda_1), \ldots, F_1(\lambda_M), F_2(\lambda_1), \ldots, F_2(\lambda_M)\}$ of the flux of the Stokes $I$ and Stokes $V$ spectra at some given wavelengths $\lambda_1, \ldots, \lambda_M$. Maximum-likelihood methods consist of choosing the parameter(s) that maximizes the likelihood function $L_0$, which is the probability of observing the data (here, the intensity and polarization profiles), given the physical parameters $\theta$ of the model (here, the average longitudinal magnetic field, e.g., Jaynes & Bretthorst 2003; Martínez González et al. 2012). The likelihood ensues simply from Equation (1) and our model for the noise (here, Gaussian; see the Appendix):

$$
L_{B_1} = \left[ \prod_{s=1}^{S} \frac{1}{(2\pi \sigma_y^2 + \alpha^2 B_2^2 \sigma_y^2)} \right]^{(L_s/2)} \times \exp \left\{ -\sum_{s=1}^{S} \frac{c_s(B_s - \hat{B}_s)^2 - c_0}{2(\sigma_y^2 + \alpha^2 B_2^2 \sigma_y^2)} \right\},
$$

where $s$ extends over all the $S$ spectral lines in the observed spectrum (each with $L_s$ wavelengths), $\sigma_y^2$ and $\sigma_y^2$ are the variances of the Gaussian noise of the circular polarization profile and the derivative of the intensity respectively, and $c_0$ and $\hat{B}_1$ are the combination of the averages of the observed $F_V$ and $F_I$ defined in the Appendix. The denominator of each term in the exponential can be understood as (twice) the variance of the linear combination $F_V + \alpha B_1 F_I$ of the two random variables $F_V$ and $F_I$: $\text{Var}(F_V + \alpha B_1 F_I) = \text{Var}(F_V) + \alpha^2 B_2^2 \text{Var}(F_I) + 2\alpha B_1 \text{Cov}(F_V, F_I) = \sigma_y^2 + \alpha^2 B_2^2 \sigma_y^2 + 2\alpha B_1 \sigma_y \sigma_V \rho$, assuming that $\rho$ is the average correlation between $F_V$ and $F_I$ (Press et al. 1992; Asensio Ramos & Manso Sainz 2011). For typical modulation schemes, $\sigma_y^2 \sim \sigma_y^2$. Hence, $\alpha^2 B_2^2 \sigma_y^2 \sim 2\alpha^2 B_2^2 \sigma_y^2$, where $R$ is the spectral resolution and $\lambda$ the characteristic wavelength. In the optical ($\lambda \approx 5000 \, \text{Å}$), for $R = 3500$, and for relatively weak fields, the second and third terms can be neglected so that Equation (3) simplifies to

$$
L_{B_1} \approx \left[ \prod_{s=1}^{S} \frac{1}{2\pi \sigma_y^2} \right] \exp \left\{ -C_1(B_s - \hat{B}_s)^2 + C_0 \right\},
$$

where $C_0$ and $\hat{B}_1$ have been redefined as in Equation (A8) (for clarity, the explicit dependence of $\sigma_y^2$ on the spectral line is not shown). Note that $\hat{B}_1$ is the maximum-likelihood estimate for $B_1$ (see Martínez González et al. 2012; Leone et al. 2014).

In a Bayesian analysis, the a posteriori probability for the presence of a magnetic field $B_0$ in the object given some observations $D$ is simply obtained from the Bayes theorem (e.g., Jaynes & Bretthorst 2003; Gregory 2005):

$$
p(B_0|D) = \frac{p(D|B_0)p(B_0)}{p(D)},
$$

where $p(D|B_0)$ is the likelihood function, $p(B_0)$ measures our priori knowledge on the value of the field, and $p(D)$ is the so-called evidence, which we will not consider explicitly in the following since it is just a scaling factor so that the posterior is normalized ($p(D) = \int p(D|B_0)p(B_0)dB_0$). There is, in principle, no a priori reason for the field pointing toward us or away from us, and it seems likely that the most probable value of $B_1$ be zero. Hence, a natural choice for $p(B_0)$ would be a normal distribution $\mathcal{N}(0, b^2)$ for some fixed variance $b^2$ (which can be potentially very large). Equation (5) may thus be used to infer the magnetic field of an object from polarimetric observations (see, for example, Asensio Ramos et al. 2007; Asensio Ramos 2009, 2011). Instead, here, we are interested in the statistical distribution of all of them and how this distribution is constrained by the observations.

We now make a simplification by assuming that all observations are statistically independent. In other words, observing an object tells you nothing about the magnetic field of another object. Repeated observations of the same star are modeled using the same $B_0$, unless the observations are obtained in very different epochs. In this case, they are considered to be different objects because of the potential variability of the source. Strictly speaking, the assumption of independence is surely not correct for different observations of the same star at different epochs and one should include the covariance between them. However, we make this simplification for the sake of obtaining a simpler analytical final result and because this covariance is difficult to model and estimate. If the previous conditions hold, we can factorize the likelihood and the priors so that the marginal posterior reads

$$
p(B_1|\ldots, B_{1N}|\{D_1\}) \propto \prod_{i=1}^{N_{\text{obs}}} p(D_i|B_{1i})p(B_{1i}),
$$

where $\{D_i\}$ is the set of all the observed Stokes profiles averaged over the stellar surface, $p(D_i|B_{1i}) \equiv \mathcal{L}_{B_{1i}}$, and $p(B_{1i})$ is a Gaussian with mean 0 and variance $b^2$. Instead of using a fixed $b$, we follow a hierarchical Bayesian approach and we introduce $b$ into the Bayesian inference scheme (Gregory 2005), so that

$$
p(B_{1i}, \ldots, B_{1N}, b|\{D_1\}) \propto \prod_{i=1}^{N_{\text{obs}}} p(D_i|B_{1i})p(B_{1i}, b).
$$

The $b$ parameters is then termed hyperparameter, since it is a parameter of the prior. Note that is does not affect the likelihood. The joint prior for $B_{1i}$ and $b$ can be factorized as

$$
p(B_{1i}, b) = p(B_{1i}|b)p(b),
$$

so that the marginal prior for $B_{1i}$ could be obtained by marginalizing $b$ (i.e., integrating out)

$$
p(B_{1i}) = \int p(B_{1i}|b)p(b)db.
$$

As discussed above, we consider $p(B_{1i}|b) = \mathcal{N}(0, b^2)$. Integrating Equation (6) over all the $B_{1i}$ variables (using Equation (4)), the marginalized posterior for $b$ is obtained, resulting in

$$
p(b|\{D_1\}) \propto p(\{D_1\})p(b),
$$

where $p(\{D_1\}|b) \equiv \mathcal{L}_b$ is given by

$$
\mathcal{L}_b = \prod_{i=1}^{N_{\text{obs}}} \int dB_{1i} p(D_i|B_{1i})p(B_{1i}|b)
\cong \prod_{i=1}^{N_{\text{obs}}} \left[ \prod_{s=1}^{S} \frac{1}{2\pi \sigma_y^2} \right] \frac{1}{(1 + 2C_{1i}b^2)^{S/2}} \times \exp \left\{ -\sum_{s=1}^{S} \frac{B_{1i}^2 C_{1i}}{1 + 2C_{1i}b^2} - \sum_{i=1}^{N_{\text{obs}}} C_{0i} \right\},
$$

where
Figure 1. Likelihood (dotted line) and posterior (solid line) for the parameter $b$. The gray lines show the results when only the data of Leone et al. (2014) is taken into account. When the data of Jordan et al. (2012) is added, the curves are updated to the blue lines. The posterior is equal to the likelihood multiplied by the Jeffreys prior (see Equation (10)).

Notes.

$^a$ Maximum-likelihood estimate of the longitudinal component of the magnetic field.

$^b$ Estimation of the field with error bars and taking into account the significant figures.

Table compiled in Leone et al. (2014) and summarized in Table 1.

A characteristic of the likelihood distribution in Equation (11) is that it only depends on the maximum-likelihood estimation of the longitudinal field, $\hat{B}_1$, and of the coefficients C$_1$ (the coefficients C$_0$ represent just a scaling of the likelihood and are of no importance for our purpose). According to Equation (A9), $C_1$ can be obtained from the uncertainty in the estimation of $\hat{B}_1$, as computed by Martínez González et al. (2012). Therefore, we can make use of the recent results of Jordan et al. (2012) and use their estimations to upgrade our observations. Note that, since their results represent a longitudinal magnetic field averaged on the stellar surface, they have to be multiplied by four to account for the dipolar dilution (Martínez González et al. 2012). According to Figure 1, the addition of the observations of Jordan et al. (2012) barely modifies the posterior distribution $p(b|D_i)$). The results point to a very small value of $b$.

From the posterior of the hyperparameter, we derive the posterior probability of the longitudinal field for all the sources as

$$\langle p(B_1) \rangle = \int dB_1 p(B_1|b) p(b|D_i)).$$

(12)

This distribution depends on the cutoff $b_{\text{min}}$, but only weakly for $b_{\text{min}}$ ranging between $10^{-6}$–$10^{-1}$ G. Although we do not display the figure, choosing $b_{\text{min}} = 1$ mG, $B_1$ is below $\sim 250$ G in absolute value with 95% probability.

More interesting is to consider the distribution of $B_{d}$, the magnetic field strength of the dipole, which can be obtained from the distribution of $B_1$ assuming that the dipole inclination angle of the different CSPN is randomly (isotropically) oriented while $p(b)$ is the prior to be chosen over the hyperparameter $b$. The previous expression can be considered as a multi-object and multiline approach to magnetic field detection.

We do not have any a priori information on $b$, which is a scale variable. A convenient uninformative prior in these cases is the Jeffreys prior $p(b) \propto 1/b$ because it distributes probability uniformly in the logarithm: it is as likely to find $b$ between 0.1 and 1 G, as between 10 and 100 G (Jeffreys 1968; Jaynes & Bretthorst 2003). This prior is improper (its integral is not finite) and here, it yields an improper posterior too. For that reason, a cutoff $b_{\text{min}}$, has to be chosen. For any informative data set (peaked $L_b$), the value of the cutoff becomes irrelevant but for, perhaps, ridiculously small values; for less informative (i.e., flatter) $L_b$, we must check the sensitivity of the results to the value of $b_{\text{min}}$.

Figure 1 shows, in gray, $L_b$ (dotted line) and the posterior $p(b|D_i)$ using a Jeffreys prior (solid line) for the CSPN data compiled in Leone et al. (2014) and summarized in Table 1. A characteristic of the likelihood displayed in Equation (11) is that it only depends on the maximum-likelihood estimation of the longitudinal field, $\hat{B}_1$ and of the coefficients C$_1$ (the coefficients C$_0$ represent just a scaling of the likelihood and are of no importance for our purpose). According to Equation (A9), $C_1$ can be obtained from the uncertainty in the estimation of $\hat{B}_1$, as computed by Martínez González et al. (2012). Therefore, we can make use of the recent results of Jordan et al. (2012) and use their estimations to upgrade our observations. Note that, since their results represent a longitudinal magnetic field averaged on the stellar surface, they have to be multiplied by four to account for the dipolar dilution (Martínez González et al. 2012). According to Figure 1, the addition of the observations of Jordan et al. (2012) barely modifies the posterior distribution $p(b|D_i)$). The results point to a very small value of $b$.

From the posterior of the hyperparameter, we derive the posterior probability of the longitudinal field for all the sources as

$$\langle p(B_1) \rangle = \int dB_1 p(B_1|b) p(b|D_i)).$$

(12)

This distribution depends on the cutoff $b_{\text{min}}$, but only weakly for $b_{\text{min}}$ ranging between $10^{-6}$–$10^{-1}$ G. Although we do not display the figure, choosing $b_{\text{min}} = 1$ mG, $B_1$ is below $\sim 250$ G in absolute value with 95% probability.

More interesting is to consider the distribution of $B_{d}$, the magnetic field strength of the dipole, which can be obtained from the distribution of $B_1$ assuming that the dipole inclination angle of the different CSPN is randomly (isotropically) oriented.
in space, which seems reasonable since there is no clear evidence for a preferential orientation of PNs themselves (Corradi et al. 1998). This computation is not possible in the general case in which $B_l$ is interpreted as an average longitudinal field over the stellar surface. Then, a priori, $B_d$ follows a Maxwellian distribution:

$$p(B_d|b) = \frac{4\pi}{(2\pi b^2)^{3/2}} B_d^2 \exp \left( -\frac{B_d^2}{2b^2} \right).$$ \hspace{1cm} (13)

Proceeding as above we derive the distribution of dipolar magnetic field strength from all the observed sources as

$$\langle p(B_d) \rangle = \int dB_d \, p(B_d|b) \, p(b|D_i).$$ \hspace{1cm} (14)

It is interesting to compare this equation with Equation (7) of Kolenberg & Bagnulo (2009) and point out the differences. Although the two formalism assume an isotropic distribution of fields, our approach is more general for the following reasons: (1) we use a fully Bayesian approach in which we model the observed Stokes profiles to correctly propagate all uncertainties in the observations to the magnetic field distribution, while Kolenberg & Bagnulo (2009) use the maximum-likelihood estimation of the $B_l$ and (2) we take into account that each source can have a different magnetic field strength and that it is known with imprecision.

Figure 2 shows the corresponding probability density function (solid) and the cumulative distribution (dotted) for the data of Leone et al. (2014) alone and what happens when we add the data of Jordan et al. (2012). Only the blue curve is conspicuous because the gray and blue curves overlap.

3. DISCUSSION AND CONCLUSIONS

An important property of $L_b$ is its ability to concentrate for large $N_{\text{obs}}$. Consider, for example, an ensemble of objects with similar spectra that are observed with identical uncertainties $\sigma_V$ (hence, they have similar $C_1$); they only differ in their magnetic field strength (i.e., $B_l$). Then, the maximum of $L_b$ (or log $L_b$) in Equation (11) will lie at

$$b_{\text{ML}} = \begin{cases} 0 & \text{if } \langle \hat{B}^2 \rangle < \frac{1}{C_1}, \\ \frac{\sqrt{2C_1\langle \hat{B}^2 \rangle - 1}}{2C_1} & \text{if } \langle \hat{B}^2 \rangle \geq \frac{1}{C_1}, \end{cases} \hspace{1cm} (15)$$

where $\langle \hat{B}^2 \rangle = \sum \frac{B_i^2}{N_{\text{obs}}}$. In the first case, the observations are inadequate (too noisy, and therefore, $C_1$ too large), for the estimated $B_l$ to be informative. $L_b$ is relatively flat near $b = 0$ and when multiplied by the Jeffreys prior, the posterior clearly diverges toward smaller values, always reaching its maximum a-posteriori (MAP) value at the cutoff, $b_{\text{MAP}} = b_{\text{min}}$, which is not very helpful. An illustration of this situation is given by one of the dotted lines in Figure 3, which corresponds to an incomplete subset of just four observed objects from Table 1. The two other dotted lines correspond to different subsets with the same number of objects. In those other cases, $L_b$ has a maximum at some non-zero value $b_{\text{ML}}$, which is noticeable also in the posterior $p(b|D_i)$. But they are notably wider (spanning several hundreds of gauss) than the likelihood obtained from the full set of observed objects (gray solid line). In fact, it can be shown that for large values of $N_{\text{obj}}$, the width of $L_b$ converges to 0 as $N_{\text{obj}}^{-1/2}$. Therefore, $L_b$ becomes more and more informative on the value of $b$ as we accumulate observations ($N_{\text{obs}} \rightarrow \infty$), even if the individual observations are too noisy to get a clear detection (cf. solid gray line in Figure 3). In a sense, this is a generalization of multiline addition techniques in which the collective contribution of many individual spectral
informative, Jeffreys) priors to \( \sigma_V \) measurements is a fundamental problem in Bayesian theory.

Their actual values have been independently estimated from the available observations. This demonstrates that, although there is not a single detection of magnetic fields, adding more objects produces a collapse of the posterior.

We have introduced two major simplifications in the method which are not essential. The first one regards noise estimation. We have assumed that the variance of the observed quantities (\( \sigma_V \) and \( \sigma_I \)) was known for the derivation the likelihood functions (see the Appendix), and that they are independent of wavelength. Their actual values have been independently estimated from the intensity fluctuations in the continuum windows between spectral lines. Estimating the unknown variance of a set of measurements is a fundamental problem in Bayesian theory which can be done independently (like here) or consistently within the Bayesian analysis itself by assigning (e.g., non-informative, Jeffreys) priors to \( \sigma_V \) and \( \sigma_I \), and marginalizing these parameters. We have not pursued this more general approach here to keep our main argument simple.

Secondly, the approximation in Equation (4) has allowed the analytical derivation of Equation (11). This approximation is accurate beyond the strict limits stated above. When the more general Equation (3) is required, the integrals in Equation (11) have to be performed numerically using Markov Chain Monte Carlo or similar methods, depending on the dimensionality of the problem.

An important characteristic of the analysis presented is that it naturally allows integration of new data to improve the magnetic field estimates. We have already shown how things change when the data of Jordan et al. (2012) is added to the observations of Leone et al. (2014). From the analysis of all the available observations so far we have obtained the upper limit of 400 G.

Our analysis here suggests several ways in which such estimates can be improved. As shown above, the mere addition of new observations helps constrain the magnetic field distribution, even when no clear detection in the individual objects is possible. The constraints on the global distribution can be even stronger when either the new observations have a better (lower) noise level, or if clear detection on individual objects is achieved.

The analysis presented in this paper is not limited to any particular spectral range, provided that the weak-field approximation holds. Observations at different spectral windows can be straightforwardly included in the analysis after computing their corresponding \( C_1 \), \( \tilde{B}_1 \), and \( \sigma_V \) values (although in some cases it might be advisable to consider the general expression for the likelihood (Equation (3)). Given that the amplitude of the Zeeman Stokes \( V \) scales with \( \lambda_0 \) (see, e.g., Landi Degl’Innocenti & Landolfi 2004), spectropolarimetry of the Paschen and Brackett series should be favored.

The joint analysis of linear and circular polarization would impose stronger constraints on the magnetic field distribution under the, very likely, assumption of isotropic distribution of fields for the observed objects. The Zeeman effect generates linear polarization patterns which are usually smaller than those of circular polarization and that are, in the weak-field approximation, proportional to the square of the transverse component \( B_{\perp} \) of the magnetic field to the LOS (e.g., Landi Degl’Innocenti 1992; Landolfi et al. 1993; Martínez González et al. 2012). However, we understand that the detection of linear polarization is extremely improbable, given that no reliable detection of circular polarization has been achieved so far.

Figure 3. Illustration of how adding two new objects with clear magnetic field detections of 200 G, 1000 G, or 1500 G, would lead to a rapid change of the posterior (blue lines). By contrast, if had observed just four objects out of the total sample, the posterior would be far less informative (dotted lines for three random realizations of four elements, superposed), than the complete sample to date (solid gray line).

(A color version of this figure is available in the online journal.)
Additionally, magnetic alignment of dust grains creates linear polarization in the continuum from which we may infer the presence of a magnetic field (e.g., Davis & Greenstein 1951; Lazarian 2007). The information thus obtained is not quantitative and cannot be directly included in our formalism. Yet, it may provide important general and symmetry constraints and bounds that could be implemented within the Bayesian methodology.

Finally, it is clear that the approach presented here can be applied to other sets of objects (e.g., white dwarfs) once they can be assumed to belong to the same magnetic class, i.e., they are all characterized by the same statistical distribution of fields.

The authors are grateful to Stefano Bagnulo for some interesting suggestions and for a careful review of the paper. We also thank C. González for useful discussions. Financial support by the Spanish Ministry of Economy and Competitiveness and the European FEDER Fund through projects AYA2010-18029 (A.A.R., M.J.M.G., and R.M.S.), AYA2012-35330 (R.L.M.C.), Consolider-Ingenio 2010 CSD2009-00038 (A.A.R. and R.M.S.), and Ramón y Cajal fellowship program (A.A.R.), is greatly acknowledged.

APPENDIX

COMPUTATION OF THE LIKELIHOOD

We assume that the observed circular polarization flux is given by Equation (1) but that it is corrupted by a normally distributed noise $\varepsilon_f \sim \mathcal{N}(0, \sigma_f^2)$ with zero mean and variance $\sigma_f^2$:

$$F_V = -\alpha B_0 \mathcal{F}_f + \varepsilon_f; \quad (A1)$$

the flux derivative, in turn, is corrupted by a noise $\varepsilon_f' \sim \mathcal{N}(0, \sigma_f'^2)$:

$$F_f' = \mathcal{F}_f' + \varepsilon_f'. \quad (A2)$$

Assuming that both sources of error are independent, then the joint likelihood of the data is

$$p(F_V, F_f'| B_0, \mathcal{F}_f', \sigma_f, \sigma_f') = p(F_V|B_0, \mathcal{F}_f', \sigma_f, \sigma_f') p(F_f'|\mathcal{F}_f', \sigma_f') = \frac{1}{2\pi \sigma_f \sigma_f'} \exp \left\{ -\frac{(F_V + \alpha B_0 \mathcal{F}_f')^2}{2\sigma_f^2} \right\} \exp \left\{ -\frac{(F_f' - \mathcal{F}_f')^2}{2\sigma_f'^2} \right\}. \quad (A3)$$

The true value $\mathcal{F}_f'$ is treated as a nuisance parameter that we can integrate out for some uniform vague prior:

$$p(F_V, F_f'| B_0, \sigma_f, \sigma_f') = \frac{1}{\sqrt{2\pi} \sigma_f} \frac{1}{\sqrt{2\pi} \sigma_f'} \frac{1}{\sqrt{2\pi} \sigma_f^2 + \alpha^2 B_0^2 \sigma_f'^2} \times \exp \left\{ -\frac{(F_V + \alpha B_0 \mathcal{F}_f')^2}{2(\sigma_f^2 + \alpha^2 B_0^2 \sigma_f'^2)} \right\}. \quad (A4)$$

Assuming statistical independence for the $L$ wavelengths and constant $\sigma_f$ and $\sigma_f'$ across the spectral line,

$$p(\{F_V(\lambda_\ell), F_f'(\lambda_\ell)| B_0, \sigma_f, \sigma_f') = \frac{1}{2\pi (\sigma_f^2 + \alpha^2 B_0^2 \sigma_f'^2)^{L/2}} \times \exp \left\{ -\frac{c_0 (B_0 - \hat{B}_0)^2}{2(\sigma_f^2 + \alpha^2 B_0^2 \sigma_f'^2)} \right\}. \quad (A5)$$

where, introducing the notation $\langle F_V^2 \rangle = \sum_\ell F_V(\lambda_\ell)^2$, $\langle F_V F_f' \rangle = -\alpha \sum_\ell F_V(\lambda_\ell) F_f'(\lambda_\ell)$, $\langle F_f'^2 \rangle = \alpha^2 \sum_\ell F_f'(\lambda_\ell)^2$, then,

$$c_1 = \langle F_V^2 \rangle, \quad c_0 = \langle F_V^2 \rangle - c_1 \hat{B}_0^2, \quad \text{and} \quad \hat{B}_0 = \frac{\langle F_V F_f' \rangle}{\langle F_f'^2 \rangle}. \quad (A6)$$

Note that $c_{0,1}$ and $\hat{B}_0$ implicitly depend on the spectral line considered and also explicitly through the effective Landé factor within $\alpha$. Extending the argument to all the $S$ spectral lines

$$L_{B_0} = \prod_{s=1}^S \frac{1}{2\pi \sigma_{f,s}^2} \left[ \frac{1}{(2\pi \sigma_f^2 + \alpha^2 B_0^2 \sigma_{f,s}'^2)^{L_s/2}} \right] \times \exp \left\{ -\sum_\ell c_1(B_0 - \hat{B}_0)^2 + c_0 \right\}, \quad (A6)$$

where $\lambda_{\ell,s}$ represents the wavelength point $\ell$ of line $s$. In Equation (A6), $\sigma_f$ and $\sigma_f'$ are, in principle, different for each spectral line; they are estimated from their adjacent continuum (for clarity, we do not write the subscript $s$). To second order on $\xi = B_0 \sigma_f'/\sigma_f$,

$$L_{B_0} = \prod_{s=1}^S \frac{1}{2\pi \sigma_{f,s}^2} \left[ \frac{1}{(2\pi \sigma_f^2 + \alpha^2 B_0^2 \sigma_{f,s}'^2)^{L_s/2}} \right] \times \exp \left\{ -C_1(B_0 - \hat{B}_0)^2 - C_0 \right\} + O(\xi^2), \quad (A7)$$

where

$$C_1 = \left( \frac{\langle F_f'^2 \rangle}{\langle F_f'^2 \rangle} - C_0 \hat{B}_0^2 \right), \quad \hat{B}_0 = \frac{\langle F_V F_f' \rangle}{\langle F_f'^2 \rangle}. \quad (A8)$$

with $\langle F_f'^2 \rangle = \sum_\ell F_f'(\lambda_{\ell,s})^2/(2\sigma_{f,s}^2)$; $\langle F_V F_f' \rangle = -\sum_\ell [\alpha_s/(2\sigma_{f,s}^2)] \sum_\ell F_V(\lambda_{\ell,s}) F_f'(\lambda_{\ell,s})$; and $\langle F_V^2 \rangle = \sum_\ell [\alpha_s/(2\sigma_{f,s}^2)] \sum_\ell F_V(\lambda_{\ell,s})^2$. Interestingly, the $C_1$ coefficient can be related to the error bar of $\hat{B}_0$ as shown by Martínez González et al. (2012):

$$C_1 = \frac{1}{2\sigma_{f,s}^2}. \quad (A9)$$

Therefore, all the ingredients to carry out our calculations are readily available from any work that tabulates the maximum-likelihood estimation of the longitudinal field and its associated error bar.
