Abstract

Existing networks directly learn feature representations on 3D point clouds for shape analysis. We argue that 3D point clouds are highly redundant and hold irregular (permutation-invariant) structure, which makes it difficult to achieve inter-class discrimination efficiently. In this paper, we propose a two-faceted solution to this problem that is seamlessly integrated in a single ‘Blended Convolution and Synthesis’ layer. This fully differentiable layer performs two critical tasks in succession. In the first step, it projects the input 3D point clouds into a latent 3D space to synthesize a highly compact and more inter-class discriminative point cloud representation. Since, 3D point clouds do not follow a Euclidean topology, standard 2/3D Convolutional Neural Networks offer limited representation capability. Therefore, in the second step, it uses a novel 3D convolution operator functioning inside the unit ball ($B^3$) to extract useful volumetric features. We extensively derive formulae to achieve both translation and rotation of our novel convolution kernels. Finally, using the proposed techniques we present an extremely light-weight, end-to-end architecture that achieves compelling results on 3D shape recognition and retrieval.

1. Introduction

The human world exists in 3D, therefore optimally understanding and interpreting 3D data is an active research problem. Although deep Convolutional Neural Networks (CNNs) have been greatly successful in 2D representation learning, they still do not provide an optimal answer to unique challenges that 3D data presents. Specifically, there are two main issues pertinent to 3D data: (a) 3D point clouds and rasterized voxel based representations encode a lot of redundant information thereby making inter-class discrimination difficult, (b) 3D convolutions generally operate in Euclidean space, whereas real-world 3D data lie on a non-Euclidean manifold. The representations thus learned fail to encode the true geometric structure of input shapes. The availability of low-cost 3D sensors and their vast applications in autonomous cars, medical imaging and scene understanding demand a fresh look towards solving the above-mentioned challenges.

The existing representation learning schemes for 3D shape description either operate on voxels [7, 55] or point clouds [37, 25]. The voxelized data representations are highly sparse, thus prohibiting the design of large-scale deep CNNs. Efficient data structures such as Octree [34] and Kdtree [6] have been proposed to solve this problem, however neural networks based representation learning on these tree-based indexing structures is an open research problem [40]. In comparison, point clouds offer an elegant, simple and compact representation for each point ($x, y, z$). Additionally, they can be directly acquired from the 3D sensors e.g., low-cost structured light cameras. On the down side, their irregular structure and high point redundancy pose a serious challenge for optimal feature learning.

We note that recent attempts on direct feature learning
from point clouds assume a simplistic pipeline (see Fig. 1) that mainly aims to extract better global features considering all points [36, 37, 25, 27]. However, all these approaches lack the capacity to work on non-Euclidean geometries and have no inherent mechanism to deal with the high redundancy of point clouds. In this work, we propose an integrated solution, called Blended Convolution and Synthesis (BCS), to address the above-mentioned problems. BCS can effectively deal with the irregular, permutation-invariant and redundant structure of point clouds. Our solution has two key aspects. Firstly, we map the input 3D shape into a more discriminative 3D space. We posit that raw 3D point clouds are sub-optimal to be directly used as input to classification models, due to redundant information. This property hampers the classification and retrieval performance by adding an extra overhead to the network, as the network should then disregard redundant features purely using convolution. In contrast, we initially synthesize a more discriminative shape by projecting the original shape to a latent space using a newly derived set of functions which are complete in the unit ball ($\mathbb{B}^3$). The structure of this latent shape is governed by the loss function, and therefore, is optimized to pick up the most discriminative features. This step reduces the number of convolution layers significantly, as shown experimentally in Sec. 5. Secondly, we propose a novel convolution operation that works on non-Euclidean topological spaces i.e., inside the unit ball ($\mathbb{B}^3$). We derive a novel set of complete functions within $\mathbb{B}^3$ that perform convolution in the spectral domain.

Furthermore, since our network operates on ‘spectral domain’, it provides multiple advantages compared to competing models that operate in Euclidean domains: 1) A highly compact and structured representation of 3D objects, which addresses the problem of redundancy and irregularity. Effectively, a 3D shape is represented as a linear combination of complete-orthogonal functions, which allows only a few coefficients to encode shape information, compared to spatial domain representations. 2) Convolution is effectively reduced to a multiplication-like operator which improves computational efficiency, thereby significantly reducing the number of FLOPS. 3) A theoretically sound way to treat non-Euclidean geometries, which enables the convolution to achieve translational and rotational equivariance and 4) Scalability to large-sized shapes with bounded complexity.

Most importantly, existing methods which perform convolution in spectral domain [12, 14, 38] use spherical harmonics or Zernike polynomials to project 3D functions to spectral domain for performing convolution. The aforementioned function spaces entail certain limitations, e.g.: 1) ‘Spherical harmonics’ only operate on the surface of the unit sphere, which causes critical information loss for non-polar shapes. 2) ‘Zernike polynomials’ cause the convolution to achieve only 3D rotational movement of the kernel. In contrast, our newly derived polynomials can handle non-polar shapes, while achieving both 3D rotational and translational movements of the convolution kernel as theoretically proved in Sec. 4.2.

The main contributions of this work are:

- A novel approach to obtain a learned 3D shape descriptor, which enhances the convolutional feature extraction process, by projecting the input 3D shape into a latent space, using newly derived functions in $\mathbb{B}^3$.
- Develop the theory of a novel convolution operation, which allows both 3D rotational and 3D translational movements of the kernel.
- Develop formulae to perform discriminative latent space projection of the input shape and 3D convolution in a single step, thereby making our approach computationally efficient.
- Implementation of the proposed latent space projection and convolution as a fully differentiable module which can be integrated into any end-to-end learning architecture, and developing a shallow experimental network which produces results on par with state-of-the-art while being computationally efficient compared to most existing architectures.

2. Related Work

3D shape descriptors: A 3D shape descriptor is a representation of the structural essence of a 3D shape. A variety of hand-crafted feature descriptors have been proposed in past research efforts. A few key such works are based on Light Field Descriptors [11], Fourier Transformation [51], Eigen Value Descriptors [21], and geometric moments [13]. Most recent hand-crafted 3D descriptors are based on diffusion parameters [9, 41, 8]. On the other hand, learned 3D shape descriptors have also been popular in the computer vision literature. Litman et al. [31] propose a supervised bag-of-features (BOF) method to learn a descriptor. Zhu et al. follow an interesting approach, where they first project the 3D shapes into multiple 2D shapes, and then perform training on the 2D shapes to learn a descriptor. Xie et al. [59] present a hybrid approach which combines both hand-crafted features and deep networks. They first compute a geometric feature vector from the 3D shape, and then employ a deep network on the feature vector to learn a 3D descriptor. Xie et al. [58] follow a similar approach, where they first calculate Heat Kernel Signatures of 3D shapes and then use two deep encoders to obtain descriptors. Our work is partially similar to this, but has a key difference: instead of computing hand-crafted features as the first step, we do a learned mapping of input 3D shape into a more discriminative 3D space, which allows us to get rid of high intra-class variances exhibited by most 3D shape descriptors. This step provides another
Orthogonal Moments and 3D Convolution: Generally, orthogonal moments are used to obtain deformation invariant descriptors from structured data. Compared to geometric moments, orthogonal moments are robust to certain deformations such as rotation, translation and scaling. This property of orthogonal moments has been exploited specially in 2D data analysis in the past [20, 30, 2, 49, 23, 45]. Extension of deformation invariant moments from 2D to 3D also has been explored by many prior work [17, 39, 10, 15]. However, the certain properties of these moments depend on the Hilbert space on which they are defined. For example, orthogonal moments defined in a sphere or a ball exhibit convenient properties to extract rotation invariants, compared to orthogonal moments defined in a cube. These unique properties of orthogonal moments have recently been used to derive convolution operations which allows 3D rotational movements of kernels [12, 14, 38]. However, the moments used in these works do not contain the necessary properties to achieve 3D translation of the kernels, and therefore, we derive a novel set of functions in \( B^3 \) to overcome this limitation.

3D Shape Classification and Retrieval: Recent prior work that has been developed for 3D shape classification and retrieval tasks can be broadly categorized into three classes: 1) hand-crafted feature based [50], [18] 2) unsupervised learning based [55], [24] 3) deep learning based [36, 37, 29]. Generally, deep learning based approaches have shown superior results compared to other two categories. However, the aforementioned deep learning based architectures operate on Euclidean spaces, which is sub-optimal for 3D shape analysis tasks, although Weiler et al. [34] has shown impressive results using SE(3)-equivariant convolutions in Euclidean domain. In contrast, our network performs convolution on \( B^3 \) which allows efficient feature extraction, since 3D rotation and translation of kernels are easier to achieve in this space.

3. Preliminaries

We first provide an overview of basic concepts that will be used later in our derivations.

3.1. Complete Orthogonal Systems

Orthogonal functions are useful tools in shape analysis. Let \( \Phi_m(X) \) and \( \Phi_n(X) \) be two functions defined in some space \( S \). Then, \( \Phi_m(X) \) and \( \Phi_n(X) \) are orthogonal over the space \( S \) if and only if,

\[
\int_S \Phi_n(X) \Phi_m(X) dX = 0, \ \forall n \neq m. \tag{1}
\]

Let \( f \) be a function defined in space \( S \), and \( \{ \Phi_m(X) : m \in \mathbb{Z}^+ \} \) be a set of orthogonal functions defined in the same space. Then, the set of orthogonal moments of \( f(X) \), with respect to set \( \{ \Phi_m(X) \} \), can be obtained by,

\[
\hat{f}_m(X) = \int_S f(X) \Phi_m(X)^\dagger, \tag{2}
\]

where \( \dagger \) denotes the complex conjugate. If a set of functions \( \{ \Phi_m(X) : m \in \mathbb{Z}^+ \} \) is both complete and orthogonal, it can reconstruct the \( f(X) \) using its orthogonal moments as follows.

\[
f(X) = \sum_m \hat{f}_m \Phi_m(X). \tag{3}
\]

3.2. Convolution in Unit Ball \( B^3 \)

The unit ball \( B^3 \) is the set of points \( x \in \mathbb{R}^3 \), where \( \|x\| < 1 \). Any point in \( B^3 \) can be parameterized using coordinates \((\theta, \phi, r)\), where \( \theta, \phi, \) and \( r \) are azimuth angle, polar angle, and radius respectively. Performing convolution on 3D shapes in non-linear topological spaces such as the unit ball \( B^3 \) has a key advantage: compared to the Cartesian coordinate system, it is efficient to formulate 3D rotational movements of the convolutional kernel in \( B^3 \) [38]. To this end, both the input 3D shape and the 3D kernel should be represented as functions in \( B^3 \). However, performing convolution in the spatial domain is difficult due to the non-linearity of \( B^3 \) space [38]. Therefore, it is necessary to first obtain the spectral representation of the 3D shape and the 3D kernel, with respect to a set of orthogonal and complete functions in \( B^3 \), and perform convolution in the spectral domain.

4. Methodology

In this section, we present our ‘Blended Convolution and Synthesis’ layer in detail. First, we construct a set of orthogonal and complete polynomials in \( B^3 \). Then, we relax the orthogonality condition of these polynomials, which allows us to project the input shape into a latent space. This projection is a learned process and depends on the softmax cross-entropy between predicted and ground-truth object classes. Therefore, projected shape is optimized to contain more discriminative structural properties across object classes. Afterwards, we convolve the latent shape space with roto-translational kernels in \( B^3 \) to map it to the corresponding class. Besides, we derive formulae to achieve both projection and convolution in a single step, which makes our approach more efficient.

Below in Section 4.1, we explain the learned projection of the object onto a latent space. Then, in Section 4.2, we derive our convolution operation, which is able to capture features efficiently using roto-translational kernels.

4.1. Learned Mapping for Shape Synthesis

In this section, we explain the projection of 3D point clouds to a discriminative latent space in \( B^3 \). First, we derive
a set of complete orthogonal functions in \( \mathbb{B}^3 \). Orthogonal moments obtained using orthogonal functions can be used to reconstruct the original object. However, our requirement here is not to reconstruct the original object, but to map it to a more discriminative shape. Therefore, after deriving the orthogonal functions, we relax the orthogonality condition to facilitate the latent space projection. Furthermore, instead of the input point cloud, we use a compact representation as the input to the feature extraction layer, for efficiency and to leverage the capacity of convolution in \( \mathbb{B}^3 \). In Section 4.1.1, we explain our compact representation.

### 4.1.1 Compact Representation of Point Clouds

Most 3D object datasets contain point clouds with uniform texture. That is, if the 3D shape is formulated as a function \( f \) in \( \mathbb{B}^3 \), for any point in \( f \), \( f(\theta, \phi, r) = c \), where \( c \) is a constant. However, formulating 3D shapes in \( \mathbb{B}^3 \) has the added advantage of representing both 2D texture and 3D shape information simultaneously [38]. Therefore, the advantage of convolution in \( \mathbb{B}^3 \) can be utilized when the input and kernel functions have texture information.

Following this motivation, we convert the uniform textured point clouds into non-uniform textured point clouds using the following approach. First, we create a grid using equal intervals along \( r, \theta \), and \( \phi \). We use 25, 36, and 18 interval spaces for \( r, \theta \), and \( \phi \) respectively. Then, we bin the point cloud to grid points, which results in a less dense, non-uniform surface valued point cloud. The obtained compact representation does not contain all the fine-details of the input point cloud. However in practice, it allows better feature extraction using the kernels. A possible reason could be that kernels are also non-uniform textured point clouds with discontinuous space representations, and they can capture better features from non-uniform textured input point clouds when performing convolution in \( \mathbb{B}^3 \).

### 4.1.2 Derivation of orthogonal functions in \( \mathbb{B}^3 \)

In this section, we derive a novel set of orthogonal polynomials with necessary properties to achieve the translation and rotation of convolution kernels. Afterwards, in Section 4.1.4, we relax the orthogonality condition of the polynomials to facilitate latent space projection.

Canterakis et al. [10] showed that a set of orthogonal functions which are complete in unit ball can take the form,

\[
Q_{nl}(r, \theta, \phi) = r^n Y_{l,m}(\theta, \phi),
\]

where \( Q_{nl} \) is the linear component and \( Y_{l,m}(\theta, \phi) \) is the angular component. The variables \( r, \theta \) and \( \phi \) are radius, azimuth angle and polar angle respectively. We choose \( Y_{l,m}(\theta, \phi) \) to be spherical harmonics, since they are complete and orthogonal in \( S^2 \).

For the linear component, we do not use the Zernike linear polynomials as in Canterakis et al. [10], as they do not contain the necessary properties to achieve the translational behaviour of convolution kernels [38]. Therefore, we derive a novel set of orthogonal functions, which are complete in \( 0 < r < 1 \), and can approximate any function in the same range. Furthermore, it is crucial that these functions contain necessary properties to achieve the translation of kernels while performing convolution. Therefore, we choose the following function as the base function:

\[
f_{nl} = (-1)^l n \sum_{k=0}^{n} \frac{(n-l)r^k}{k!}.
\]

It can be seen that,

\[
f_{nl} \approx (-1)^l n \exp(r(n - l)),
\]

as \( n \) increases, for small \( r \). Therefore, we use the approximation given in Equation 6 in future derivations. As we show in Section 4.2, this property is vital for achieving the translation of kernels. Next, we orthogonalize \( f_{nl}(r) \) to obtain a new set of functions \( Q_{nl}(r) \). Consider the orthogonality

\[
\int_{B} Q_{nl}(r) Q_{nl'}(r) r^2 dr = 0, \forall n \neq n', l \neq l', m \neq m'.
\]

If we consider only the linear component, the orthogonality condition should be

\[
\int_{0}^{1} Q_{nl}(r) Q_{nl'}(r^2 dr = 0, \forall n \neq n', l \neq l'.
\]

Therefore, \( Q_{nl} \) should be orthogonal with respect to the weight function \( w(r) = r^2 \). We define,

\[
Q_{nl}(r) = f_{nl}(r) - \sum_{k=0}^{n-l} \sum_{m=0}^{k} C_{nlkm} Q_{km}(r)
\]

where \( n \geq 0, n \geq l \geq 0 \) and \( C_{nlkm} \) is a constant. Since \( Q_{nl} \) should be an orthogonal set, the inner product between any two different \( Q_{nl} \) functions is zero. Therefore, we obtain,

\[
\langle Q_{nl}, Q_{nl'} \rangle = \langle Q_{nl}, Q_{nl'} \rangle - \sum_{k=0}^{n-l} \sum_{m=0}^{k} C_{nlkm} \langle Q_{km}, Q_{nl'} \rangle = 0
\]

\[
\langle Q_{nl}, Q_{nl'} \rangle = C_{nlnl'} \langle Q_{nl}, Q_{nl} \rangle = 0,
\]

\[
C_{nlnl'} = \frac{\langle f_{nl}, Q_{nl'} \rangle}{\| Q_{nl'} \|^2}. \tag{8}
\]

Following this process, we can obtain the set of orthogonal functions \( Q_{nl} \) for \( n \geq 0, n \geq l \). The derived polynomials up to \( n = 5, l = 5 \) are shown in Appendix A. In Section 4.1.3, we prove the completeness property of the derived functions.

### 4.1.3 Completeness in \( \mathbb{B}^3 \)

In this section, we prove the completeness in \( \mathbb{B}^3 \) for the set of functions \( \{Q_{nl}\} \) derived in Section 4.1.2.

\[
Q_{nl}(r, \theta, \phi) = Q_{nl}(r) Y_{l,m}(\theta, \phi),
\]

where \( Q_{nl} \) is the linear component and \( Y_{l,m}(\theta, \phi) \) is the angular component. The variables \( r, \theta \) and \( \phi \) are radius, azimuth angle and polar angle respectively. We choose \( Y_{l,m}(\theta, \phi) \) to be spherical harmonics, since they are complete and orthogonal in \( S^2 \).
Condition 1: Consider the orthogonal set \( \{ p_n \} \) defined in \( L^2(0, 1) \). Then, \( \{ p_n \} \) is complete in space \( L^2(0, 1) \) if and only if there is no non-zero element in \( L^2(0, 1) \) that is orthogonal to every \( \{ p_n \} \).

To show that \( f_{nl} \) is complete over \( L^2[0, 1] \), we first prove the completeness of the set \( \{ \Phi_n \} \), which is obtained by orthogonalizing the set \( \{ 1, x, x^2, x^3, \ldots \} \). Let \( \Psi(x) \) be an element in \( L^2[0, 1] \), which is orthogonal to every element of \( \{ 1, x, x^2, x^3, \ldots \} \). Then, suppose following relationship is true:

\[
\langle \Psi, e^{2\pi i k x} \rangle = \sum_{n=0}^{\infty} \frac{(2\pi i n)^n}{n!} \langle \Psi, x^n \rangle = 0, \tag{9}
\]

where \( k \) is a constant. However, we know that \( \{ e^{2\pi i k x} \}_{k=0}^{\infty} \) is the complex exponential Fourier basis, and is both complete and orthogonal. Therefore, if Equation 9 is true, \( \Psi = 0 \), which gives us the result, i.e., \( \langle \Psi, x^n \rangle = 0 \Leftrightarrow \Phi = 0 \). Equivalently, since \( \{ \Phi_n \} \) is obtained by orthogonalization of \( \{ 1, x, x^2, x^3, \ldots \} \), \( \langle \Psi, \{ \Phi_n \} \rangle = 0 \Leftrightarrow \Psi = 0 \). Hence, according to Condition 1, \( \{ \Phi_n \} \) is complete in \( L^2[0, 1] \).

Next, we consider the set \( Q_{nl} \). Since \( Q_{nl} \) is orthogonalized using the basis functions in Equation 22, it is enough to show that \( f_{nl} \) is complete over \( L^2[0, 1] \). Let \( \Theta \) be a function defined in \( L^2[0, 1] \). Then, suppose the following relationship is true:

\[
\langle \Theta, f_{nl} \rangle = (-1)^l n \sum_{k=0}^{n} \frac{(n-l)^k}{k!} \langle \Theta, r^k \rangle = 0. \tag{10}
\]

For Equation 10 to be true, \( \langle \Theta, r^k \rangle = 0 \) for \( k = \{ 0, 1, 2, \ldots \} \). But we showed that this condition is satisfied if and only if \( \Theta = 0 \). Therefore, \( \langle \Theta, f_{nl} \rangle = 0, \forall n \geq l \geq 0 \Leftrightarrow \Theta = 0 \). Hence, \( f_{nl} \) is complete in \( L^2[0, 1] \).

### 4.1.4 Relaxation of orthogonality of functions in \( \mathbb{B}^3 \)

Computing \( \mathcal{C}_{nl}^{\mathcal{T}_v} \) using Equation 8 ensures the orthogonality of \( \mathcal{Q}_{nl} \). Since \( Q_{nl} \) and \( Y_{lm} \) are both orthogonal and complete, projecting the input shape \( f \) onto the set of functions \( Z_{nlm} \), \( n \geq l \geq m \geq 0 \), enables us to reconstruct \( f \) as follows:

\[
f(\theta, \phi, r) = \sum_{n=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \Omega_{n,l,m}(f) Z_{n,l,m}(\theta, \phi, r), \tag{11}
\]

where spectral moment \( \Omega_{n,l,m}(f) \) can be obtained using,

\[
\Omega_{n,l,m}(f) = \int_0^1 \int_0^{2\pi} \int_0^\pi f(\theta, \phi, r) Z_{n,l,m}^r r^2 \sin \phi d\phi dr d\theta. \]

Representing \( f \) using spectral terms, as in Equation 11, enables easier convolution in spectral space, as derived in Section 4.2.

However, we argue that since 3D point clouds across different object classes contain redundant information, projecting the point clouds in to a more discriminative latent space can improve classification accuracy. Our aim here is to reduce redundant information and noise from the input point clouds and map it to a more discriminative point cloud, which concentrates on discriminative geometric features. Therefore, we make \( \mathcal{C}_{nl}^{\mathcal{T}_v} \) trainable, which allows the latent space projection \( \hat{f} \) of the input shape \( f \) as follows:

\[
\hat{f}(\theta, \phi, r) = \sum_{n=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \hat{\Omega}_{n,l,m}(f) \hat{Z}_{n,l,m}(\theta, \phi, r), \tag{12}
\]

where spectral moment \( \hat{\Omega}_{n,l,m}(f) \) can be obtained using,

\[
\hat{\Omega}_{n,l,m}(f) = \int_0^1 \int_0^{2\pi} \int_0^\pi \hat{f}(\theta, \phi, r) \hat{Z}_{n,l,m}^r r^2 \sin \phi d\phi dr d\theta,
\]

and,

\[
\hat{Z}_{n,l,m}(\theta, \phi, r) = \hat{Q}_{nl}(r) Y_{lm}(\theta, \phi), \tag{13}
\]

where,

\[
\hat{Q}_{nl}(r) = f_{nl}(r) - \sum_{k=0}^{n-1} \sum_{m=0}^{k} W_{nlkm} \hat{Q}_{km}(r). \tag{14}
\]

Here, the set \( \{ W_{nlkm} \} \) denotes trainable weights. It should be noted that since the final orthogonal function is a product of the linear part and the angular part, making both functions learnable is redundant.

### 4.2. Convolution of functions in \( \mathbb{B}^3 \)

Let the north pole be \( y \) axis of the Cartesian coordinate system, and suppose the kernel is symmetric around \( y \). Let \( f(\theta, \phi, r) \), \( g(\theta, \phi, r) \) be the functions of object and kernel respectively. Then we define the convolution of functions in \( \mathbb{B}^3 \) as follows:

\[
f \ast g(\alpha, \beta, r') := \langle f(\theta, \phi, r), T_{r'}^r \{ \tau(\alpha, \beta) (g(\theta, \phi, r)) \} \rangle \tag{15}
\]

\[
= \int_0^1 \int_0^{2\pi} \int_0^\pi f(\theta, \phi, r) \left( T_{r'}^r \{ \tau(\alpha, \beta) (g(\theta, \phi, r)) \} \right) \sin \phi d\phi dr d\theta,
\]

where \( \tau(\alpha, \beta) \) is an arbitrary rotation that aligns the north pole with the axis towards \((\alpha, \beta)\) direction (\( \alpha \) and \( \beta \) are azimuth and polar angles respectively) and \( T_{r'}^r \) is translation by \( r' \).

To achieve both latent space projection and convolution in \( \mathbb{B}^3 \) in single step, we present the following theorem.

**Theorem 1**: Suppose \( f, g : X \rightarrow \mathbb{R}^3 \) are square integrable complex functions defined in \( \mathbb{B}^3 \) so that \( \langle f, f \rangle < \infty \) and \( \langle g, g \rangle < \infty \). Further, suppose \( g \) is symmetric around the north pole and \( \tau(\alpha, \beta) = R_y(\alpha) R_z(\beta) \) where \( R \in SO(3) \)
and $T_r'$ is translation of each point by $r'$. Then,

$$
\int_0^1 \int_0^{2\pi} \int_0^{\pi} P\{f(\theta, \phi, r)\} T_r' \{\tau(\alpha, \beta)\}(g(\theta, \phi, r)) \sin \phi \, d\phi \, d\theta \, dr \\
\approx \frac{4\pi}{3} \sum_{n=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \langle f_{nl}(r), Q_{n'l'}(r) \rangle (e^{(n-l)r} - e^{(n'-l)r'}),
$$

(16)

where, $\hat{\Omega}_{n,l,m}(f, \theta, \phi, r)$ and $\hat{\Omega}_{n,l,m}(\theta, \phi)$ are $(n, l, m)^{th}$ spectral moment of $f$, $(n, l, 0)^{th}$ spectral moment of $g$, and spherical harmonics function, respectively. $P\{\cdot\}$ is the projection to a latent space, $\tau(\alpha, \beta) = R_y(\alpha)R_z(\beta)$ where $R \in SO(3)$ and $T_r$ is translation of each point by $r$. The proof to this theorem can be found in Appendix A.

4.3. Network Architecture

Our experimental architecture consists of two convolution layers and a fully connected layer. We employ four kernels in the first convolution layer and 16 kernels in the second convolution layer, each followed by group normalization [56] and a ReLU layer. The experimental architecture is illustrated in Figure 2. We use $n = 5$ for implementing Equation 15 and softmax cross-entropy loss as the objective function during training. For training, we use a two step process. First, we train polynomial weights using a learning rate of $10^{-5}$, and then train kernel weights using a learning rate of 0.01. We used the Adam optimizer for calculating gradients with parameters $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1 \times 10^{-8}$, where parameters refer to the usual notation. We use $20k$ iterations to train polynomials weights and $30k$ iterations to train kernel weights. We use a single GTX 1080Ti GPU for training and the model takes around 30 minutes to complete a single epoch during training on ModelNet10 dataset.

5. Experiments

We conduct experiments to evaluate the performance of the proposed methodology. Firstly, we compare our BCS approach with state-of-the-art in a 3D object classification task. Secondly, we apply our approach to 3D object retrieval, and evaluate the performance against other recent work. We use four recent datasets for our experiments: ModelNet10, ModelNet40, McGill 3D dataset, and SHREC’17. We also conduct a thorough ablation study to demonstrate the effectiveness of our derivations and design choices.

5.1. 3D Object Classification Performance

A key feature of our proposed pipeline is the projection of the input 3D shapes into a more discriminative latent shape, before feeding them into convolution layers. One critical advantage of this step is that original subtle differences across object classes are magnified in order to leverage the feature extraction capacity of convolution layers. Therefore, the proposed network should be able to capture more discriminative features in the lower layers, and provide better classification results with a smaller number of layers, compared to other state-of-the-art works which directly extract features from the original shape. To illustrate this, we present a model depth vs accuracy analysis on ModelNet10 and ModelNet40 in Table 1, and compare the effectiveness of our network with other comparable state-of-the-art approaches.

State-of-the-art work can be mainly categorized into three types: volume based, RGB based and Points based. Volume based methods generally rely on volumetric representation of the 3D shape such as voxels. VoxNet [33] shows the best performance among volume based models, with an accuracy of 92.0% in ModelNet10 and 83.0% in ModelNet40, which is lower than our model’s accuracy. It is interesting to see...
that 3DShapeNets [57], and VRN [7] have significantly more layers compared to our model, although accuracies are lower. In general, our model performs better and has a lower model depth compared to volume based methods.

RGB based models generally follow the projection of the 3D shape into 2D representations, as an initial step for feature extraction. We perform better than all the RGB based methods, except for MHBN [60], which has accuracies 95.0% and 94.7% over ModelNet10 and ModelNet40 respectively. However, MHBN contains six views and for each view they employ a VGG-M network for initial feature extraction. This results in a significantly complex setup, which contains 96 trainable layers. In contrast, our model uses a single view and 3 trainable layers. Generally, RGB based models use multiple views, pre-trained deep networks and ensembled models, which results in increased model complexity. In contrast, our model use a single view and does not use pre-trained models, and achieves the second highest performance compared to RGB based models.

Point based models directly consume point clouds. Our model achieves the second highest performance in point based model category, the highest being SO-NET [27]. However, SO-NET contains 11 fully connected layers, while our model only contains 3 layers. Our model is able to outperform the other point based setups, although their model depths are higher.

Overall, our model achieves the third highest accuracy out of all the three categories, with a shallower architecture. Our model contains the lowest number of trainable layers compared to all the models. This analysis on ModelNet10 and ModelNet40 clearly reveals the efficiency and better feature extraction capacity of our approach. Table 2 depicts the computational efficiency of our network compared to state-of-the-art. As illustrated, with just 1.31B FLOPs, we outperform the closest contender PCNN [3] by a significant 3.39B margin.

### 5.2. 3D Object Retrieval Performance

In this section, we compare the performance of our approach in 3D object retrieval task. We use McGill 3D dataset and SHREC’17 dataset for our experiments. We first obtain the feature vectors computed by each kernel in the second layer, and concatenate them. Then, we apply an autoencoder on the concatenated vector and retrieve a 1000-dimensional descriptor. Then we measure the cosine similarity between input and target shapes to measure the 3D object retrieval performance. We use the nearest neighbour performance and the evaluation metric. Table 3 depicts the results on the McGill Dataset. Out of the six state-of-the-art models compared, our model achieves the best retrieval performance. Table 4 illustrates the performance comparison on SHREC’17 dataset, where our approach gives the second best performance, below Furuya et al. [16]. Figure 4 depicts our training curves for polynomial weights and kernel weights. The training curves are obtained for ModelNet10.

### 6. Ablation Study

In this section, we conduct an ablation study on our model and discuss various design choices, as illustrated in Figure 3. Firstly, we use a single convolution layer instead of two, and achieve an accuracy of 74.2% over ModelNet10. Then, we investigate the effect of using a higher number of convolution layers. We get accuracies 91.3% and 87.5%, when using three and four convolution layers respectively. Therefore,
using two convolution layers yield the best performance. An important feature of our convolution layer is the translation of convolution kernels, in addition to rotation. To evaluate the effect of this, we use only rotating kernels and measure the performance, and achieve an accuracy of 80.2%. Therefore, it can be concluded that having the translational movements of the kernel has caused an accuracy increment of 14%, which is significant. Next, we measure the effect of latent space projection. To this end, we use orthogonal polynomials derived in Equations 7-8 for convolution, instead of making them learnable. This removes the latent space projection of the input, as the original object is reconstructed using spectral moments. After removing the latent space projection, the accuracy is dropped by 20.3%, which clearly reveals the significance of this feature. Then, we replace our convolution layers with volumetric convolution [38] layers and spherical convolution layers [12] and get 88.5% and 77.3% accuracy respectively. This shows that our convolution layer has a better feature extraction capacity compared to other convolution operations. One key reason behind this can be the translational movements of our kernels and the combined latent space projection step, which the aforementioned convolution methods lack.

Moreover, we test our model using basis functions in Equation 22 as the projection functions, instead of learnable functions. Also, we again test the model using orthogonal functions. In both cases, the performance is lower compared to learnable functions. Furthermore, instead of soft-max cross entropy, we use WSofmax [32] and GASofmax [32] and achieve only 84.0% and 83.0% respectively. Therefore, using soft-max cross entropy as the loss function is justified. We also evaluate the effect of sampling density on accuracy. As shown in Figure 3, accuracy drops below 94.2%—which is reported by final architecture—when using a denser representation. Similarly, accuracy drops to 86.7% when using $r = 10, \theta = 18, \phi = 9$ as sampling intervals. Therefore, using $r = 25, \theta = 36, \phi = 18$ as in the final architecture seems to be the ideal design choice. We use four different distance measures in 3D object retrieval task and compare the performance: cosine similarity, Euclidean distance, KL divergence, and Bhattacharya distance. Out of these, cosine similarity yields the best performance, with a mAP of 0.466.

7. Conclusion

In this paper, we propose a novel approach called ‘Blended Convolution and Synthesis’ to analyse 3D data, which entails two key operations: (1) learning a 3D descriptor obtained by projecting the input 3D shape into a discriminative latent space and (2) convolving the 3D descriptor in $B^3$ with roto-translational 3D kernels for extracting features. We derive a novel set of polynomials in $B^3$, and project the input data into a spectral space using the derived polynomials to join these two operations into a single step. Furthermore, we use a compact representation of the input data to reduce the density of the data distribution and leverage the advantage of convolving functions in $B^3$. Finally, we present a light-weight architecture and achieve compelling results in 3D object classification and 3D object retrieval tasks.

B. Combined latent space projection and Volumetric Convolution with Roto-Translational Kernels

Theorem 1: Suppose $f, g : X \rightarrow \mathbb{R}^3$ are square integrable complex functions defined in $\mathbb{B}^3$ so that $\langle f, f \rangle < \infty$ and $\langle g, g \rangle < \infty$. Further, suppose $g$ is symmetric around north pole and $\tau(\alpha, \beta) = R_y(\alpha)R_z(\beta)$ where $R \in SO(3)$ and $T_{r'}$ is translation of each point by $r'$. Then,

$$f * g(r', \alpha, \beta) := \int_0^1 \int_0^{2\pi} \int_0^\pi P\{f(\theta, \phi, r)\}, T_{r'} \{\tau(\alpha, \beta)(g(\theta, \phi, r))\} \sin \phi d\phi d\theta dr \approx \frac{4\pi}{3} \sum_{n=0}^{\infty} \sum_{n'=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \langle f_{n,l}(r), Q_{n',l}(r) \rangle (e^{(n-l)r'} - e^{(n'-l)r'}) \hat{\Omega}_{n,l,m}(f) \hat{\Omega}_{n',l,0}(g) Y_{l,m}(\alpha, \beta),$$

where $\hat{\Omega}_{n,l,m}(f)$ and $Y_{l,m}(\theta, \phi)$ are the $n$th spectral moment of $f$, $(n', l, 0)^{th}$ spectral moment of $g$, and spherical harmonics function respectively. $P\{\cdot\}$ is the projection to a latent space, $\tau(\alpha, \beta) = R_y(\alpha)R_z(\beta)$ where $R \in SO(3)$ and $T_{r'}$ is translation of each point by $r'$.

Proof: The input function $f$ is projected to the latent space shape $\hat{f}$ by,
\[
\hat{f}(\theta, \phi, r) = \sum_{n=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \hat{\Omega}_{n,l,m}(f) \hat{Z}_{n,l,m}(\theta, \phi, r),
\]

where spectral moment \( \hat{\Omega}_{n,l,m}(f) \) can be obtained using,

\[
\hat{\Omega}_{n,l,m}(f) = \int_{0}^{1} \int_{0}^{2\pi} \int_{0}^{\pi} f(\theta, \phi, r) \hat{Z}_{n,l,m}(r)^{2} \sin \phi \, dr \, d\phi \, d\theta.
\]

and,

\[
\tilde{Z}_{n,l,m}(\theta, \phi, r) = \hat{Q}_{nl}(r) Y_{lm}(\theta, \phi),
\]

where,

\[
\hat{Q}_{nl}(r) = f_{nl}(r) - \sum_{k=0}^{n-1} \sum_{m=0}^{k} W_{nlkm} \hat{Q}_{km}(r),
\]

\[
f_{nl} = (-1)^{l} n \sum_{k=0}^{n} \frac{(n-l)r^{k}}{k!},
\]

and,

\[
Y_{l,m}(\theta, \phi) = (-1)^{m} \sqrt{\frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!}} P_{l}^{m}(\cos \phi) e^{im\phi},
\]

where \( \phi \in [0, \pi] \) is the polar angle, \( \theta \in [0, 2\pi] \) is the azimuth angle, \( l \in \mathbb{Z}^{+} \) is a non-negative integer, \( m \in \mathbb{Z} \) is an integer, \( |m| < l \), and \( P_{l}^{m}(\cdot) \) is the associated Legendre function,

\[
P_{l}^{m}(x) = (-1)^{m} \frac{(1-x^{2})^{m/2}}{2l!} \frac{d^{l+m}}{dx^{l+m}}(x^{2} - 1)^{l}.
\]

In Equation 21, the set \( \{W_{nlkm}\} \) denotes trainable weights. Using this result, we can rewrite \( f \ast g(r', \alpha, \beta) \) as,

\[
f \ast g(r', \alpha, \beta) = \sum_{n=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \hat{\Omega}_{n,l,m}(f) \tilde{Z}_{n,l,m}(\theta, \phi, r),
\]

\[
T_{r'}\{\tau(\alpha, \beta)\}(\sum_{n'=0}^{\infty} \sum_{l'=0}^{n'} \sum_{m'=-l'}^{l'} \tilde{Z}_{n',l',m'}(g) \tilde{Z}_{n',l',m'}(\theta, \phi, r'))\}\mathbb{B}^{3}
\]

Using the properties of inner product, this can be rewritten as,

\[
f \ast g(r', \alpha, \beta) = \sum_{n=0}^{\infty} \sum_{l=0}^{n} \sum_{l'=0}^{n} \sum_{m=-l'}^{l'} \sum_{l''=0}^{l} \sum_{m''=-l''}^{l''} \hat{\Omega}_{n,l,m}(f) \hat{\Omega}_{n',l',m'}(g)
\]

\[
\langle \tilde{Z}_{n,l,m}(\theta, \phi, r), T_{r'}\{\tau(\alpha, \beta)\}(\tilde{Z}_{n',l',m'}(\theta, \phi, r'))\rangle_{\mathbb{B}^{3}}
\]

Consider the term,

\[
\Gamma = \langle \tilde{Z}_{n,l,m}(\theta, \phi, r), T_{r'}\{\tau(\alpha, \beta)\}(\tilde{Z}_{n',l',m'}(\theta, \phi, r'))\rangle_{\mathbb{B}^{3}}
\]

\[
= \langle \hat{Q}_{nl}(r) Y_{lm}(\theta, \phi), T_{r'}\{\tau(\alpha, \beta)\}(\hat{Q}_{n'l'}(r) Y_{l'm'}(\theta, \phi))\rangle_{\mathbb{B}^{3}}
\]

\[
\Gamma \text{ can be decomposed into its angular and linear components as,}
\]

\[
\Gamma = \int_{0}^{1} \hat{Q}_{nl}(r) T_{r'}\{\hat{Q}_{n'l'}(r)\} r^{2} \, dr \int_{0}^{2\pi} \int_{0}^{\pi} Y_{lm}(\theta, \phi) \tau_{(\alpha, \beta)}(Y_{l'm'}(\theta, \phi)) \sin \phi \, d\phi \, d\theta.
\]
First, consider the angular component,

\[
\text{Ang}(\Gamma) = \int_0^{2\pi} \int_0^{\pi} Y_{lm}(\theta, \phi) \tau_{(\alpha, \beta)}(Y_{l'm'}(\theta, \phi)) \sin \phi \, d\phi \, d\theta.
\] (29)

Since \(g(\theta, \phi, r)\) is symmetric around \(y\), using the properties of spherical harmonics, Equation 29 can be rewritten as,

\[
\text{Ang}(\Gamma) = \int_0^{2\pi} \int_0^{\pi} Y_{lm}(\theta, \phi) \sum_{m'=-\ell}^{\ell} Y_{l'm'}(\alpha, \beta) \sin \phi d\phi d\theta
\] (30)

where \(D_{mm'}\) is the Wigner-D matrix. But \(D_{mm'} = Y_{l',m'}\), and hence,

\[
\text{Ang}(\Gamma) = \sum_{m'=-\ell}^{\ell} Y_{l'm'}(\alpha, \beta) \int_0^{2\pi} \int_0^{\pi} Y_{lm}(\theta, \phi) Y_{l'm'}(\theta, \phi) \sin \phi d\phi d\theta
\] (31)

Since spherical harmonics are orthogonal,

\[
\text{Ang}(\Gamma) = C_{\text{ang}} Y_{l,m}(\alpha, \beta),
\] (32)

where \(C_{\text{ang}}\) is a constant. Consider the linear component of Equation 28. It is important to note that for simplicity, we derive equations for the orthogonal case and use the same results for non-orthogonal case. In practice, this step does not reduce accuracy.

\[
\text{Lin}(\Gamma) = \int_0^1 \hat{Q}_{nl}(r) T_{r'}(\hat{Q}_{n'l'}(r)) r^2 \, dr.
\] (33)

Since \(\hat{Q}_{nl}(r)\) is a linear combination of \(f_{nl} \approx (-1)^{l} n \exp(r(n-l))\), it is straightforward to see that,

\[
\langle Q_{nl}(r + r'), Q_{n'l'}(r) \rangle = \langle f_{nl}(r) \exp((n-l)r') - \sum_{k=0}^{n-1} \sum_{m=0}^{k} C_{nlkm} Q_{km}(r) \exp(k-m)r' \rangle.
\] (34)

Also, we have derived that \(l = l'\) from the result in Equation 32. Applying this result and Equation 34 to Equation 33 gives,

\[
\langle Q_{nl}(r + r'), Q_{n'l'}(r) \rangle = \langle f_{nl}(r) \exp((n-l)r') - \sum_{k=0}^{n-1} \sum_{m=0}^{k} C_{nlkm} Q_{km}(r) \exp(k-m)r' \rangle.
\] (35)

\[
\langle Q_{nl}(r + r'), Q_{n'l'}(r) \rangle = \langle f_{nl}(r) e^{(n-l)r'} - \sum_{k=0}^{n-1} \sum_{m=0}^{k} C_{nlkm} Q_{km}(r) e^{(k-m)r'}, Q_{n'l'}(r) \rangle.
\] (36)

Since \(Q_{km}\) and \(Q_{n'l'}\) are orthogonal,

\[
\langle Q_{nl}(r + r'), Q_{n'l'}(r) \rangle = \langle f_{nl}(r) e^{(n-l)r'} - C_{nl'm'0} e^{(n-l)r'} ||Q_{n'l'}||^2.
\] (37)

But since for orthogonal case, \(C_{nl'm'} = \frac{\langle f_{nl}, Q_{n'l'} \rangle}{||Q_{n'l'}||^2}\),

\[
\langle Q_{nl}(r + r'), Q_{n'l'}(r) \rangle = \langle f_{nl}(r) Q_{n'l'}(r) e^{(n-l)r'} - \langle f_{nl}(r), Q_{n'l'}(r) \rangle e^{(n-l)r'} \rangle.
\] (38)

\[
\langle Q_{nl}(r + r'), Q_{n'l'}(r) \rangle = \langle f_{nl}(r), Q_{n'l'}(r) \rangle (e^{(n-l)r'} - e^{(n'-l)r'})
\] (39)

Combining Equation 32 and Equation 39 for Equation 26 and choosing the normalization constant to be \(\frac{4\pi}{3}\) (since the integration is over unit ball) gives,

\[
f * g(r', \alpha, \beta) \approx \frac{4\pi}{3} \sum_{n=0}^{\infty} \sum_{n'=0}^{\infty} \sum_{l=0}^{n} \sum_{m=-l}^{l} \langle f_{nl}(r), Q_{n'l'}(r) \rangle (e^{(n-l)r'} - e^{(n'-l)r'}) \hat{Q}_{n,l,m}(f) \hat{Q}_{n',l,0}(g) Y_{l,m}(\alpha, \beta).
\] (40)

Q.E.D.
