Abstract

ABSTRACT: We present a systematic characterisation by means of dynamic light scattering and particle tracking techniques of the viscosity and of the linear viscoelastic moduli, \( G'(\omega) \) and \( G''(\omega) \), for two different DNA hydrogels. These thermoreversible systems are composed by tetravalent DNA-made nanostars whose sticky sequence is designed to provide controlled interparticle bonding. While the first system forms a gel on cooling, the second one has been programmed to behave as a re-entrant gel, turning again to a fluid solution at low temperature. The frequency-dependent viscous and storage moduli, and the viscosity reveal the different viscoelastic behavior of the two DNA hydrogels. Our results show how little variations in the design of the DNA sequences allow to tune the mechanical response of these biocompatible all-DNA materials.

1. Introduction

DNA nanotechnology, a fast growing field originating from the insightful vision of N. Seeman, has expanded the interest in DNA beyond genetics and biology. Over the last decades, DNA has acquired a remarkable role as a molecular building block at the nanoscale. Several protocols and techniques have been developed for the design of complex 2D and 3D geometries and networks. The binding specificity and programmability of the DNA nucleotides, together with the continuous reduction in the costs of production of synthetic DNA, permit to design DNA sequences programmed to self-assemble in bulk quantities of desired nanostructures with controlled binding properties and tuneable response to external phenomena such as pH, temperature, or light. In this line, beside being thoroughly investigated in single-molecule studies, DNA has been also successfully applied to investigate the kinetic control of oil droplets functionalized colloids to drive the assembling of nanoparticles into macroscopic materials to organize nanocrystal molecules and to guide the crystallization of colloidal nanoparticles. In addition, the hydrophilic character of DNA is exploited for the formation of 3D networks able to hold large amounts of water, similarly to polymeric hydrogels, a property of major interest for the development of drug delivery, sensing, and tissue engineering applications.

Most of the literature on rheological properties of DNA solutions has focused on long single and double stranded DNA, interpreted with models of entangled semiflexible polymer coils. An experimental characterisation of the mechanical properties of materials created starting from purposefully designed DNA-particles is highly welcome and, only very recently, a microrheology study of a three-functional Y-DNA particles has been submitted.
A novel experimental microfluidic-based active microrheology approach to investigate how designed three-functional DNA-hydrogels evolve from diffusive liquid-like systems to shear-thinning fluids on cooling, passing through a series of intermediate power-law fluid states has recently been published. Here, we focus on the rheological properties of two DNA hydrogels composed by tetrafunctional DNA nanostars (NS in the following). In both cases, the NS are assembled by four properly designed DNA single-strands of about forty bases. At the end of each of the four arms, a short self-complementary single-strand sequence provides a well characterised binding overhang, commonly indicated as sticky end. Below the melting temperature of the sticky end sequence, the particles bind in a three-dimensional tetravalent network in which each NS acts as a network site. The first, the NS system is a well characterised all-DNA sample that progressively gels on cooling. The second system has been designed to display re-entrant gelation (RG system in the following). As for the NS system, the RG system evolves from a fluid at high temperature to a well developed highly connected network in which all DNA NS are bonded on cooling. This gel then transforms to a fluid phase on further cooling, a behavior that is achieved due to the additional presence in solution of short DNA sequences acting as competitors. Exploiting competitive interactions, these short DNA sequences, at low temperature, contend with the sticky sequences completely capping the NS overhangs. As a result, the system melts both at high and at low temperature. The self-assembling pathways for both systems as a function of temperature (T) are depicted in Fig. 1.

We report Dynamic Light Scattering (DLS) and particle tracking microrheology (PTM) experiments to quantify the mechanical properties of these two DNA hydrogels in a frequency (ω) domain ranging from 1 rad/s to 10^5 rad/s and their viscosities (η). DLS provides an easy-to-implement experimental set-up in which only the size and concentration of the colloidal tracers has to be carefully selected. PTM provides measurements of the sample η by tracking over long times, thus significantly extending the DLS range, the relative position between two colloids embedded in the same field of view. These two methods result in valuable
Figure 1: Self-assembly process, from high to low temperatures, both for the NS (Fig. (a)-(d)) and the RG (Fig. (e)-(h)) systems. Fig. (a) and (e) represent the very high temperature case, where all DNA sequences are not hybridized, remaining single-stranded in the buffer solution. When the $T$ is lowered down to $\sim 65^\circ C$, the four strands (designed to self-assemble in tetrafunctional units both in the NS (b) and in the RG (f) systems are now hybridised. In the RG case, the competitor sequences (in green and red colors) are still in solution in a non-hybridised state, being characterized by a lower melting temperature. At intermediate $T \sim 35^\circ C$ the NS start to bind to each other via complementary sticky ends (Fig. (c) and (g)), resulting in both cases in the formation of a connected network. In the RG case the competitor sequences are still in single strand form. Finally, at low $T$ the two systems behave differently. In the NS case (d) NS form a fully bonded network with very long living inter-particle bonds (thus mimicking the behavior of a chemical gel). In the RG system, the competitors have displaced the bonds that were previously forming the network, creating a solution of freely diffusing particles.

information about the mechanical properties of these materials and about their flow and deformation properties as functions of $\omega$ at different $Ts$.

2. Materials and Methods

2.1. DNA hydrogels preparation. Both examined samples are based on tetravalent networks whose nodes are provided by tetrafunctional DNA-NS. In the NS case, the tetra-
functional DNA $NS$ interact directly $via$ a self-complementary sticky sequence of six bases. In the case of the RG gel the tetrafunctional $A$ particles are bonded $via$ a self-complementary sticky sequence of eight bases. These eight bases are both preceded and followed by three extra bases which act as toehold easing the attachment of the competitor $B$ sequences. A detailed discussion of the bases sequences for both systems can be found in the original articles$^{28,30}$ and in the Section II of the Supplementary Information (S.I.).

Samples at tetrafunctional units concentrations of $248 \mu M$ (NS system) and $142 \mu M$ (RG system) in H$_2$O 100 mM NaCl buffer have been prepared. To grasp the meaning of these concentrations, these values should be compared with the values requested to form a fully bonded network, respectively of $\sim 220 \mu M$ (NS system$^{30}$) and $\sim 110 \mu M$ (RG system$^{28}$). Thus, both systems lie well within the equilibrium gel$^{31}$ concentration window. Samples were slowly annealed at high $Ts$ to guarantee the proper self-assembly of the tetrafunctional units before the formation of the gel and sealed in 2.4 mm inner diameter borosilicate glass capillaries. Detailed observation with a videocamera equipped with a 100x magnification lens confirmed that no phase separation occurred for none of the investigated samples. One sample was prepared for each one of the systems to evaluate their dynamic transition throughout the selected range of $Ts$.

2.2. DLS microrheology. To perform passive microrheology measurements we add to the DNA solution polystyrene (PS) colloids (530 nm size) coated with streptavidin from Sigma-Aldrich at a volume fraction $\phi = 3.4 \cdot 10^{-4}$. As discussed in Section I of the S.I., this concentration is sufficiently small to prevent colloid-colloid interactions and at the same sufficiently large to provide a scattering signal significantly larger than the one generated by the DNA particles. In this way, the measured scattered intensity provides essentially information on the self-motion of the PS tracer particles. DLS measurements were performed with a He-Ne $\lambda = 633$ nm laser at fixed angle $\theta = 90^\circ$. Temperatures were controlled by a programmable thermostat and an independent thermometer in contact with the sample bath, allowing for 40 minutes of thermalisation prior to 40 min long measurements. A Brookhaven
correlator provides the intensity autocorrelation functions $g_2(t) \sim \langle I(q,t)I(q,0) \rangle$ where $q$ is the wave vector. The electric field correlation function $g_1(t)$ is then evaluated exploiting the Siegert relationship.\(^{32}\) The well-established constrained regulation method for continuous distributions\(^{33}\) (CONTIN) was used to provide a well-behaved representation of the $g_1(t)$ correlation functions via a sum of exponential decays. The viscoelastic moduli $G'(\omega)$ and $G''(\omega)$ are then evaluated as described in detail in Section IV of the S.I.

**2.3. PTM microrheology.** DLS experiments access the time window 1\(\mu\)s - 10 s. With particles of size $\sim 530$ nm, viscosities lower than few Pa\(\cdot\)s are accessed. At higher values of $\eta$, the measured $g_1(t)$ relaxes at times larger than the maximum experimental accessible correlation time thwarting the acquisition of accurate measurements, especially in the $T$ region in which a highly connected network of long-lived bonds is formed. To access this larger $\eta$ window we performed tracking measurements with PTM.

We used a custom-built microscope equipped with a 100X Nikon objective (1.4 numerical aperture). For each $T$, brightfield images were acquired over a temporal window of 10 min at frame-rates ranging from 10 to 50 fps. In bright field, a 530 nm PS microsphere gives a strong intensity peak in the image when the focal plane is positioned slightly below it. We isolate the intensity peak applying a threshold to the image. Subsequently the 2D coordinates of the microsphere can be extracted by applying a "center of mass" tracking algorithm.\(^{34,35}\) Due to the high viscosity of the medium, the microspheres’ displacements were limited (from $\sim 1 \mu m$ at the highest $T$, down to $\sim 20$ nm at the lowest $T$). In order to reach an accurate measurement of the diffusion coefficient it was crucial to eliminate inevitable drifts and vibrations of the setup. These were ruled out by considering the relative position between two microspheres that were found in the same field of view. At all the investigated $T$'s, the same two particles were tracked, and the relative position vector coordinates between the two microspheres undergoes a diffusive motion with an effective diffusion coefficient given by the sum of the single particles’ diffusion coefficients. The diffusion coefficient was extracted from a linear fit of the measured mean square displacement (MSD), and subsequently the viscosity
was calculated by means of the Stokes-Einstein relation (eq. 17 of the S.I.). Hydrodynamic interactions between the two microspheres were neglected since the correction to the diffusion coefficient for the selected particle sizes and distances (> 7µm) is expected to be below 1%. Such a correction is smaller than the error introduced by the particles’ radii polydispersity which is of the order of ∼ 5%.

3. Results and Discussion

DLS microrheology lies within the class of passive microrheological techniques in which no stress is externally applied on the probes but just their passive motion originated from the thermal fluctuations is measured.\textsuperscript{37,38} Specifically, we observe the thermally driven motion of a tracer particle added in solution (a streptavidin coated polystyrene (PS) particle) by measuring the time correlation of the scattered light, \textit{e.g.} the electric field autocorrelation function \( g_1(t) \) as a function of time \( t \), and at a fixed scattering angle \( \theta = 90^\circ \). Our experimental set-up and capillary sample couvette does not allow us to investigate the \( q \)-dependence. We provide proof of a diffusive motion of the tracer particles by comparing the DLS results with PTM techniques (see Section 3.3 of the main text and Section III of the S.I. for details) which by measuring trajectories over long-times allows us to directly visualize the colloidal diffusive motion. In addition, the good agreement of the results from independent measurements and experimental techniques supports the assumption of diffusive motion of the probe colloids and of the absence of \( q \)-dependent effects.

3.1. DNA Nanostars hydrogel

The autocorrelation functions \( g_1(t) \) for the NS system are displayed in Fig. 2(a) in the range of \( T_s \) between 63°C and 37°C. For lower \( T_s \), the system relaxes at times beyond the largest experimentally accessible time (10 s). The experimental data are superimposed to the CONTIN\textsuperscript{33} regularization results, which provide a smooth representation of the measured
correlation functions. Fig. 2(b) shows the corresponding CONTIN distribution of relaxation times for each $T$. The MSD of the tracer particles, calculated as discussed in sec IV of the S.I., are shown in Fig. 2(c). The three sets of equivalent data manifest the change in dynamics on cooling. At high $T$ the correlation function decays with a single characteristic time (a single-peak in the CONTIN distribution) and the MSD displays a linear time dependence, consistent with a pure diffusive motion of the tracer particles and a viscous behaviour typically associated to newtonian fluids. This single-peak profile constitutes a hallmark of one single source of scattering and it is consistent with the 20 times larger scattering intensity of the solution with probe colloids compared to the pure DNA-water system. On progressively cooling, the formation of the bonds between distinct NS slows down the tracers dynamics and deviations from the viscous-like response appears, consistent with the gradual emergence of elastic forces originating by the progressive formation of the viscoelastic network. At low $T$ the tracer particles become trapped in the gel network for times comparable to the bond lifetime. In these conditions, the correlation function develops a clear two-step relaxation with two different amplitudes, the CONTIN distribution of relaxation times displays a two-peak behaviour and correspondingly, a clear plateau emerges in the MSD, whose value indicates the amplitude of the tracers motion in the cage. The amplitude of the slow relaxation process, now different from one, and the corresponding plateau in the MSD indicate the predominant elastic nature of the NS hydrogel (see following discussion of $G'(\omega)$ and $G''(\omega)$) on the time scale of the NS-NS bond lifetime.

Fig. 3 shows the linear viscoelastic moduli at four significative $T$s, calculated according to the procedure described in the Methods section. At the highest $T$ (58°C) the viscous component $G''(\omega)$ of the complex modulus $G^*(\omega)$ takes higher values than those of the elastic modulus $G'(\omega)$ showing the typical $\omega$ and $\omega^2$ scaling at low frequency and a growth consistent with a power-law with exponent $0.75\pm0.03$ at large $\omega$. Such power-law exponent is close to the value predicted for polymers by the Zimm model (in $\Theta$ solvent) $\omega^{2/3}$. In fact, at these $T$s all NS are independently floating in the solution and thus the viscous behavior
Figure 2: (a) Autocorrelation functions measuring the motion of a probe particle immersed in a NS solution at a concentration of 248 µM. Experimental data is represented by circles. Solid lines indicate the result of applying CONTIN to the experimental $g_1(t)$. (b) Corresponding distribution of relaxation times as calculated from CONTIN. (c) Corresponding MSD of the probe particles (symbols). The coloured shadow backgrounds represent the statistical error calculated following Section V of the S.I. The errors are not shown for values $\Delta \text{MSD}(t)/\text{MSD}(t) > 1$. The figure also shows for comparison the MSD of the same tracers dispersed in a buffer of $H_2O$ and 100 mM NaCl (see Section I of the S.I.).
of the material is expected to be predominant. On cooling (see 47°C and 52°C), $G'(\omega)$ and $G''(\omega)$ start to develop more complex functional dependence. At 47°C both moduli are characterised by a parallel power-law growth $\sim \omega^n$ at large frequencies with $n \approx 0.47$, signatures of the proximity to a percolation point.

While the power-law dependence is a clear indication of a system approaching the percolation threshold, the transformation of $n$ into a structural quantity as the fractal dimension $d_f$ requires some approximations. In previous works, the value of $n$ has been found to vary significantly depending on the network properties, clusterizing around the value $n = 0.5$. Factors like stoichiometry, chain length and dilution of the critical gels play a role on the composition and structure of the systems and therefore significantly variations in the $n$ values have been reported. To name a few, in the case in which excluded volume interactions can be neglected and hydrodynamic interactions are fully screened theory predicts that $G'(\omega) = G''(\omega) \sim \omega^{2/(d_f+2)}$. For three-dimension percolation universality class, $d_f = 2.5$ and $G'(\omega) = G''(\omega) \sim \omega^{0.41}$. We observe a similarity in the response of the two moduli over a limited frequency range. Differently from chemical gels where the self-similar response of moduli occurs over a wide frequency range and terminal flow is not observed, here the finite lifetime of the bonds between NS introduces a lower-frequency crossover as observed in Fig. 3 (c).

At 37°C (Fig. 3(d)) the system is well within percolation. $G'(\omega)$ becomes predominant over $G''(\omega)$ while $G''(\omega)$ shows a minimum at $\omega \approx 20$ rad/s, suggesting that the diffusive motion of the colloids is arrested at the corresponding time scale. In addition, $G'(\omega)$ and $G''(\omega)$ crossover at $\omega_c \sim 1$ rad/s. This crossover frequency reflects the inverse of the relaxation time of the system and it conventionally indicates the transition from a fluid-like (viscous) to a rubbery, solid-like (elastic) frequency region. For comparison, at 47°C, the crossover is found at a higher $\omega$, in accordance to a faster relaxation time of the probe colloid (see Fig. 2(a)) for a weaker network stabilised at higher $T_s$. In all the investigated samples, at $\omega < \omega_c$ a terminal fluid behavior is recovered with $G'(\omega) \sim \omega^2$ and $G''(\omega) \sim \omega^1$.
Figure 3: Loss ($G''$) and storage ($G'$) moduli of the NS system for (a) 58°C, (b) 52°C, (c) 47°C, and (d) 37°C. The coloured shadows indicate the error bars calculated according to Section V in S.I. Error bars are displayed only for $\Delta G'/G' < 1$ and $\Delta G''/G'' < 1$.

When a clear plateau in $G'(\omega)$ is present, its value can be used to provide an estimate of the cage size $\xi$ confining the probe particle (of radius $a$), according to the relation in eq. 15 of the S.I. We observe plateau values of $G'(\omega)$ up to 7 Pa, corresponding to $\xi \approx 26$ nm. As a reference, we note that the order of magnitude of the elastic modulus can be estimated by the product of the density of elastically effective chains times the thermal energy.$^{45,46}$ In the fully bonded low $T$ limit, each NS contributes to two effective chains, suggesting as the (DLS experimentally unaccessible) low $T$ limiting value $G'(\omega_{\text{plateau}}) \approx 600$ Pa. Unfortunately, as commented before, at such low $T$ $g_1(t)$ would decorrelate at much longer times than the maximum accessible experimental time of DLS techniques.

3.2. Re-entrant hydrogel

The RG system was originally proposed as a proof of concept of the possibility to design DNA constructs mimicking peculiar colloidal particles at the nanoscale. Specifically, it exploits the competition between different bonding patterns resulting in a system of tetravalent DNA particles that can be either a fluid state of diffusive clusters or a spanning tetravalent network i.e. a highly viscous gel (see Fig. 1). Interestingly the gel phase is designed to be
sandwiched between two fluid phases. On cooling, the system exhibits a cross-over from fluid to solid to fluid again, providing a theoretical example of a material that can be hardened on heating. Here we explore the viscoelastic properties of this novel material to reveal this double cross-over in a sequence of states that evolves from fluid to percolation to fully bonded gel to percolation and to fluid again.

The corresponding experimental $g_1(t)$ for the RG system are displayed in Fig. 4 (a) together with their CONTIN analysis. The $g_1(t)$ functions clearly show an increase in the relaxation times on cooling from 50°C to 32°C. On further lowering the $T$ the relaxation times become faster and faster, recovering a typical fluid-like value at the lowest investigated $T$s. This behavior is replicated in the associated MSD curves in Fig. 4 (c) for the high $T$ regime (where the dynamics gets slower on cooling) and in Fig. 4 (d) for low $T$s (where the dynamics gets faster on cooling). Thus, the viscous high and low $T$ behavior is comprised (see the MSD at $T \approx 30°C$) by the caging regime typical of non linear viscoelastic systems, similar to the one observed in the NS system at low $T$s (see Fig. 2 (c)).

Fig. 5 shows the corresponding viscoelastic moduli for different characteristic $T$s. The data clearly show on cooling the viscoelastic behavior typical of a fluid (a), of a percolating system (b), of an elastic gel (c), and again of a percolating system (d) and of a low $T$ fluid (e). Indeed, panels (a) and (e) are characterised by $G''(\omega) > G'(\omega)$ in such a way that the loss modulus prevails over the elastic modulus in the absence of crossovers in the whole $\omega$ range. Panels (b) and (d) are characterised by $G''(\omega) \approx G'(\omega)$ for $\omega > 10^2$ rad/s and by clear power-law frequency dependences with a scaling exponent $n$ again around 0.5 (best fit values of $n = 0.46$ and $n = 0.58$ respectively). Finally, panel (c) shows the typical behavior of a viscoelastic solid where $G''(\omega)$ shows a minimum at $\omega \approx 500$ rad/s and a corresponding plateau value of $G'(\omega)$ of about 8 Pa. We associate this conduct to an elastic response where the colloidal particle is trapped in a cage. It must be noted that our DNA hydrogels is a physical gels in which the bond breaking and formation events, absent in chemical gels, are responsible for the final relaxation behaviour observed in the low frequency region. This
Figure 4: (a) $g_1(t)$ measuring the motion of a probe particle dissolved in the RG hydrogel at NS concentration of 110 µM. Experimental data is represented by circles and the result of applying CONTIN procedures is indicated with solid lines. (b) Corresponding distribution of relaxation times as calculated from CONTIN. (c) MSD for $T_s$ ranging between 50°C and 32°C and (d) for $T_s$ ranging between 28°C and 5°C. The coloured shadow backgrounds represent the statistical error calculated following Section V of the S.I. The errors are not shown for values $\Delta \text{MSD}(t) > \text{MSD}(t)$. 
inevitable crossover to a standard low frequency relaxation determines the observed crossover between $G'(\omega)$ and $G''(\omega)$ at 28°C.

3.3. Viscosities

In this subsection we complement the passive microrheology data by computing $\eta$ for both the NS and the RG systems, using DLS and PTM techniques to measure the motion of tracer particles immersed in the sample. From the DLS data we extract $\eta$ in two different ways. In the first method we evaluate the time $t_{1/e}$ at which $g_1(t_{1/e}) = 1/e$, with $e \equiv 2.7182$, (which for a pure diffusive process coincides with $(Dq^2)^{-1}$) and convert it to $\eta$ according to the Stokes-Einstein relation

$$\eta = \frac{k_B T}{6\pi a t_{1/e}}$$

In the second method we extract the long time limit of the MSD (see Fig. 2 (c) and 4 (c-d)) calculated after CONTIN regularization to evaluate the diffusion coefficient. The two methods provide comparable results and the corresponding $\eta$ are reported in Fig. 6.

In addition, it is possible to estimate the bulk viscosity $\eta$ directly from the rheological data as limit for $\omega \to 0$ of $G''(\omega)/\omega$. As shown in Fig. 6, the reported values by the three methods are all consistent.

Beside providing a set of independent measurements to validate the $\eta$ values estimated from DLS, the PTM technique gives access to a different time window compared to DLS and allows us to extend the range over which $\eta$ measurements are possible by further three orders of magnitude.

From the PTM data we extract the positions over time of two tracer particles to compute the interparticle displacement, which undergoes a diffusive motion that is not affected by systematic errors associated to any source of global drift in the optical set-up. As discussed in detail in Section III of the S.I., the selected exposure time does not allow us to quantify the
Figure 5: $G'$ and $G''$ moduli of the RG system from high (top) to low (bottom) $T$s, showing mechanical features characteristic of different states: (a) fluid at 50°C, (b) close to the percolation threshold at 36°C, (c) viscoelastic solid at 28°C, and again (d) close to the percolation at 20°C and (e) fluid at 5°C. The coloured shadows indicate the error bars calculated according to Section V in S.I.
amplitude of the short-time vibrational motion of the probe that would result in a positive $t = 0$ intercept of the MSD. In addition, the finite exposure time, as well as the tracking precision, introduce artefacts that make unphysical any interpretation of the intercept values.\textsuperscript{[27]} These values have been subtracted in the MSD presented in Fig. [7]. Nevertheless, all this does not affect the evaluation of the slope of the MSD vs time and thus of the diffusion coefficient, allowing us to compute the $\eta$ \textit{via} the Stokes-Einstein relation.

![Figure 6: Comparison of the viscosities $\eta$ in the NS (light and dark blue, and turquoise symbols) and in the RG (red, dark and light orange, and yellow symbols) systems. The inset shows the Arrhenius plot for the NS system in the gel region (at $T_s$ below the melting temperature). The dashed line represents the best fitting with an exponential Arrhenius-like function with an activation energy $E_A \approx 105$ kcal/mol. The error bars are calculated as explained in Section III and Section V of the S.I.](image)

Around $T_s \approx 38^\circ C$, where both DLS and PTM measurements are possible, the agreement between DLS and PTM is highly satisfactory. On further cooling, $\eta$ progressively increases as a result of the longer lifetime of the interparticle bonds. As expected for a strong network-forming fluid,\textsuperscript{[28]} at low $T$, $\eta$ follows an Arrhenius behavior with an activation energy $E_A \approx 105$ kcal/mol which reflects the enthalpy of the inter particle bonds (44.6 kcal/mol).\textsuperscript{[29]}

For the RG $\eta$ was evaluated \textit{via} DLS, also shown in Fig. [3]. The $T$-dependence of $\eta$ shows a clear maximum at intermediate $T_s$. Consistently with the behavior displayed by the linear viscoelastic moduli, $\eta$ first increases on cooling when the network progressively forms and
Figure 7: MSD measured via PTM technique at $T_s$ ranging from 21.4°C up to 38.6°C. The time-independent offset, which is affected by the finite exposure time and by tracking artefacts, has been subtracted from the curves. The error bars are computed as detailed in Section III of the S.I.

then decreases again when the competitor sequences start binding, capping the NS sticky ends until the point at which, at very low $T_s$, the network is completely disentangled and a fluid-like behavior is recovered. At this point a $\eta$ comparable to the one reported at 50°C is again observed, which is only few times higher than the solvent $\eta$. In the case of the RG an accurate estimate of the activation energy is not possible, since the system is designed to evolve back to a fluid at low $T$. In the region of $T$ where $\eta$ increases, the slope of $\ln \eta$ vs. $T^{-1}$ progressively changes with $T$ preventing an accurate estimate of the activation energy.

4. Conclusions

We have presented an experimental characterisation of two DNA hydrogels resulting from the thermoreversible association of DNA-made nanoparticles with functionality four. The possibility to exploit base-pair selectivity and the self-assembly properties of DNA sequences
of different length permitted to tune the viscoelastic properties as desired, providing significant design flexibility compared to tetravalent star polymers. Specifically, we have compared a system that gels on cooling (NS system), with a system that gels both on cooling, when starting from high $T$, and on heating, when starting from low $T$ (RG system). We can envision that the mechanical properties of all-DNA hydrogels can be controlled by the functionality of the NS, by their concentration and stoichiometry. This may offer control over the viscoelastic properties of this class of materials.

The frequency-dependent viscoelastic moduli measured with DLS passive microrheology revealed the different viscoelastic properties of the two systems as a function of $T$. The data showed the crossover from fluid to gel for the NS system via a percolation transition, and a multiple sequence of transitions from a fluid to a percolating system to an elastic gel to a percolating system and to a fluid again on cooling, for the RG system. Similarly, $\eta$ monotonically increased on cooling in the NS system while it first increased and then decreased again in the RG system. The combination of DLS and PTM techniques allowed us to explore more than six orders of magnitude in $\eta$.

In conclusion, we provide evidence of the possibility of measuring material properties in hydrogels built by controlled association of DNA-made particles, with specified functionality and binding sequences. The comparison between the NS and RG systems highlights both the flexibility offered by the design of the DNA sequences and the possibility to tune the mechanical response of these biocompatible all-DNA materials with minor changes in the DNA sequences. The biocompatibility and thermoreversible character of these materials opens the possibility for a large number of applications related to biomedicine and drug delivery fields in which a fine control of the materials’ mechanical properties is required.
