Abstract: Metallic thin-film materials and nanoparticles (mainly Silver (Ag)-based) are recently being used in many nano-technological applications including solar panels, reflective heat-mirror coatings, and antibacterial coatings as well. The physical vapor deposition technique attracts significant attention for Ag-based nanocomposites with tailoring the structural and optical properties of metallic thin films thus allowing further improvements and application possibilities in various existing fields namely electronics, catalysis, magnetics, optics in alongside the environment and health and new emergent fields in, particularly thin-film coatings. This study highlights the preparation, characterization, properties, and possible future application directions of several types of Silver (Ag)-based nanocomposite thin films prepared by using physical vapor deposition techniques.

Keywords: nanocomposite; thin-film materials; coatings; spectrally-selective coating.

1. Introduction

Nowadays, there has been rising a substantial scientific interest in engineering and characterization of unconventional nanocomposite materials for various applications ranging from construction to technological discovery [1–7]. Solar windows, in particular, large-area transparent luminescent solar concentrators (LSC) are recently receiving increasing attention in the field of photovoltaics (PV) devices and systems. Most commercial energy-generating solar glass or window technologies suited for building-integrated PV (BIPV) applications currently have a semi-transparent look (up to around 40% spectrally-averaged visible-range transmission) and lack color-neutral characteristics [7–11]. Also, regardless of the materials or technologies employed, the electric outputs of solar window-type systems drop as visible-range transparency increases. This is true for light-concentrating or light-trapping (e.g., LSC) technologies, as well as systems based on solar cells for direct wide-area PV conversion. BIPV technologies are intended to combine energy-saving and aesthetic features (due to superior thermal insulation properties provided by advanced glazing systems and low-emissivity coatings). Smart-window technology allows for active management of window transparency, as well as the potential for considerable energy-harvesting performance in progressively high-transparent glazings [11–16].

However, in the last decade, due to the boom of many new industrial applications, thin film science and technology has experienced dramatic advancements, and it is still
regarded as a frontier field of research and development across the world. Modern city buildings and skyscrapers typically have large windows mostly made of specialized thin-film coated glass. These coated glasses are mainly known as low-emissivity (Low-E) coatings. These products possess the features of energy efficiency in terms of reducing the heating or cooling-related electric energy usage in buildings. The Low-E coatings are typically structured as metal-dielectric multilayer thin films deposited by various methods, where pure metal (i.e., silver, gold, or copper) layers are currently considered in industrial practice. However, most silver (Ag)-based multilayer coatings have some limitations related to their manufacturing, storage, handling, and use [1,13,17,18]. Despite the widespread commercial use of silver-based multilayer coatings, these are inherently unstable in the environment and cannot tolerate lengthy (weeks-scale) exposure to either ambient atmospheric air or lamination temperatures. The degradation of the optical and physical properties of silver-based multilayer coating structures is mainly due to the stability problems affecting the thin metal layer. The very thin silver layer (typically, less than 20 nm) suffers quick morphological and chemical changes due to the processes such as oxidation and other chemical reactions naturally initiated by the surrounding layers inside the multilayer structures. Also, the ultra-thin Ag layers mostly develop as nano-islands of silver rather than continuous ultra-thin layers, which has an impact on the multilayer structures’ overall performance. Furthermore, material layers placed on top of ultrathin pure Ag layers have a tendency to “sink” into the gaps between the Ag nano-islands, altering the shape and effective optical thickness of these layers next to silver [1,13,17–20].

Persuasively, in this nanotechnological century, these issues are now an important subject matter for the studies intended to design, develop, and establish the optimized growth processes for ultra-thin, and comparatively smoother layers of nanocomposite-type metallic materials (on arbitrary substrate sublayer types) to overcome the problems related to ultra-thin layer materials growth. The motivation to solve the physical and structural issues related to ultrathin metal layer originates from our very recently published article [21], where the possible effects of metal dilution importing dielectric substance on their physical and apparent visual aesthetics were explained. However, in this work, we propose to develop a new nanocomposite-type thin-film material (Ag+ SiC) that can be found suitable for broadening the application range of advanced thin-film materials in ultra-stable coating design options with better control over their properties.

SiC is a well-known semiconductor material and many reports have been found about the properties of Silicon carbide (SiC) materials of its various compositions. Wide bandgap, high breakdown voltage, high thermal conductivity, high electron drift velocity, high surface hardness, high bulk plasticity, and low density are all characteristic of SiC. Silicon carbide is chemically inert at high temperatures and has good abrasion and radiation resistance. Silicon carbide’s superior physical and chemical properties make it ideal for a wide range of applications, including optoelectronics, high-temperature, high-power, and high-frequency electronic devices, X-ray mask materials, solar selective coatings, solar cells, high-temperature gas sensors, phototransistors, blue-light diodes, and wear and corrosion-resistant applications [22–29]. The properties of SiC films could be easily tailored in the coating composition for any film thicknesses with the optimal microstructural, optical, and electrical properties for different reflective or antireflective optical and optoelectronic applications (in terms of composition and deposition process as well). The intrinsic properties of SiC thin films are highly affected by the incorporation of dopant elements during the growth processes. The inclusion of dopants enables for the regulation of SiC-based thin film characteristics, particularly the optical bandgap and electrical conductivity, which are appealing for a variety of applications. Ironic is the literature on SiC thin-film growth and customising characteristics based on applications [22,30,31].

However, our new nanocomposite (Ag+ SiC) material can enable cost-effective mass-production of smart coatings of multiple types, useful for energy efficiency applications, particularly in building-integrated products for smart city infrastructure.
2. Materials, methods, and characterization techniques

The metal-based nanocomposite films were deposited onto optical glass substrates (Corning Eagle XG) using low-pressure argon plasma (at room temperature) in an RF magnetron sputtering system. The single-layer Ag+ (SiC) nanocomposite films were sputtered using two separate sputtering targets. From the independently measured partial deposition rates of the deposition sources utilised, the volumetric content of extra MgF₂ or SiC relative to the pure-metal content was determined. The externally applied RF power densities provided to the targets regulated the deposition rates for both sputtering targets.

A post-deposition dry heat exposure experiment has been conducted with the as-deposited thin composite layers to investigate the optical and physical properties in terms of environmental stability. A spectrophotometer (Agilent Technologies Cary5000) was used to measure the transmission spectra of both the as-deposited and the heat-treated composite films. A scanning electron microscope (Hitachi SU3500) was used to perform the surface morphology characterization of these newly developed nanocomposite films.

3. Results and evaluations

3.1. Features and properties of Ag thin layer

Despite the challenges of deposition of ultra-thin Ag films with minimal surface roughness, homogeneous layer morphology, and perfect thickness control, silver is a well-known noble metal with the lowest optical losses throughout a very broad spectral range extending from the blue to the near-infrared wavelengths [32]. Another field of today’s fast-paced research and development is plasmonics nano-sensor development, which has lately seen a number of important breakthroughs [33–38]. Due to their great sensitivity to the refractive index change in dielectric media put on top of ultra-thin plasmonics metal films, these surface plasmon resonance-based optical sensors have various commercial applications in oil and gas, biochemical, medical, and chemical sensing (Ag). Figure 1 (which is partially reproduced from Ref. [32]) presents the important parameters and optical characteristics of sputtered Ag thin-layers.

![Figure 1](image-url)

**Figure 1.** Extrapolated digitized optical constants dispersion data (a b), Optical (c) [32], and the color (d) characterization results for thin sputtered Ag layers. The color values (measured using...
Minolta 508D) for different Ag thicknesses show the variation in $\Delta RFY$ versus Ag layer thickness which reflects the importance of characterization for optimum film development.

The dispersion function of Ag layers’ optical constants (refractive index and absorption coefficient) is found to be patchy, partly owing to film thickness dependence and partly due to investigations being confined to a small wavelength range. We gathered all available information on the optical constants of Ag layers from all accessible sources throughout our coatings development work (conducted between 2011 and 2015, mainly unpublished so far) and discovered data inconsistencies in the 1000-2000 nm range. To acquire an acceptable quality of optical constant data between 300 and (7000) nm, we experimentally modelled and fitted numerous transmission spectra of deposited Ag films of varied thicknesses (12.5-40 nm). The revised dataset is shown in Figure 1 (a, b), in which our fitted data is combined with data from [39]-[40], resulting in close agreement between the modelled and observed transmission spectra for all film thicknesses. Figure 1 (c) shows the fitted transmission spectrum of an as-deposited Ag layer of around 20 nm thickness obtained using OptiLayer modelling and spectrophotometry (Agilent Technologies, Cary 5000) using this data set. We were able to establish that the thickness of our originally deposited layer was around 19 nm, which is correct to within 5%. Figure 1 (d) shows the Ag layer thickness-dependent variation of color values mainly the lightness function ($\Delta RFY$). In our work, we define the value of $\Delta RFY$ by subtracting the obtained value of Y (which is Yxy values as reported in CIE Chromaticity Coordinates) on the Ag layer from the Y value of clear glass substrate.

3.2. Features and properties of RF sputtered SiC thin films

Amorphous SiC films have been chosen because of their comparatively low growing temperature, which ensures greater compatibility with silicon-based technologies. However, in order to maximise the growing circumstances, high-quality films must be obtained.[33]. We have sputtered SiC thin films from a ceramic-type solid SiC sputtering target (sourced from China) using the RF magnetron sputtering technique. The transmission spectrum of sputtered SiC film is shown in Figure 2.

![Figure 2](https://example.com/figure2.png)

**Figure 2.** Optical transmission spectrum of an amorphous SiC layer prepared by using RF magnetron sputtering technique.
It is well known that the refractive index of amorphous SiC strongly depends on film composition and the film thickness as well. According to Aakash Mathur et al., the refractive index of SiC thin films decreased from 2.97 to 2.77 with increasing film thickness, confirming that the performance of SiC in diverse applications may be improved by tuning of optical characteristics.

3.3. Properties of Ag+ SiC nanocomposite layers on optical glass substrates

Figure 3 shows the optical characterization results obtained. It can be seen that the measured transmission spectrum has been fitted with the modeled transmission spectrum, to re-confirm the actual layer thickness. It has been found that the transmission spectrum of the as-deposited composite films matched that of a 50 nm modeled layer. However, after the heat treatment (trialed annealing runs between 200 - 450 °C for an hour), slight changes in the transmission spectra have been observed (as can be seen in Fig. 3a).

![Graph showing optical characterization results](image)

**Figure 3.** Optical characterization results were obtained from Ag+ SiC thin-film nanocomposite layers.

A small hump on the spectral response of the as-deposited composite layer was observed in comparison to that of the modeled layer, however, significant spectral shifts were observed in all of the high-temperature (above 300 °C) heat-treated films. The
modeling of the nanocomposite-layer transmission involved using a weighted average of dielectric permittivities of the material components, using OptiLayer software. All of the heat-treated samples showed comparatively smoother transmission spectra, which might imply that the additional SiC compound transforms from the amorphous phase to the quasi-crystal stage, and this helps protect the pure-silver content from agglomeration or turning into nanoparticles. From the measured transmission spectrum of the as-deposited composite layer, we numerically evaluated the possible range of the absorption coefficient of the composite film, across a wide spectrum. Figure 3(b) shows the obtained wavelength-dependent absorption coefficient plotted within its possible upper and lower limits, compared to that of a pure silver layer. The upper and lower limits were evaluated by considering the maximum of ±5% thickness error.

Figure 4 shows the morphological study results obtained on pure silver (Ag) and nanocomposite (Ag+ SiC) layers (were subjected to dry heat exposure at the same condition). It can be seen that the pure Ag layer turned into nanoparticles (the size and shape of the nanoparticle were observed relatively large, Fig. 4 (a, b)) while the composite layer showed resistance to turn into distinguishingly notable sizes nanoparticles.

![Figure 4](image_url)

**Figure 4.** Morphological study of heat-treated pure-Ag and Ag + SiC (5 vol. %) composite layers. SEM images of Ag thin layer were obtained after annealing at 350 °C for 1 h (a, b) and, Ag + SiC composite thin layer was imaged after exposure to the same temperature (350 °C for 1 h) (c, d). Surface imperfections in images (c) and (d) may be due to surface contamination, or slight precipitation.

Figure 5 shows all the elemental constituents present in the Ag-based (SiC dilute) metallic composite thin films. It can be noticed that there is a big peak of Si observed which we believe due to the presence of Si in the substrates (glass).
4. Conclusions

The development of metal-based advanced nanocomposite material systems will potentially enable the next-generation innovative optical components suitable for the development of cost-effective optical coatings on glass for various advanced applications including spectrally selective coatings and mirrors for thermal and heat regulation thus enabling new directions in energy-efficient construction materials. This is due to the improved environmental exposure stability demonstrated in early experiments. In addition, the ultra-fast sensing devices for various biomedical applications also can possibly be designed and manufactured, based on using the metallic layer features and properties of these types of nanocomposite materials.
