An improved ITU-R rain attenuation prediction model over terrestrial microwave links in tropical region

Rafiqul MD Islam1, Yusuf A Abdulrahman2* and Tharek A Rahman2

Abstract
An improved approach of predicting rain attenuation cumulative distribution (CD) over terrestrial microwave links operating in tropical regions is presented in this article. The proposed method offers a better extrapolation approach for determining the values of rain attenuation at different exceedance probability from the measured attenuation at 0.01% of the time. The experimental data consist of measured rainfall rates and rain attenuation over six geographically spread DIGI MINI-LINKs operating at 15 GHz in Malaysia. A new set of numerical coefficients was derived for improved rain attenuation CD predictions in the Malaysian tropical climate. In order to test the applicability of the proposed extrapolation method, a validation was performed using rain rate and rain attenuation measurements from five Brazilian and seven Nigerian tropical locations. When tested against measurements, the proposed method seems to provide a significant improvement over the current extrapolation method adopted by ITU-R Recommendations P.530-14, for the prediction of rain attenuation CD over tropical regions.

1. Introduction
Heavy traffic in the C-band has forced telecommunications service providers to migrate to higher frequency bands, which have enough band-widths to support numerous users. However, rain-induced attenuation is the major issue at frequencies above 10 GHz, more especially in tropical regions which experience heavier rainfall intensities [1]. Rain attenuation plays significant role in the design of terrestrial and Earth-satellite radio links especially at frequencies above 10 GHz [2].

The major difficulty faced by engineers working on higher bands is balancing the trade-off between band-width availabilities and rain attenuation issues. Even though ITU-R has provided a methodological approach for predicting the rain attenuation on any terrestrial radio link, the model does not perform well in tropical climates because it is based on data collected from temperate regions [2,3]. A number of research works have been published to emphasize the inappropriateness of ITU-R method in tropical regions [2-4]. Generally, the required inputs in most attenuation prediction models are the rainfall rate exceeded at %p of time, the effective propagation path length, and the link’s operating frequency [5].

Da Silva Mello et al. [3] have reported that the extrapolation procedure of Equation (4) adopted by the current ITU-R P.530-14 [6] is the major limitation of the prediction method. This is because the same rain attenuation will be predicted for two regions with different rainfall rate regimes but similar values of $A_{0.01}$. In his efforts to correct the inappropriateness, the method of using the full rainfall rate distribution is introduced as input for predicting the rain attenuation cumulative distribution (CD).

In this article, nonlinear multiple regression and moving average techniques have been employed for fitting the measured rain attenuation at different time percentages. Based on the numerical results obtained, a more accurate prediction method has been proposed for extrapolating determining the values of attenuation at different exceedance probability %p from the measured attenuation at 0.01% of the time. The measured attenuation data have been tested against the proposed method and ITU-R predictions; and it was found that the proposed method seems to be more suitable than the ITU method for the Malaysian tropical climate.
2. Background

2.1 Definitions

Rain attenuation is defined as the product of specific attenuation (dB/km) and the effective propagation path length (km). The product of path reduction factor and the physical path length of a microwave link is referred to as the effective path length. Attenuation can be obtained from direct measurements or predicted from the knowledge of rain rate. The rain attenuation $A_{0.01}$ exceeded at $p$% of time is calculated as follows:

$$A_{0.01} = \gamma_{0.01} d_{\text{eff}}$$  \hspace{0.5cm} (1a)$$

$$\gamma_{0.01} = k R_{0.01}^\alpha$$  \hspace{0.5cm} (1b)$$

$$d_{\text{eff}} = d R_{0.01}$$  \hspace{0.5cm} (1c)$$

where $R_{0.01}$ (mm/h) is the rain rate exceeded at 0.01% of the time, $\gamma_{0.01}$ is the path reduction factor at 0.01% of the time, $d$ (km) is the link path length. Parameters $k$ and $\alpha$ depend on frequency, rain drop shape, rain temperature, and polarization; and the values of these parameters can be obtained from ITU-R P.838-3 [7].

2.2. ITU-R rain attenuation prediction method

According to Recommendation ITU-R P.530-14 [6], the rain attenuation $A_{0.01}$ (in dB) at 0.01% of the time on any terrestrial link is obtained by simply substituting $p = 0.01$ in Equation (1). This method assumes that an equivalent rain cell of uniform rainfall rate and length $d_0$ can model non-uniform rainfall rate along the propagation path. The reduction factor is given by:

$$r = \frac{1}{1 + \frac{d}{d_0}}$$  \hspace{0.5cm} (2)$$

where

$$d_0 = 35e^{-0.015R_{0.01}}$$  \hspace{0.5cm} (3)$$

The attenuation exceeded for other time percentages, $p$, of an average year may be calculated from the value of $A_{0.01}$ by using the following:

$$A_{p} = 0.12A_{0.01}p^{-0.546+0.043\log_{10}(p)}$$  \hspace{0.5cm} (4)$$

The major drawback of the extrapolation approach of Equation (4) is that it does not perform well in tropical regions, especially at higher rain rates [3].

3. Methodology and Analyses of experimental data

One-year rain attenuation data were sampled every second, collected from five operational point-to-point microwave links of DiGi Telecommunications Sdn. Bhd., Malaysia. Each of the microwave systems consists of a microwave MINILINK operating at 15 GHz with data acquisition and processing system. Both transmit and receive antennas are horizontally polarized; and the elevation angle is approximately zero degrees. In order to achieve reliable results, the antennas were covered with radome to ensure that the measured rain attenuation was not contaminated by wet antenna losses during measurement. Moreover, scintillations and other atmospheric absorptions along the propagation path have not been considered in the study. This is because the vapor absorption is significant at 22 GHz (0.16 dB/km) and the oxygen absorption at 60 GHz (15 dB/km) [5]. The MINILINKs have availability of 99.95% and their specifications are given in Table 1. The positioning of the antennas (transmitter and receivers) ensures that the radiation pattern is such that the sidelobes are not pointing to the ground. So, the level of ground contamination (noise) entering the sidelobes is negligible. This implies that there would be negligible interference from any other radiating sources. The dynamic range of the maximum signal strength is about 50 dB for excess (i.e., rain) attenuation. This is adequately suitable for covering the entire dynamic range of rain attenuation for this investigation, since the highest total path attenuation measured is 49.32 dB at 0.001% of the time.

In addition, 1-min rainfall rate data were collected for 4 years at both campuses of Universiti Teknologi Malaysia (UTM), Malaysia (UTM-Skudai and UTM Kuala-Lumpur campuses). The Skudai campus is located at Johor, southern part of Malaysia peninsula close to Singapore with annual average accumulation as high as 4184.3 mm. The average values of the 4-year rainfall rate measurements have been correlated with the 1-year measured attenuation data for these two locations due to seasonal variability of the rainfall pattern. Since rain rate CD varies from year to year, most especially at higher rain rates, we have assumed that 4-year CD will be fairly stable; and take care of any anomalies that might have been observed during the rain rate data collection. For instance, the average annual value

| Table 1 Specifications of the 15 GHz link in Malaysia |
|-----------------------------------------------------|
| **Type of antenna** | Front-fed parabolic |
| **Frequency band (GHz)** | 14.80 - 15.30 |
| **Polarization** | Horizontal |
| **Maximum transmit power (dBm)** | +18.0 |
| **BER Received threshold (dBm)** | -84.0 |
| **Antenna beam width** | 2.3° |
| **Dynamic range (dB)** | 50.00 |
| **Antenna for both transmit and receive side** | Size (m) | Gain (dBi) |
| | 0.6 | 37.0 |
of the 4-year rainfall rate data will have a lower variance and thus smaller variation.

For the remaining four sites (Alor Star, Penang, Taiping, and Temerloh), the average of 12-year rain-rate data collected from Malaysian Meteorological Station have been used in the study. These rain-rate data have 1-h integration time, so we used Chebil and Rahman’s model [8,9] for converting them to the equivalent 1-min integration time. Again, the average values of the 12-year rainfall rate measurements have been correlated with the 1-year measured attenuation data for the four sites due to seasonal variability of the rainfall pattern. Chebil and Rahman’s model was based on rainfall data of 1-h integration time collected from over 70 locations in Malaysia, Indonesia, and Singapore. The conversion method has been found to be quite accurate and reliable, within reasonable limit of statistical accuracy, for the Malaysian tropical region and other tropical regions [10]. However, the conversion method is limited to $0.001% \leq p \leq 1.0%$ of the time when rainfall rate is exceeded. Due to this constraint, the method could not offer accurate results for high rainfall rates when $p \leq 0.001%$. Nevertheless, our analyses were limited to the time percentages within the validity range of the rain rate conversion method.

The Casella rain gauge is of tipping bucket type and the bucket size is 0.5 mm of rain. Rain gauge’s availability is 100%, and it has operating temperature range of -10 to 50°C. The gauge is highly reliable with a tipping accuracy of $\pm 1.00%$. Note that about 0.5-mm bucket size is recommended for tropical countries. For instance in Malaysia, 0.01% rain rate is higher than 120 mm/h, which occurs 4 tips per minute with very good resolution. The bucket size of 0.2 mm needs more than 10 tips per minute for higher rain rate and causes error due to mechanical inertia at higher than 100 mm/h rain rate. Figures 1 and 2 show the CDs of measured rain attenuation and rainfall rates for each of the six MINILINKs, while the equal probability plots of concurrently measured rainfall rate and rain attenuation are shown in Figure 3.

In the ITU-R P.530-14 model, the rainfall rate exceeded at 0.01% of the time is used for predicting the corresponding rain attenuation value. The other percentages of time, within the range of 0.001 to 5.0%, are estimated by an extrapolation approach. The ITU-R predicted value of $A_{0.01}(\text{dB})$ is much smaller compared to the measured data [11]. In this study, a modification is proposed to the extrapolation formula used in the ITU-R method, based on the results presented in Figures 1, 2, and 3.

More over, possibly more information may be extracted by analyzing the same set of experimental data presented in Figures 1, 2, and 3. For instance, the relationship between the ITU-R predicted-specific rain attenuation, given in Equation (1b), and effective specific rain attenuation, calculated from experimental data, is shown in Figure 4.

The studies conducted on the microwave propagation characteristics of the six DIGI MINILINKs have shown that there exists a linear between measured attenuation $A_M(p)$ and logarithmic value of time percentage, $p$:

$$A_M(p) = 11.0833 - 4.6833 \log (p)$$  \hspace{1cm} (5)

The correlative coefficients between $A_M(p)$ and $\log (p)$ are almost -1 for the percentage time $p$ within the range 1.0 to 0.001%. By adopting the generalized expression, given below
\[ \frac{A_p}{A_{0.01}} = \psi \times p^{-(c + m \log(p))} \]  \hspace{1cm} (6)

where \( \psi \), \( c \), and \( m \) are regression coefficients whose numerical values were obtained by fitting the measured data shown in Figure 1. The numerical coefficients of the ITU-R method, given in Equation (4), have been adjusted accordingly, based on measurement data in the Malaysian tropical climate, by using nonlinear regression and moving average techniques. Therefore, for predicting \( \%p \) of the time at which attenuation \( A_p \) is exceeded, we propose

\[ A_p = 0.1689 A_{0.01} p^{-(0.5895 + 0.0996 \log_{10}(p))} \]  \hspace{1cm} (7)

4. Results and discussions

The comparison between the measured and predicted rain attenuation over the six terrestrial links in Malaysia at equiprobable exceedance probability \( 0.0001\% \leq p \% \leq 1.0\% \) is shown in Figure 5. As can be clearly seen from this figure, the ITU-R model does not accurately predict the measured attenuation for the six links. The model shows some dramatic behavior, underestimating the measurements at low rain rates, while overestimating the measured rain attenuation at high rain rates. One of the reasons for these inaccuracies may be due to the much smaller ITU-R predicted value for \( A_{0.01} \). Another reason maybe that the ITU-R extrapolation
method predicts that same rain attenuation will be pre-
dicted for two regions with different rainfall rate regimes
but similar values of $A_{0.01}$.

On the other hand, the modified ITU-R model seems
to closely match the measured rain attenuation for all
the six links. For instance, the predictions of the pro-
posed modified model are in good agreement with mea-
surements in the range of $1.0\% \leq \% H \leq 0.001$ for three links
(Alor Star, Kuala Lumpur, and Temerloh). Moreover,
the proposed model accurately predicts measurements
for the remaining three links (Johor Bahru, Penang, and
Taiping) in the range of $1.0\% \leq \% H \leq 0.01$. The prediction
errors associated with proposed model are generally less
than 10%, compared to the ITU-R whose errors are
close to 30%, especially at extremely high rain rates.

Moreover, the performance of the proposed method
was tested against measured data collected from five
Brazilian and seven Nigerian tropical locations. The
rainfall rate and rain attenuation data for the Brazilian
tropical climate were sourced from [12]. The measured
point rainfall rate $CD$ of Rio de Janeiro, Brazil, is repro-
duced in Figure 6a, while the characteristics of the five
terrestrial links over which rain attenuation was mea-
sured are shown in Table 2. Figure 6b shows

![Figure 4 Effective specific rain attenuation against ITU-R predictions](image4)

![Figure 5 Comparison between measured and predicted rain attenuation in Malaysia](image5)
comparison between the measured and predicted rain attenuation over the terrestrial links at equiprobable exceedance probability (0.0004% ≤ \( p \% \) ≤ 1.0%).

Due to scarcity of rain attenuation data in Nigeria, the measured point rainfall rates with 1-min integration time, range 0.001% ≤ \( p \% \) ≤ 1.0% [13], were used for

Figure 6 (a) Rainfall rate exceedance at \( \%p \) of the time for Rio de Janeiro, Brazil. (b) Comparison between measured and predicted rain attenuation in Brazilian tropical climates.
calculating the terrestrial attenuation over seven geographically spread locations. These locations are Warri, Port Harcourt, Calabar, Lagos, Akure, Ile-Ife, and Ilorin. The first four locations are classified as coastal climates; and a vertically polarized link operating at 18 GHz, with a path length 7.5 km, is assumed for each of the locations. The remaining three locations are classified as rain forests; and a horizontally polarized link operating at 15 GHz, with a path length 12.8 km, is assumed for each of the locations. Figure 7 shows comparison between the measured and predicted attenuations over the terrestrial links at equiprobable exceedance probability (0.001% \( \leq p \leq 1.0\% \)).

Figure 8 shows the scatter plots of predicted attenuation values against the measurements available from Malaysia, Brazil, and Nigeria.

As shown in Figures 6b, 7, and 8, the ITU-R method does not match with measurements for all the exceedance probability at which rain rate is exceeded. The method largely underestimates the measured values at low rain rates, while overestimating them at extremely high rain rates. On the other hand, the proposed method seems to match the measured values more accurately, with up to 80% reduction in relative RMS errors compared to ITU-R method.

The relative error variable used to assess the proposed model performance is given as

\[
E = \frac{A_{\% p,\text{predicted}} - A_{\% p,\text{measured}}}{A_{\% p,\text{measured}}} \times 100\%; \quad 0.001 \% < p < 1\% \quad (8)
\]

The measured data were tested against the ITU-R and proposed methods, as shown in Table 3, using the test variable recommended by the ITU-R P. 311-13 [14]. The new set of coefficients given in Equation (7) resulted in an improvement in terms of the RMS of the relative error variable compared to the RMS obtained with the original ITU-R parameters in Equation (4).

5. Conclusions

This article has presented the results on rainfall rate, and rain attenuation CDs on six microwave links operating at 15 GHz in tropical Malaysia. The relationship between effective specific attenuation and ITU-R predicted one is investigated. The experimental results have clearly shown that the extrapolation approach adopted by the current ITU-R method seems to be unsuitable for predicting rain attenuation CD from the knowledge of measured rain attenuation \( A_{0.01} \) in Malaysia and similar tropical climates. A new set of numerical coefficients

was derived for improved rain attenuation CD predictions in tropical Malaysia.

The applicability of the proposed method was validated using rain measurements from 12 tropical locations. When tested against measurements, the proposed method seems to provide a significant improvement over the current extrapolation method adopted by ITU-R Recommendations P.530-14, for the prediction of rain attenuation CD over tropical regions. The test results presented in Table 3 have also shown that the proposed approach seems to provide a better and more reliable alternative to the ITU-R method in tropical Malaysia, and probably other tropical climates, regardless of link’s operating frequencies and polarizations. The new set of parameters resulted in an improvement in terms of the RMS of the relative error variable compared to the RMS obtained with the original ITU-R parameters.
