Pseudomonas aeruginosa Exhibits Deficient Biofilm Formation in the Absence of Class II and III Ribonucleotide Reductases Due to Hindered Anaerobic Growth

Anna Crespo, Lucas Pedraz, Josep Astola and Eduard Torrents*

Bacterial Infections and Antimicrobial Therapies, Institute for Bioengineering of Catalonia, Barcelona, Spain

Chronic lung infections by the ubiquitous and extremely adaptable opportunistic pathogen Pseudomonas aeruginosa correlate with the formation of a biofilm, where bacteria grow in association with an extracellular matrix and display a wide range of changes in gene expression and metabolism. This leads to increased resistance to physical stress and antibiotic therapies, while enhancing cell-to-cell communication. Oxygen diffusion through the complex biofilm structure generates an oxygen concentration gradient, leading to the appearance of anaerobic microenvironments. Ribonucleotide reductases (RNRs) are a family of highly sophisticated enzymes responsible for the synthesis of the deoxyribonucleotides, and they constitute the only de novo pathway for the formation of the building blocks needed for DNA synthesis and repair. P. aeruginosa is one of the few bacteria encoding all three known RNR classes (Ia, II, and III). Class Ia RNRs are oxygen dependent, class II are oxygen independent, and class III are oxygen sensitive. A tight control of RNR activity is essential for anaerobic growth and therefore for biofilm development. In this work we explored the role of the different RNR classes in biofilm formation under aerobic and anaerobic initial conditions and using static and continuous-flow biofilm models. We demonstrated the importance of class II and III RNR for proper cell division in biofilm development and maturation. We also determined that these classes are transcriptionally induced during biofilm formation and under anaerobic conditions. The molecular mechanism of their anaerobic regulation was also studied, finding that the Anr/Dnr system is responsible for class II RNR induction. These data can be integrated with previous knowledge about biofilms in a model where these structures are understood as a set of layers determined by oxygen concentration and contain cells with different RNR expression profiles, bringing us a step closer to the understanding of this complex growth pattern, essential for P. aeruginosa chronic infections.

Keywords: ribonucleotide reductases, DNA synthesis, Pseudomonas aeruginosa, biofilm formation, anaerobic metabolism, oxygen diffusion, nrd genes, vitamin B12
INTRODUCTION

Pseudomonas aeruginosa is a common Gram-negative bacterium that is recognized for its ubiquity and its advanced antibiotic resistance mechanisms. It is also relevant for its great adaptability, being able to inhabit many different environments; it can live free in soil and water and can grow in human and plant host-associated environments. This bacterium is related to clinically relevant human infections in immunocompromised patients and other risk groups. In particular, it causes severe chronic lung infections in patients suffering from cystic fibrosis (CF) or chronic obstructive pulmonary disease (COPD; Lyczak et al., 2002; Davies et al., 2007; Ito and Barnes, 2009).

The establishment of chronic P. aeruginosa infections correlates with the formation of biofilm, a structure with clusters of cells encapsulated in a complex extracellular polymeric matrix. Bacteria in biofilms display different patterns of gene expression and phenotypes, reducing their metabolic rate and increasing cell-to-cell communication (Costerton et al., 1999) while becoming less sensitive to chemical and physical stresses, and they show increased chances of developing new antibiotic resistances (Xu et al., 1998; Stewart and Franklin, 2008). Oxygen does not diffuse freely through the biofilm structure, leading to the formation of an oxygen concentration gradient, which generates anaerobic microenvironments (Yoon et al., 2002; Alvarez-Ortega et al., 2010). Furthermore, it has been shown that in low-oxygen environments within mucus plugs or biofilms lung infections, it has been shown that P. aeruginosa is essential for full biofilm establishment (Stewart and Franklin, 2008).

As another manifestation of its metabolic versatility, P. aeruginosa is one of the few microorganisms that encodes the three different ribonucleotide reductase classes in its genome. Ribonucleotide reductases (RNRs) are key enzymes that catalyze the reduction of all four ribonucleotides to their corresponding deoxyribonucleotides, providing the necessary precursor molecules for DNA synthesis and repair in all organisms (Cotruvo andStubbe, 2011; Sjoberg and Torrents, 2011; Hofer et al., 2012; Torrents, 2014; Lundin et al., 2015). RNRs are divided into three classes (I, II, and III) based on their structural differences, metallofactor requirements, and the mechanisms used for radical generation. Class I RNRs require oxygen to produce a tyrosyl radical using a diferric iron or a dimanganese iron center and, thereby, function only under aerobic conditions. Class II RNRs require adenosylcobalamin (AdoCob) for radical generation and do not depend on oxygen (Torrents et al., 2005; Sjoberg and Torrents, 2011). Class III RNR belongs to the family of glycol radical enzymes. The radical is generated by an activating enzyme with a (4Fe-4S) cluster that catalyzes the reduction of S-adenosylmethionine (SAM). This class can only function under anaerobic conditions. Genes for active representatives of all three classes are present in P. aeruginosa metabolism: class I, subclass Ia (nrdAB), class II (nrdJab), and class III (nrdDG). Exceptionally the P. aeruginosa class II RNR is splitted and expressed in two different polypeptides (denoted as nrdJa and nrdJb; Torrents et al., 2005; Crona et al., 2015).

The presence and coordinated activity of the three classes is essential to ensure a supply of precursor molecules for DNA synthesis under both aerobic and anaerobic conditions (Sjoberg and Torrents, 2011). However, specifically in P. aeruginosa the synthesis of vitamin B12 only occurs in aerobic conditions (Lee et al., 2012) and its availability determines the class II RNR activity. Unfortunately, the exact role of each class and how they are genetically regulated is not yet fully understood.

In this work we aimed to study the importance of the different P. aeruginosa RNR classes for biofilm formation. We assessed the effect of class II and class III RNR deletion on static and continuous-flow biofilm formation and examined the phenotypic effects of this inactivation to establish the essential roles of RNRs in proper biofilm development. We also studied the genetic regulation responsible for modulating class II and class III RNR gene expression in biofilms, and we incorporated our data into a model where the P. aeruginosa biofilm is considered a set of layers determined by oxygen concentration gradients, vitamin-B12 and cells with different RNR expression profiles.

MATERIALS AND METHODS

Bacterial Strains, Plasmids, and Growth Conditions

All bacterial strains and plasmids are listed in Supplementary Table S1. Escherichia coli and P. aeruginosa cells were routinely grown in Luria-Bertani broth (LB) at 37°C. Anaerobic growth occurred in LB medium containing KNO3 (10 g/l; LBN medium) or 1 mM S-nitroso glutathione (GSNO) in screw-cap tubes (Hungate Tubes) that were purged with N2 (Garriga et al., 1996;
Arai, 2003). For the anaerobic culture of *P. aeruginosa* *anr*, *dnr*, and *narL* isogenic mutant strains, which are not able to grow anaerobically, cells were first grown under aerobic conditions in LB medium to a mid-exponential phase (OD560 = 0.5) and then the cultures were pelleted, resuspended in the same volume of LBN medium, and inoculated into screw-cap tubes containing anaerobic LBN medium. Finally, they were incubated for 3 h to induce anaerobic metabolism.

When necessary, antibiotics were added at the following concentrations: for *E. coli*, 10 μg/ml gentamicin and 50 μg/ml ampicillin and for *P. aeruginosa*, 150 μg/ml gentamicin, 300 μg/ml carbenicillin and 50 μg/ml tetracycline. Vitamin B12 was added when necessary at a concentration of 1 μg/ml.

**DNA Manipulations and Construction of Plasmids and Strains**

Recombinant DNA techniques were performed using standard procedures (Sambrook et al., 1989). DNA fragments were amplified via PCR using High-Fidelity PCR Enzyme Mix (Fermentas, Thermo Scientific). All primers used in this study are listed in Supplementary Table S2. DNA fragments were digested by the corresponding restriction enzymes (Fermentas, Thermo Scientific) and ligated with T4 DNA ligase (Fermentas, Thermo Scientific) according to the manufacturer's instructions. Plasmid DNA was isolated using the GeneJET Plasmid Miniprep Kit (Fermentas, Thermo Scientific). DNA was transferred into *P. aeruginosa* cells either via electroporation using a Gene Pulser Xcell™ electroporator (Bio-Rad) or via conjugation, as previously described (Crespo et al., 2015).

pETS191 and pETS192 plasmids were generated by applying PCR-based site-directed mutagenesis at the putative Anr/Dnr binding boxes of the *PnrD* and *PnrD* promoter regions (TTGAT/CNNNN/A/CTCAA, from the PRODORIC database) and then cloning the resultant mutant promoters into pETS130-GFP plasmids. Anr/Dnr box mutagenesis was performed according to previously published procedures (Urban et al., 1997) using the following primers: for the *PnrD* promoter region, mutantJ-up/mutanJ-low as the inner primers and PnrDJ BamHI new-up/PnrDJ SmaI new-low as the outer primers; for the *PnrD* promoter region, mutantR-up/mutanR-low as the inner primers and PnrDR-up/PnrDR new-low as the outer primers. The mutant fragments obtained from this process were cloned into pGEM-T Easy vectors, and the Anr/Dnr box mutation was verified via DNA sequencing. Finally, the fragments were digested with the corresponding restriction enzymes (BamHI/SmaI for *PnrD* and BamHI/ClaI for *PnrD*) and cloned into pETS130-GFP plasmids.

For pETS193 generation, the *oprF* promoter region was amplified from *P. aeruginosa* PA01 genomic DNA using the following primer pair: PoprFBIH-up/PoprFClai-low. The amplicon (460 bp) was cloned into pGEM-T Easy vectors, verified via DNA sequencing, digested with BamHI/ClaI and cloned into pETS130-GFP plasmids.

For pETS195 generation, an amplicon containing the *dnr* promoter region and the full ORF (1128 bp) was amplified from *P. aeruginosa* PA01 genomic DNA using the following primer pair: Pdnr-BHI up/Dnr-low. The amplicon was cloned into pGEM-T Easy vectors, verified via DNA sequencing, digested with BamHI/Sall and cloned into pUCP20T plasmids.

A *P. aeruginosa* ΔnrDΔnrD double mutant strain (ETS125) was constructed from the *P. aeruginosa* PA01 nrD::ΩGm; TrR (ETS103) strain (Sjoberg and Torrents, 2011) through the insertion of the gentamicin-resistance gene (*aacC1*) into the *nrD* gene using homologous recombination with the pETX100-Tlink vector, as previously described (Quenee et al., 2005). Briefly, two 400 bp areas surrounding the *nrD* gene were amplified via PCR with the following primer pairs: Jmut1HIIup/Jmut2BIw and Jmut3BIup/Jmut4SIw. The two amplicons obtained were then cloned separately into pGEM-T Easy vectors. A plasmid containing both fragments was generated by BamHI/Sacl digestion. The gentamicin resistance gene *aacC1* was obtained using BamHI digestion of pUCGmlox, and the corresponding cassette was ligated inside the two previous fragments. Next, the construct was cloned into the pEX100-Tlink vector. The obtained plasmid pET100-Tlink-nrD::ΩGm was transferred into the S17.1λpir strain and conjugated to *P. aeruginosa* ETS103 strain. Transformants were selected by plating them with tetracycline and gentamicin; 5% sucrose was added for *sacB*-mediated counterselection of the plasmids. The insertion of *aacC1* was screened via PCR with the primer pair Jmut1HIIup/Jint-2-3lw and later confirmed via DNA sequencing.

**Quantitative Reverse Transcription PCR (qRT-PCR)**

RNA from *P. aeruginosa* PA01 cells (either planktonic or from a biofilm) was isolated with RNAprotect Bacterial Reagent (Qiagen), according the manufacturer's instructions. RNA purification steps were carried out using the RNaseasy Mini Kit (Qiagen), according the manufacturer's instructions. DNase I (Turbo DNA-free, Applied Biosystems) was used to remove the remaining DNA, and RNA samples were subjected to PCR to verify the absence of DNA. For cDNA synthesis, RNA was quantified using a NanoDrop 1000 spectrophotometer (Thermo Scientific), and 0.5 μg of RNA was reverse transcribed with SuperScript III Reverse Transcriptase (Applied Biosystems) using the following primers for each gene: nrDA-TaqM2-low for *nrDA*, nrD1-TaqM2-low for *nrD1*, nrD1-TaqM2-low for *nrD1*, and gapTaM-low for *gapA*. qRT-PCR quantification used nrDA-FAM, nrD1-FAM, nrD2-FAM, and gap-FAM qRT-PCR probes (Crespo et al., 2015).

**Western Immunoblot Analysis**

Western blotting was carried out as previously described (Sjoberg and Torrents, 2011), using anti-NrdJ (Agrisera, Sweden; and Thermo Fisher, USA) at a 1:1000 dilution. The detection of primary antibodies was performed using donkey anti-rabbit (Bio-Rad) horseradish peroxidase-conjugated secondary antibodies at a 1/50,000 dilution. The antibody-antigen complex was detected using the Amersham™ ECL™ Prime western blotting reagent.

[^1]: http://www.prodoric.de/vfp/
(GE Healthcare), according to the manufacturer’s protocol. Proteins were visualized and analyzed using an ImageQuant™ LAS4000 mini system (GE Healthcare).

Static and Continuous-Flow Biofilm Formation

To determine the biomass of static biofilms grown under aerobic conditions, cells were grown on 96-well plates (Nunclon Delta Surface, Thermo Scientific) in LB containing 0.2% glucose for 3 days at 37°C. Fully anaerobic static biofilms were grown in the same plates using LBN medium containing 0.2% glucose, and they were incubated inside GENbag ANAER (Biomerieux) devices. After the incubation period, the culture supernatant was removed, and both kinds of biofilm plates were washed three times with 1x phosphate buffered saline (PBS) to eliminate any remaining planktonic cells. Cells attached to the wells were then fixed with methanol and stained with 1% crystal violet (Cendra Mdel et al., 2012). After staining, excess crystal violet was eliminated with water, and 33% acetic acid was used to dissolve the remaining dye. Biofilm mass was finally determined as a function of the concentration of this dye based on the absorbance at 570 nm (A570).

Continuous-flow biofilms were cultured as previously described (Christensen et al., 1999; Baelo et al., 2015) with the following modifications. Biofilms were grown into three-channel flow cells made of Perspex [poly(methyl methacrylate), channel size 40 mm × 4 mm × 1 mm; DTU Systems Biology, Technical University of Denmark] covered with a n°1 24 mm × 50 mm glass coverslip (Deltalab, ref. D102450) which served as the biofilm substratum. Flow cells were supplied with LB broth supplemented with 0.2% glucose, pumped by a high precision multichannel peristaltic pump (Ismatec ISM 943, Idex). Flow cells were inoculated using a 1-ml syringe with a 26 G needle and kept static for 1 h. After this point, flow was initiated at a rate of 3 ml/channel/hour. After 5–6 days of growth, biofilms were analyzed through staining the formed biofilm with the LIVE/DEAD BacLight Bacterial Viability Kit (Molecular Probes, Life Science), according to the manufacturer’s instructions, and the biofilms were visualized with a Leica TCS SP5 confocal scanning laser microscope (CSLM; Leica Microsystems, Wetzlar, Germany). The excitation wavelength was 488 nm and the emission wavelength was 500 nm. Images were obtained using a 20×/0.70 air objective. Simulated fluorescence projections and sections were generated using ImageJ software, and COMSTAT 2 software was used to quantify the biomass and thickness of the biofilms (Weiss Nielsen et al., 2011).

Green Fluorescent Protein Gene Reporter Assay

Promoters of the different RNR genes fused to GFP in pETS130-GFP plasmids were used to determine RNR gene expression [pETS134 (PnrdA::GFP), pETS180 (PnrdJa::GFP) and pETS136 (PnrdDb::GFP)], pETS191 (PnrdJΔAnr/Dnr-box::GFP) and pETS192 (PnrdDΔAnr/Dnr-box::GFP) plasmids were used to evaluate the effect of an Anr/Dnr box mutation on nrdJ and nrdD expression, respectively. pETS193 (PopFa::GFP) plasmids were used as a control.

For liquid culture experiments, GFP fluorescence was measured in 96-well plates (Costar® 96-Well Black Polystyrene Plate, Corning) on an Infinite 200 Pro Fluorescence Microplate Reader (Tecan), as previously described (Crespo et al., 2015). Briefly, three independent 1-ml samples of cells harboring the corresponding gene reporter assay plasmids grown to the mid-logarithmic phase (OD550) were collected and pelleted. Cells were fixed with 1 ml of a freshly prepared 1x PBS solution containing 2% formaldehyde and stored in the dark at 4°C. Three measurements were performed for each independent sample.

To determine gene expression during biofilm formation, experiments were performed on static biofilms formed in 96-well plates (Nunclon Delta Surface, Thermo Scientific) after the incubation of a liquid culture of the corresponding strain in LB containing 0.2% glucose at 37°C. After incubating the plate for a specific time (from 3 to 72 h), the culture supernatant was removed, and each well was washed three times with PBS to eliminate and remaining planktonic cells. The biofilm cells attached to the wells were then fixed with PBS containing 2% formaldehyde. Finally, fluorescence measurements were performed on an Infinite 200 Pro Fluorescence Microplate Reader (Tecan).

RESULTS

Anaerobic RNR Classes Play an Important Role in P. aeruginosa Biofilm Formation

The P. aeruginosa genome encodes genes for three different ribonucleotide reductase (RNR) genes, two of them (class II and III) able to function enzymatically under anaerobic conditions, as previously described (Sjoberg and Torrents, 2011). The individual ΔnrdF and ΔnrdD mutant strains showed a strong reduction in their anaerobic growth capacity (Supplementary Table S3). The ΔnrdD strain was able to grow under anaerobic conditions when supplemented with adenosylcobalamin or vitamin B12 to enhance class II RNR activity, agreeing with our previous report (Torres et al., 2005; Sjoberg and Torres, 2011). In this work, we generated a double class II (ΔnrdJ and class III (ΔnrdD) RNR mutant (ETS125) that was unable to grow anaerobically (only growing to OD550 = 0.05 after a standard overnight anaerobic culture) and only was capable to grow under aerobic conditions (OD550 = 3.8). These growth patterns indicate the simultaneous need for class II and III RNRs in P. aeruginosa for anaerobic metabolism (Supplementary Table S3).

As anaerobic growth is needed to support full biofilm establishment (Stewart and Franklin, 2008), we explored the role of the different RNR classes in P. aeruginosa biofilm formation. The P. aeruginosa PA01 wild-type strain, single ΔnrdJ (class II RNR) and ΔnrdD (class III RNR) isogenic mutant strains and double ΔnrdJΔnrdD mutant strain were assayed for their ability to form static biofilms under aerobic and anaerobic conditions (Figure 1A). The class I RNR mutation (ΔnrdA)
strain is not viable and was not used in the current study (Sjoberg and Torrents, 2011). The results show that deficiencies in class II RNR activity (in ETS102 ΔnrdJ strain) and in class III RNR activity (in ETS103 ΔnrdD strain) resulted in decreased static biofilm formation under both aerobic and anaerobic initial conditions. Complementation of the mutation with a copy of the corresponding wild-type RNR gene (nrdJ or nrdD) cloned into plasmids pEST159 and pETS160, respectively).
returned biofilm formation to a level similar to that of the wild-type strain. The double ΔnrdJΔnrdD RNR mutant (ETS125) showed almost no biofilm formation, and the decrease was even stronger in anaerobic biofilm formation experiments, demonstrating the key role of anaerobic RNR activity in *P. aeruginosa* biofilm formation. However, our results suggest that anaerobic RNR activity is needed for biofilm formation even when the experiment is performed under aerobic conditions. A *P. aeruginosa* Δdnr mutant strain (PW1965), unable to grow anaerobically, was used to compare the results from the RNR mutant with those from a strain unable to perform general anaerobic metabolism. Dnr is a transcriptional factor that regulates the expression of essential genes during *P. aeruginosa* anaerobic growth (Trunk et al., 2010). As expected, the PW1965 strain showed strong differences in biofilm formation when compared with the wild-type strain, even when the initial culture conditions were aerobic, and its ability to form biofilms resembled the ability shown by the ETS125 double RNR mutant strain.

To further corroborate our previous static biofilm formation experiments, we explored the importance of the different RNR classes in continuous-flow biofilm formation performed in flow cells. This technique better mimics the biofilms found in nature and specifically in the mucus plaques within the lungs of CF patients (Weiss Nielsen et al., 2011; Lebeaux et al., 2013). Biofilm cultures of different strains were cultivated under a continuous flow of LB medium over 6 days to obtain a robust and mature biofilm. The formed biofilms were then stained and visualized using confocal laser scanning microscopy (CLSM), as described in the section “Materials and Methods.”

Figure 1B shows the images obtained for the biofilms formed by the different strains that were evaluated and their corresponding orthogonal views. The thickness and total biomass values for each biofilm, estimated by COMSTAT software, are presented in Figure 1C. The biomass (µm³/µm²) and average thickness (µm) of the biofilms formed by all RNR mutant strains were decreased; biomass of the wild-type strain biofilm was 2.2, 1.8, and 2.7 times higher than the corresponding biomass of the anaerobic RNR mutant strains (ETS102 ΔnrdJ, ETS103 ΔnrdD and ETS125 ΔnrdDΔnrdJ, respectively). The greatest thickness observed was in the *P. aeruginosa* wild-type strain biofilm (49.40 µm), while the different class II and III RNR mutant strains formed significantly thinner biofilms, with an average thickness of 24.84, 15.5, and 14.53 µm for ETS102 ΔnrdJ, ETS103 ΔnrdD, and ETS125 ΔnrdDΔnrdJ, respectively. It is important to note that the *P. aeruginosa* double RNR class mutant (ETS125 ΔnrdDΔnrdJ) grew in a discontinuous pattern and showed difficulties in attaching to the glass surface. These results confirm our previous observations in static biofilms, highlighting the importance of anaerobic RNRs in biofilm formation even when culture conditions are initially aerobic.

**RNR Enzymes Contribute to Proper Cell Division in a Biofilm**

Figure 2 shows the CLSM analysis of the longitudinal cell morphology in a structured biofilm formed by the different
P. aeruginosa strains (PAO1 wild-type, ETS102 ΔnrdJ, ETS103 ΔnrdD and ETS125 ΔnrdDΔnrdJ). As described previously, the different RNR mutant strains showed elongated morphologies during anaerobiosis (Lee et al., 2012). The P. aeruginosa wild-type cells showed a normal rod-shape cell morphology throughout the biofilm in both the aerobic and anaerobic regions (top and bottom segments of the biofilm, respectively). However, the P. aeruginosa ETS102 ΔnrdJ mutant strain showed significant cell elongation in both the top and the bottom parts of the biofilm structure, indicating some disturbances in cell growth and division, as was clearly demonstrated in previous planktonic anaerobic cultures (Yoon et al., 2011; Lee et al., 2012). Some P. aeruginosa ETS103 ΔnrdD cells also showed cell elongation but only in the bottom layer of the biofilm (anaerobic region), while rod-shaped cells were found in the upper region that were similar to the shapes of the wild-type strain. Finally, the P. aeruginosa double mutant (ETS125 ΔnrdJΔnrdD) exhibited cell elongated along the entire span of the biofilm, similar to the results seen in the II RNR mutant (ETS102 ΔnrdJ).

### During Biofilm Formation, Expression of the nrdJ and nrdD Genes Is Increased

Our previous results demonstrate the importance of class II and class III RNRs for anaerobic growth and biofilm formation in P. aeruginosa and show that these two processes are related as biofilm growth is characterized by a decrease oxygen tension that results in anaerobic conditions in the bottom regions of the structure (Werner et al., 2004; Stewart and Franklin, 2008). We hypothesized that the expression of class II and class III RNRs could be induced under these growing conditions. To explore this, we studied the induction of the different RNR genes using RT-PCR.

First, we explored the induction of RNR genes by comparing anaerobic growth with aerobic growth in liquid cultures at the stationary phase (Table 1). The results showed a strong increase in nrdJa and nrdD expression (85.2 and 110.6), while nrdA expression (2.1 times) was only slightly increased under anaerobic conditions.

### Class II RNRs Are Transcriptionally Activated by a dnr Transcription Factor

To this point, we have demonstrated that class II and class III RNRs are of great importance for biofilm formation and that biofilm growth and an anaerobic environment strongly induce their expression. Therefore, the key transcriptional factors involved in P. aeruginosa anaerobic metabolism (Anr, Dnr, and NarL) were studied as putative transcriptional regulators for inducing RNR anaerobic expression (Arai, 2011; Arat et al., 2015).

The different transcription factors (Anr, Dnr, and NarL) are responsible for the regulation of different parts of the reduction chain in anaerobic respiration in P. aeruginosa [from NO3 to N2, through NO2 and NO (Trunk et al., 2010)]. Therefore, in the anaerobic transcriptional regulation study, P. aeruginosa was grown using KNO3 and GSNO (a NO donor) as final electron acceptors to obtain more information about which transcriptional regulator might be involved in the RNR transcriptional regulation under anaerobic conditions.

Transcriptional fusions of the nrdJ and nrdD promoter regions to GFP (present in the pETS180 and pETS136 plasmids, respectively) were transformed in different P. aeruginosa strains (PAO1, PW3784 Δanr, PW1965 Δdnr and PW7549 ΔnarL) and used for gene reporter assays (see Materials and Methods). As seen in Figure 3A, the results show an increased expression of both nrdJ and nrdD under anaerobic growth in the presence of both NO3 (321 and 188, respectively) and GSNO (351 and 163, respectively) compared to the expression during aerobic growth (146 and 101, respectively).

Comparing nrdJ expression between the P. aeruginosa anr, dnr, and narL knockout mutant strains and the wild-type strain...
FIGURE 3 | Transcriptional regulation of nrdJ and nrdD during anaerobic growth. (A) Transcriptional expression of nrdJ (pETS180) and nrdD (pETS136) promoters in P. aeruginosa wild-type, PW3784 Δanr, PW1965 Δdnr and PW7549 ΔnarL strains. Cells were grown aerobically to a mid-logarithmic phase (A550 0.5) and then were grown anaerobically (with NO3 or GSNO as electron acceptors) for 3 h to induce anaerobic metabolism. Values are the means SD from more than three independent experiments. *Significantly different from the P. aeruginosa wild-type strain in unpaired t-test (p-value 0.05). kRfu 1000 relative fluorescence units. (B) NrdJ protein expression analysis in PAO1 wild-type, PW1965 Δdnr and PW1965 Δdnr + pETS195 (dnr complementation plasmid) via western blot analysis performed at a mid-logarithmic phase after 0 h or 3 h of anaerobic induction. A representative blot of three independent western blot analyses is shown. An unknown, unspecific band that is present at an almost constant intensity in all samples is shown in the blot and served as a loading control.

(Figure 3A), we identified a reduced anaerobic induction of nrdJ expression in the Δanr (PW3784) and Δdnr (PW1965) mutant strains compared with the values of the wild-type strain. No effect was observed on nrdJ transcription when the narL gene was mutated. Our results show the dependence of the anaerobic induction of nrdJ gene expression on Anr and Dnr transcriptional regulators. As the effect is shown when any of these two genes are mutated and Dnr is controlled by Anr (which acts early in the regulatory chain of anaerobic metabolism), Dnr was considered the most likely candidate for being responsible for regulating nrdJ.

This control of nrdJ expression by Dnr was later verified at the protein level using a western blotting assay (Figure 3B). Although no differences were found in the amount of NrdJ protein between P. aeruginosa wild-type and PW1965 Δdnr mutant strains when measured during aerobic growth, 3 h of anaerobic metabolism induced a strong reduction in NrdJ levels in the Δdnr strain relative to expression in the wild-type cells. This effect was reverted back to near wild-type levels by Dnr complementation using the pETS195 complementation plasmid.

We failed to identify any regulation on nrdD expression by anaerobiosis-related Anr, Dnr, or NarL factors, as demonstrated in our results (Figure 3A).

To determine if the anaerobiosis-related transcriptional factors bind specifically on the RNR promoters, a bioinformatic search of putative Anr-Dnr binding sites was performed on the PnrdJ and PnrdD promoter regions. One Anr/Dnr-box was identified on both PnrdJ and PnrdD promoters (see Materials and Methods) according to the TTGA\text{T/C}\text{NNNN/A/G}\text{TCAA} consensus present in PRODORIC database. The putative Anr/Dnr boxes identified are shown in Figure 4.

To confirm the binding of Anr/Dnr to the promoters, we specifically mutated the essential nucleotides of the putative Anr/Dnr-boxes identified, fused the mutant promoters to GFP
and constructed plasmids for gene reporter assays (pETS191 for the nrdJ promoter and pETS192 for the nrdD promoter). In the corresponding assay, PnrdJ expression decreased when the Anr/Dnr-box was mutated. Moreover, the ΔAnr/Dnr-box PnrdJ (pETS191) expression was similar to that found in Δanr and Δdnr mutant strains (Figure 4A). However, no significant results were obtained when mutating the PnrdD Anr/Dnr-box (Figure 4B).

The Presence of Anaerobic Environments in the Biofilm Increases nrdJ Expression Through dnr Activation

Our previous results demonstrate that class II and class III RNRs are of great importance for biofilm formation and anaerobic growth in P. aeruginosa and that their expression is specifically induced under these conditions. As the induction of anaerobic metabolism increases as biofilm growth advances, we expected to detect a progressive induction of the expression of both RNRs during biofilm establishment and maturation.

To determine this, a GFP-based gene reporter assay was performed on a static biofilm culture over time. The expression of wild-type PnrdA, PnrdJ, and PnrdD was determined together with that of the mutant versions of PnrdJ and PnrdD (carrying mutant Anr/Dnr-boxes); a promoterless GFP plasmid (pETS130) was used as a negative control, and the oprF promoter (PoprF) was used as a positive control for anaerobic induction. OprF is a membrane protein that has its highest expression under anaerobic conditions, and it can be used as a marker of infection in a CF patient’s lung or sputum (Yoon et al., 2002; Eichner et al., 2014).

As expected (Figure 5A), PoprF expression increased greatly during mature biofilm development, demonstrating the progressive establishment of anaerobic conditions in the deep layers of the biofilm structure. Simultaneously, the PnrdJ and PnrdD promoter expression increased, although PnrdD expression increased only in the later stages when a mature and robust biofilm was formed. Mutating the Anr/Dnr-box severely reduced PnrdJ expression, while the anaerobic induction of PnrdD remained unaffected.

As a P. aeruginosa Dnr deficient strain is still able to grow as a biofilm, we further explored how Dnr controls RNR expression during biofilm formation by comparing nrdA, nrdJ and nrdD transcription in planktonic cells with that in biofilm-forming cells using the PW1965 Δdnr mutant strain. Comparing the results obtained (Figure 5B) with those from a P. aeruginosa wild-type biofilm vs. planktonic comparison (Table 1), we can see that when mutating the Dnr gene, the induction of nrdJ expression in biofilms becomes severely reduced but not completely abolished. Surprisingly, we also noticed that the

**FIGURE 4 | nrdJ and nrdD expression in P. aeruginosa wild-type, PW3784 Δanr, PW1965 Δdnr and PW7549 ΔnarL strains.** GFP fluorescence of (A) PnrdJ and PnrdJ ΔAnr/Dnr-box and (B) of PnrdD and PnrdD ΔAnr/Dnr-box measured in the wild-type, PW3784 Δanr, PW1965 Δdnr and PW7549 ΔnarL strains at a mid-logarithmic phase after 3 h of anaerobic induction. A fragment of the sequence of the corresponding promoter regions surrounding the putative Anr/Dnr-box is added at the right, and the sequence of the box is indicated in bold letters. In the mutant Anr/Dnr-boxes, mutated nucleotides are indicated in capital letters and underlined. The Anr/Dnr box is centered at −84 and −98 bp from the translation start site of the nrdJ and nrdD genes, respectively. *Significantly different from the wild-type strain in an unpaired t-test (P < 0.05). Error bars represent the standard deviation for three independent experiments.
induction of \textit{nrdD} expression was also strongly reduced in the PW1965 $\Delta dn r$ strain, which is in contrast with what was observed in the gene reporter assays (Figures 3A and 4B).

**DISCUSSION**

\textit{Pseudomonas aeruginosa} is well known for its genetic diversity. It has a relatively large genome (6.3 Mb) for a bacterium, and contains a large number of genes involved in different metabolic activities, which might contribute to the environmental adaptability of this bacterium. Its ability to grow in the absence of oxygen using nitrates or other forms of oxidized nitrogen as electron acceptors is an important example of \textit{P. aeruginosa}'s anaerobic growth capacity (Trunk et al., 2010; Arañ et al., 2015), which opens up a wide range of environments in which \textit{P. aeruginosa} can grow.

Such anaerobic environments are present in a mature biofilm, in which different nutrient gradients and differential physical properties appear. Previous reports have highlighted the oxygen concentration heterogeneity in biofilms using microelectrodes, and have described the oxygen diffusion profiles in continuous biofilms (Werner et al., 2004). The oxygen concentration throughout the biofilm is thus a crucial parameter for bacterial growth in a mature biofilm (Stewart and Franklin, 2008) and strongly defines its morphogenesis and final structure (Dietrich et al., 2013; Kempes et al., 2014; Okegbe et al., 2014). Metabolites and oxygen easily diffuse in the outer layers of the biofilm; however, the free oxygen concentration becomes reduced in lower layers, resulting in strict anaerobic conditions in the depths of the mature biofilm. The three ribonucleotide reductase classes encoded by \textit{P. aeruginosa} (class Ia, encoded in \textit{nrdA} and \textit{nrdB}; class II, encoded in \textit{nrdJa} and \textit{nrdJb}; and class III, encoded in \textit{nrdD} and \textit{nrdG}) are likely to increase the capacity of this bacterium to grow in the different environments generated throughout biofilms (Torrents et al., 2005; Sjoberg and Torrents, 2011).

Class Ia activity is strictly oxygen dependent, while class III is oxygen sensitive and can only function under strict anaerobic conditions. Class II is oxygen independent but needs vitamin B$_{12}$ (S-adenosylcobalamin) for the completion of its catalytic cycle (Torrents et al., 2005). In accordance of these different levels of oxygen dependence, we hypothesized that all three RNR classes would have a predominant role in the progressively deeper layers of the biofilm structure, with class II and class III RNRs essential for anaerobic growth and therefore for the establishment of fully mature biofilms.

The most basic study was performed to analyze the differential ability of $\Delta nrdJ$ and $\Delta nrdD$ mutant strains and a $\Delta nrdJ\Delta nrdD$ double mutant strain to grow in aerobic and anaerobic liquid cultures. The large reduction in anaerobic growth found after altering class II or class III RNRs highlights the importance of both RNR classes for anaerobic growth (Supplementary Table S3). In addition, the ability of class II RNRs alone to sustain anaerobic growth when the culture was supplemented with exogenous S-adenosylcobalamin suggests that class II RNRs can theoretically synthesize enough dNTPs to maintain normal growth rates, with S-adenosylcobalamin levels under anaerobic conditions being the limiting step.

**FIGURE 5 | Regulation of RNR expression during biofilm formation. (A) GFP-based gene reporter assay of \textit{P. aeruginosa} cells growing as a static biofilm. The induction factor is expressed as the quotient of the fluorescence units measured from one strain at one point in time relative to the corresponding value measured at the first time point (3 h of culture). Each strain was monitored between 3 and 72 h of biofilm growth. Wild-type RNR promoters (P\textit{nrdA}, P\textit{nrdJ}, and P\textit{nrdD}) are represented in continuous lines, and mutant RNR promoters (P\textit{nrdJ} and P\textit{nrdD}) carrying a mutant version of the putative Anr/Dnr-box identified) are plotted in dotted lines. A promoterless GFP in pETS130 plasmids was used as a negative control, and the P\textit{PoprF} promoter in pETS193 plasmids was used as a positive control for anaerobic induction of gene expression. (B) Fold change in \textit{P. aeruginosa} PW1965 $\Delta dn r$ P\textit{nrdA}, P\textit{nrdJ}, and P\textit{nrdD} promoter transcription was determined through real time PCR in 4-day-old cells grown as a static biofilm and compared with transcription in 16-h-old planktonic cells, both of which were cultured under aerobic conditions. The gap gene was used as an internal standard. The results shown represent the mean of three independent experiments ± standard deviation.**
The next step was to study how these same effects act on the natural formation of the anaerobic environments that appear during biofilm formation. Static biofilm formation was severely diminished when class II or class III RNRs were mutated (Figure 1A). This effect was higher when biofilms were built directly under anaerobic conditions but was also present under aerobic conditions. We associated this effect to the formation of anaerobic microenvironments in the biofilm depths that will undoubtedly occur if biofilms grow thick enough, and this was demonstrated by the analogous effect observed when mutating the dnr gene, which is one of the main transcriptional regulators of anaerobic metabolism (Schreiber et al., 2007). In this case, the impaired anaerobic metabolism implies that biofilm biomass will be reduced even when conditions are initially aerobic.

As static biofilm formation in microplates can be considered an artificial lab condition, we also studied the effect of class II and class III RNR alterations on continuous-flow biofilm formation, a technique that is thought to better the mimic biofilms present in nature and in clinically relevant cases, such as lung infections in CF patients (Weiss Nielsen et al., 2011; Lebeaux et al., 2013). Agreeing with our previous results, both biofilm biomass and thickness were considerably reduced when mutating the class II and/or class III RNRs (Figures 1B,C). The structure of the so-formed biofilm also changed compared with that of the wild-type biofilm. It is particularly important that in the ΔnrdJ ΔnrdD double mutant strain, a growth pattern of discontinuous patches appeared, showing the dependence on aeration of this strain.

All these data can be incorporated into a model in which the biofilm is considered a set of layers where the free oxygen concentration is progressively reduced with depth (Figure 6). Interestingly, vitamin B₁₂ can only be synthesized under aerobic conditions (Lee et al., 2012); to our knowledge the diffusion properties of vitamin B₁₂ in the biofilm have never been formally determined, but we can expect it to be gradually diffused throughout the biofilm layers and actively consumed when crossing them, therefore the deeper layers would not only be anaerobic but also limited in adenosylcobalamin. Therefore, at the top of the biofilm, class I RNRs would be the main enzyme responsible for dNTP synthesis, while class II RNRs would gain more importance in the middle layers (characterized by reduced oxygen levels but within the range of vitamin B₁₂ diffusion) and class III RNRs would support growth in the lower layers as it does not depend on oxygen or metabolite diffusion from the outer regions.

Additionally, we studied the cell morphology in the different layers of the biofilm. A cell elongation phenotype is associated with impaired cell division, which can be triggered by depletion of the dNTP pool when RNR metabolism is affected. According to our model, the ΔnrdJ mutant strain and the ΔnrdJΔnrdD double mutant strain showed elongated cells throughout almost the entire biofilm depth, while the ΔnrdD strain only presented elongation in the lower layers (Figure 2). These results must be interpreted by also taking into account the fact that reductions in biofilm biomass and thickness were also happening, so the thin layer in which class the III RNR mutation seems to affect cell morphology means only that strictly anaerobic areas were unable to form.

Given the importance of class II and class III RNRs for anaerobic growth and biofilm formation, we expected an up-regulation of these enzymes under these conditions. It

![FIGURE 6 | Model of ribonucleotide reductases expression during P. aeruginosa biofilm formation. Oxygen concentration is progressively reduced throughout the biofilm structure in a well-established gradient (Xu et al., 1998; Stewart and Franklin, 2009). Vitamin B₁₂ and NO gradient concentrations also presented here are hypothetical (see the Discussion section).](image-url)
is known that as much as half of the *P. aeruginosa* genome is differentially expressed during biofilm development, including many genes involved in anaerobic metabolism, which are up-regulated in mature biofilms (Waite et al., 2006). Some studies have highlighted that the differential gene expression of class II RNRs depends on levels of oxygenation and have shown a 3.2-fold up-regulation under anaerobic conditions compared with expression during aerobicosis (Filatratul et al., 2005). *nrdJ* up-regulation has also been noticed in anaerobic sputum (Palmer et al., 2007), and NrdJ and NrdD proteins were also identified to have an increased concentration under anaerobic conditions (Wu et al., 2005).

In agreement with these observations, we observed a large increase in *nrdJ* and *nrdD* mRNA levels under anaerobic conditions (compared with aerobicosis) and in biofilm-forming cells (compared with planktonic cells; Table 1). These results imply the existence of a direct or indirect mechanism to activate *nrdJ* and *nrdD* transcription as a result of anaerobic metabolism and/or due to specific biofilm-related factors. The comparison between the expression in initially aerobic biofilm cells and in anaerobic planktonic cells shows that *nrdJ* transcription was mainly activated by anaerobiosis, while *nrdJ* expression levels appeared to also be regulated by specific biofilm factors, as *nrdJ* induction in the biofilm (where only some anaerobic and microaerophilic areas are present) is higher than in fully anaerobic planktonic cultures.

To sustain anaerobic metabolism, *P. aeruginosa* uses NO3 or other more oxidized forms of nitrogen (NO2, NO) as final electron acceptors for anaerobic respiration: the final product of the full chain of reductions is molecular nitrogen (N2; Schreiber et al., 2007). Anr acts as a general regulator of all anaerobic metabolism, activating the transcription of all metabolic enzymes thought to be involved in the pathway and that of the more specific regulators *dnr* and *narL*. NarL and Dnr transcription factors are in turn responsible for the control of the enzymes acting in the first reduction (from NO3 to NO2) and in the whole pathway, respectively. When analyzing the effects of mutations of these transcription factors on the RNR expression levels measured in a gene reporter assay, we observed a strong reduction in the anaerobic induction of *nrdJ* expression in the Δdnr and Δanr mutant strains, while no effect was observed when mutating the *narL* gene, and *nrdD* expression was not altered (Figure 3).

Therefore, we suggest that regulation by Anr/Dnr is partially responsible for class II RNR anaerobic induction. If Anr is active in the upper part of the regulation cascade, a simple transcriptional activation by Dnr would be the easiest explanation for the results obtained. Furthermore, as *nrdJ* expression was increased when GSNO, as an NO donor, was used as an electron acceptor, and NO levels affect the denitrification process by modulating Dnr regulation (Van Alst et al., 2007; Castiglione et al., 2009), these findings support the hypothesis of transcriptional control of *nrdJ* expression by Dnr. According to the biofilm reaction-diffusion theory (Stewart, 2003) we hypothesize that NO, described to be the main metabolite accumulated as a consequence of anaerobic metabolisms (Ye et al., 1994), should see its concentration increased in the lower layers, enhancing the effect of Dnr regulation (see Figure 6).

The genes belonging to the Anr/Dnr regulons are associated with Anr and Dnr binding boxes (Trunk et al., 2010), although the binding sites are still not well determined and more studies are needed to distinguish between them. Surprisingly, we identified a putative Anr/Dnr binding box in both class II and class III RNR promoters (*PndD* and *PndD*; Figure 4). In our gene reporter assays, we determined that the mutation of the putative Anr/Dnr box in *PndD* dramatically reduced the anaerobic induction of class II RNR expression (resembling the effect of *dnr* or *anr* gene mutation), while mutating the putative Anr/Dnr box in *PndD* had no significant effect.

According to these results, we can assume that under anaerobic conditions or in the anaerobic and microaerophilic environments generated during biofilm formation, NrdJ activity is essential for proper growth and that it is activated under these conditions by Dnr or Anr/Dnr via direct binding with its promoter. However, further studies are needed to determine if there are other specific biofilm-related factors activating NrdJ transcription and to define the mechanism for class III RNR anaerobic induction. This could be due to other factors that have not yet been studied, or it could even be related to Anr/Dnr pathways (as suggested the putative box found in the promoter) that may only be detectable under specific conditions that have not yet been tested.

Integrating our experiments on the effects of RNR mutation on biofilm formation and on RNR regulation in biofilm growth and under anaerobic conditions, we performed a gene reporter assay during biofilm formation, which supported our model: as the *P. aeruginosa* PAO1 wild-type biofilm structure matured, anaerobic areas were generated (as defined by the induction of the control promoter *PogF*) and *PndD* and *PndD* were consequently induced (Figure 5A). Again, mutating the putative Anr/Dnr boxes reduced class II RNR induction and had no effect on class III RNRs. However, analyzing the difference in expression in a PAO1 Δdnr mutant strain between biofilm forming cells and planktonic cells, we not only observed a reduced anaerobic induction of class II RNRs but also, surprisingly, a considerably reduced induction of class III RNRs (Figure 5B), reinforcing the hypothesis that there could be an as-yet-undefined direct or indirect mechanisms by which Anr/Dnr controls *PndD* expression.

The model of a *P. aeruginosa* biofilm as a set of layers with different RNR expression profiles that are determined by oxygen concentration and B12 diffusion gradients and by cells with specific genetic regulation to support the differential RNR activities is of great importance for our understanding of this particular growth pattern. These results could play an important role in understanding the virulence of bacterial biofilms as it has been shown that the growth conditions in the lungs of CF patients include oxygen-limited growth and anaerobic environments (Schobert and Jahn, 2010) and that susceptibility to antibiotics in biofilms is modulated by limited oxygen availability (Borriello et al., 2006).
AUTHOR CONTRIBUTIONS

AC, LP, and ET designed the study. AC, LP, and JA performed the experiments. All authors analyzed the data, wrote the paper, read and approved the final version.

FUNDING

This work was supported in part through grants to ET from the Ministerio de Economía y Competitividad (BFU2011-24066 and BIO2015-63557-R), Generalitat de Catalunya (2014 SGR01260) and Catalan and Spanish Cystic Fibrosis foundations. ET was also supported by the Ramón y Cajal I3 program from the Ministerio de Economía y Competitividad.
