Abstract

**Background:** Atrial fibrillation (AF) is one of the most common arrhythmias in clinical practice. Alcohol consumption has been linked to the occurrence of AF.

**Methods:** A comprehensive search of electronic databases (PubMed, Cochrane Library, OVID, Google scholar, and Web of Science) was performed. The search yielded a total of 1177 articles, and 12 cohort studies from the total were included in the meta-analysis. The effects of different doses of alcohol consumption on the risk of AF in men and women were compared using hierarchical analysis. Dose-response curves of alcohol consumption and risk of AF were plotted for the two groups according to sex.

**Results:** The risk of AF increased with increased alcohol consumption in both men and women. In the male population, light-moderate alcohol consumption did not increase the risk of AF (HR: 1.07, 95%CI: 0.92-1.23, P=0.38), while heavy alcohol consumption significantly increased the risk of AF (HR: 1.38, 95%CI: 1.23-1.54, P<0.01). In the female population, the risk of AF was not significantly increased by either light-moderate or heavy alcohol consumption (light-moderate drink: HR: 1.00, 95%CI: 0.92-1.10, P=0.95; heavy drink: HR: 1.05, 95%CI: 0.90-1.23, P=0.55).

**Conclusions:** In women, the risk of AF was not associated with any degree of alcohol consumption while high levels of alcohol consumption significantly increased the risk of AF in men.

1. Introduction

Atrial fibrillation (AF) is one of the most common form of clinical arrhythmia with 1–2% prevalence in the general population [1]. In patients with AF, effective treatment measures to control heartbeat rhythm and avoid complications exist. However, a number of adverse lifestyle factors including alcohol consumption still contribute to the increasing prevalence of AF [2].

Studies have shown that dietary components such as alcohol consumption influence cardiovascular disease morbidity and mortality [3]. The relationship between alcohol intake and AF incidence was observed when arrhythmia recurred after ablation and left atrial remodeling were done [4]. However, the relationship between AF and alcohol consumption remains controversial because a study has indicated that alcohol consumption can reduce the incidence of myocardial infarction to some extent [5]. In addition, some studies have suggested that there are no connections between AF and light-to-moderate alcohol consumption [6]. Nonetheless, alcohol consumption to some extent has been associated with an increased risk of AF in some studies [7]. A study reported that heavy alcohol consumption is associated with a higher risk of AF among men. However, this correlation was not strong among women [8].

Due to the complex association between alcohol consumption and health, we designed a dose-response meta-analysis based on cohort studies to determine the association between various levels of alcohol consumption and the risk of AF. This study also aimed at evaluating the differences between men and women in their reaction to alcohol consumption.

2. Materials And Methods

2.1. Search Strategy and Eligibility Criteria

This systematic review and meta-analysis study adhered to PRISMA guidelines (preferred reporting items for systematic reviews and meta-analyses), and followed a pre-specified protocol. A comprehensive search was done on the PubMed database, Google scholar, Web of Science, Cochrane Library, and OVID with no date restriction up to 1st June, 2020. In the search, the following key medical subject headings (MeSH) terms and Emtree terms were used: atrial fibrillation, alcohol, and ethanol. The search was restricted to randomized controlled trials (RCTs) and clinical research. Reference lists of selected studies and previous reviews were also searched for potential eligible trials. Case reports, editorials, expert opinions, review articles, editorials, guidelines, and non-English studies were excluded.

2.2. Data Abstraction and End Points
Two independent reviewers extracted the following data from pre-specified reports: authors, year of publication, alcohol consumption, cohort study number, number of cases of AF, and follow-up time.

Weekly alcohol intake was used to classify the level of consumption by the participants as light-moderate (1–6 drinks/week for general people, 1–14 drinks/week for men or 1–6 drinks/week for women) and high (> 14 drinks/week for general people, > 21 drinks/week for men or > 14 drinks/week for women). In addition, 12 g of ethanol was converted into 1 drink.

2.3. Statistical Analysis

Microsoft Excel 2016, Revman 5.4 and Stata SE 15 were used to analyze the extracted data. Extraction of different alcohol intakes and their corresponding hazard ratio (HR) were obtained from each article. $I^2$ values of 25, 50 and 75% indicated low, medium and high degree of heterogeneity respectively. A random effects model was used where analysis of the relationship between different levels of alcohol consumption and risk of AF based on the sex of the individual was represented through plotting of dose-effect curves.

3. Results

3.1. Search Results

1177 relevant literature were searched from the electronic databases when “atrial fibrillation”, “alcohol”, and “ethanol” key words were used. A decision on which articles to include in the study was made after reading the abstract and further examination of the full-text. Finally, 11 eligible articles were included with the analyzed data including a total of 396717 participants. 44.3% of the participants were male and the follow-up duration ranged between 4.7 to 17.6 years. The alcoholic drinks involved included beer, wine, liquor and mixed drinks. The drinks were converted into grams of ethanol on the basis of serving size, alcohol content and the density of ethanol with 12 g of ethanol being converted into 1 drink. The PREDIMED study [6] was not included because the extracted data could not meet the full criteria for inclusion.

The weekly alcohol intake was used to classify participants’ level of consumption where for the general population, consumption of 1–6 drinks/week was classified as light-moderate consumption while consumption of > 14 drinks/week was described as high consumption. There was no significant association between alcohol consumption and AF risk when an individual consumed 1–6 drinks per week (HR: 0.98, 95% CI: 0.88–1.08, P = 0.63). However, the risk of AF was significantly increased by consumption of more than 14 drinks per week (HR: 1.26, 95% CI: 1.16–1.37, P < 0.01).

3.2. Analysis of alcohol consumption and atrial fibrillation risk according to sex

In most cases, women tend to drink less than men. Therefore, most studies consider 1–6 drinks per week for women and 7–14 for men as light-moderate consumption while drinking > 14 drinks per week for women and > 21 drinks per week for men is classified as heavy consumption.

Five studies reported follow-up results of the relationship between light drinking and AF in men, and six reported follow-up results of heavy drinking in men. There was no significant association between alcohol consumption and AF risk in the men who consumed between 1–14 drinks per week (HR: 1.07, 95% CI: 0.92–1.23, P = 0.38). However, consumption of more than 21 drinks per week significantly increased the risk of AF (HR: 1.38, 95% CI: 1.23–1.54, P < 0.01).

In addition, five studies reported follow-up results of the relationship between light drinking and AF in women while seven reported follow-up results of heavy drinking in women. Light- moderate or heavy alcohol consumption did not significantly increase the risk of AF in the women (light- moderate drink: HR: 1.00, 95% CI: 0.92–1.10, P = 0.95; heavy drink: HR: 1.05, 95% CI: 0.90–1.23, P = 0.55). There was still no significant association between alcohol consumption and the risk of AF even when we defined heavy drinking among women as being more than 21 drinks per week (HR: 1.15, 95% CI: 0.97–1.37, P = 0.11).

3.3. Dose response relation between alcohol consumption and atrial fibrillation risk
A dose-response curve was plotted for daily alcohol consumption dose and risk of AF on the basis of average daily alcohol consumption in different populations. A solid curve represents hazard ratios with its accompanying area representing the 95% confidence intervals. In the group of men, the curve was based on a restricted cubic spline regression model with knots at 0, 12.1, 36.1 and 102 g/day alcohol consumption. The curve indicated that the risk of AF increased rapidly with the consumption of more than 40 grams of alcohol per day. The curve was also based on a restricted cubic spline regression model in the women group with knots at 0, 6.4, 15.6 and 102 g/day alcohol consumption. Similarly, the risk of AF in women also increased rapidly with consumption of more than 40 grams of alcohol per day.

4. Discussion

This meta-analysis study indicates that there was no significant association between consumption of 1–6 drinks/week and AF risk. However, consumption of more than 14 drinks per week significantly increased the risk of AF. Dose response association showed an increasing nonlinear trend of AF with increased alcohol consumption. Results after the analysis of men and women groups indicated that there were sex-related differences between alcohol consumption and risk of AF. Light to moderate alcohol consumption by men did not increase the risk of AF while heavy alcohol consumption was associated with an increased risk of AF. On the other hand, light to moderate and heavy alcohol consumption by women did not increase the risk of AF indicating that there was no significant association between alcohol consumption and the risk of AF in women.

AF is the most common and persistent arrhythmia in humans affecting more than 33 million people worldwide. AF is often associated with multiple comorbidities and thus it poses a huge medical and economic burden. An increasing number of studies have indicated that alcohol consumption may play a role in the pathogenesis of AF [18]. A study has reported that for many individuals with AF, heavy alcohol drinking was associated with high mortality risk among men (HR: 1.51, 95% CI: 1.20–1.89), and high thromboembolism risk in women (HR: 1.71, 95% CI: 0.81–3.60) [19]. However, some studies have indicated that low-moderate intake of alcohol is associated with cardio-protective effects and improvement in vascular health. A study reported that low-moderate alcohol consumption can prevent coronary heart disease and reduce the incidence of heart failure, atherosclerosis and peripheral vascular disease to a certain extent [20]. Therefore, long-term impacts of alcohol consumption on AF are controversial.

Our findings indicated that light-to-moderate alcohol consumption did not increase the risk of AF which is consistent with results from a study which reported that consumption of alcohol in moderation reduces the risk of heart failure and does not increase the risk of AF [17]. Moderate ethanol intake can prolong the duration of the action potential of atrial myocytes by inhibiting potassium currents (I_{KV1.5} and I_{HERG}), thereby preventing to some extent the occurrence and persistence of AF [21]. These results can be attributed to the fact that most people in the study drank red wine which might have some cardio-protective effects. Red wine differs from other alcoholic beverages because it contains various phenolic compounds. Resveratrol, one of the phenolic compounds in red wine, has been reported to have a protective effect on the heart [22].

Acute heavy drinking during the holiday season is often accompanied by a higher incidence of AF, a phenomenon known as holiday heart syndrome [23]. Observational studies indicated that alcohol consumption is associated with autonomic imbalance and might lead to sympathetically triggered AF [24]. Alcohol consumption may elicit AF through vagal activation after eating and acute alcohol exposure which is able to shorten the atrial action potential and refractory period. 22–34% of paroxysmal atrial fibrillation (PAF) were reported after alcohol consumption with up to 38% PAF events being associated with vagal activity [25]. Intracellular Ca^{2+} signaling plays an important role in the regulation of contraction of cardiac cells. Exposure to ethanol or acetaldehyde (a byproduct of ethanol) can lead to abnormal concentrations of intracellular Ca^{2+} [26]. Therefore, alcohol exposure activates stress kinases in atrial myocytes thereby prompting aberrant Ca^{2+} waves which results in increased susceptibility to atrial arrhythmias [27].

Acute drinking can result in the prolonging of intra- and inter-atrial conduction and reduction in the atrial effective refractory period, while long-term drinking can lead to cell damage and fibrosis [28]. Heavy drinkers had longer QTc intervals than non-drinkers with approximately 1.4-fold higher odds of having a prolonged QTc interval (OR: 1.43, 95% CI: 1.033–1.982, P < 0.05) than non-drinkers [29]. A substantial proportion of the association between alcohol and AF is mediated by the left atrial
dimension (LAD). Chronic alcohol consumption can be cardiotoxic thereby leading to pathological atrial structural change. Every additional 10 g of alcohol consumed per day was associated with a 0.16 mm (95% CI, 0.10–0.21 mm) enlargement of LAD with an estimated 24% (95% CI, 8–75) of the association between alcohol and AF risk being associated with left atrial enlargement [30]. Therefore, alcohol consumption not only induces AF but it can also cause cardiac remodeling to maintain AF.

A Women's Health Study reported that heavier consumption of two or more drinks per day was associated with a small increase in the risk of AF, and the risk of AF increased with the quantity of alcohol consumed [12]. In this study, the dose-response curve indicated that the risk of AF in women increased with increased alcohol consumption. However, stratified comparisons showed that there was no significant difference between alcohol consumption and AF risk even when women consumed more than 21 drinks per week. A Danish Diet, Cancer, and Health Study indicated that alcohol consumption increased risk of AF especially in men with 25%-46% higher risks of AF associated with intake of more than 20 g/day of alcohol in men but not in women [20]. The lower risk of AF in women can be attributed to the role of estrogen in speeding up alcohol metabolism [31]. However, the explanation is undermined by the conflicting views on the role of estrogen in alcohol metabolism. In most cases, there is moderate alcohol consumption by women with only few women drinking more than 36 g of ethanol per day. In the women group, the fit of the model was not significantly different from that of the non-linear regression model (P = 0.36). In addition, the dose-response curve deviated greatly when alcohol consumption exceeded 36 g/day which may change the results to some extent. Therefore, evidence from more cohort studies is required to clarify the effect of alcohol consumption on the risk of AF in women.

**Conclusions**

The risk of AF increased with increased alcohol consumption in both men and women. There was limited association between light-moderate drinking (1-14 drinks per week for men and 1-7 drinks per week for women) and the risk of AF. On the other hand, there was a significant association between heavy drinking and risk of AF in men which was not observed in women. Therefore, increased alcohol consumption in men results in a significant increase in the likelihood of having AF.

**Study Limitations**

Participants in this study were enrolled in an observational cohort thus our findings may not be applicable to the general clinical population. In addition, the female population generally consumes less alcohol, and there was some bias in the stratified analysis and dose-response curves reflection of the risks of AF in heavy alcohol consumption.
