Word-to-Word Models of Translational Equivalence

I. Dan Melamed ∗
University of Pennsylvania

Parallel texts (bitexts) have properties that distinguish them from other kinds of parallel data. First, most words translate to only one other word. Second, bitext correspondence is noisy. This article presents methods for biasing statistical translation models to reflect these properties. Analysis of the expected behavior of these biases in the presence of sparse data predicts that they will result in more accurate models. The prediction is confirmed by evaluation with respect to a gold standard — translation models that are biased in this fashion are significantly more accurate than a baseline knowledge-poor model. This article also shows how a statistical translation model can take advantage of various kinds of pre-existing knowledge that might be available about particular language pairs. Even the simplest kinds of language-specific knowledge, such as the distinction between content words and function words, is shown to reliably boost translation model performance on some tasks. Statistical models that are informed by pre-existing knowledge about the model domain combine the best of both the rationalist and empiricist traditions.

1 Introduction

The idea of a computer system for translating from one language to another is almost as old as the idea of computer systems. The earliest written record of this idea is a 1949 memorandum by Warren Weaver. More recently, Brown et al. (1988) have proposed methods for constructing machine translation systems automatically. Instead of codifying the human translation process from introspection, Brown et al. appealed to machine learning techniques to induce models of the process from examples of its input and output. The proposal generated much excitement, because it held the promise of automating a task that fifty years of research have proven extremely labor-intensive and error-prone. Yet, very few other researchers have taken up the cause, partly because Brown et al.'s approach was quite a departure from the paradigm in vogue at the time.

Formally, Brown et al. built statistical models of translational equivalence (or translation models, for short). Translational equivalence is a relation that holds between two expressions with the same meaning, where the two expressions are in different languages. As with all statistical models, the best translation models are those whose parameters correspond best with the sources of variance in the...
Translation models whose parameters reflect existing knowledge about particular languages and language pairs and/or universal properties of translational equivalence benefit from the best of both the empiricist and rationalist traditions. This article presents three such models, along with methods for efficiently estimating their parameters.

More specifically, in this article, I introduce methods for modeling three universal properties of translational equivalence in parallel texts (bitexts):

1. Most word tokens translate to only one word token. I capture this tendency in a one-to-one assumption.

2. Most text segments are not translated word-for-word. I build an explicit noise model.

3. Different linguistic objects have statistically different behavior in translation. I show a way to condition translation models on different word classes to help account for the variety.

Quantitative evaluation with respect to a gold standard has shown that each of the three methods effects a significant improvement in translation model accuracy.

A review of previously published translation models follows an introduction to the different kinds of possible translation models. The core of the article is a presentation of the model estimation biases described above and an analysis of their expected behavior in the face of sparse data. The last section reports the results of a variety of experiments designed to evaluate these innovations.

Throughout this article, I shall use **CALLIGRAPHIC** letters to denote entire text corpora and other sets of sets, **CAPITAL** letters to denote collections, including strings and bags, and *italics* for scalar variables. I shall also distinguish between **types** and tokens by using **bold font** for the former and plain font for the latter.

### 2 Translation Model Decomposition

There are two kinds of applications of translation models: those where word order plays a crucial role and those where it doesn’t. Empirically estimated models of translational equivalence among word types can play a central role in both kinds of applications.

Applications where word order is not important (or at least not essential) include

- cross-language information retrieval (*e.g.* Oard & Dorr, 1996),
- computer-assisted language learning (*Narbonne et al.,* 1997),
- certain machine-assisted translation tools (*e.g.* Macklovitch, 1994; Melamed, 1996a).
• concordancing for bilingual lexicography (Catizone et al., 1993; Gale & Church, 1991),
• corpus linguistics (e.g. Svartvik, 1992),
• “crummy” machine translation on the internet (Church & Hovy, 1993).

For these applications, empirical models have a number of advantages over hand-crafted models such as on-line versions of printed bilingual dictionaries. Two of the advantages are the possibility of better coverage and the possibility of frequent updates by non-expert users to keep up with rapidly evolving vocabularies.

A third advantage is that empirical models can provide more accurate information about the relative importance of different translations. Such information is crucial for applications such as cross-language information retrieval (CLIR). In CLIR, the query vector $Q'$ is in a different language (a different vector space) from the document vectors $D$. Matrix multiplication by a word-to-word translation model $T$ can map $Q'$ into a vector $Q$ in the vector space of $D$: $Q = Q'T$.

In order for the mapping to be accurate, $T$ must be able to encode many levels of relative importance among the possible translations of each element of $Q'$. A typical machine-readable bilingual dictionary says only what the possible translations are, which is equivalent to positing a uniform translational distribution. The performance of cross-language information retrieval with a uniform $T$ is likely to be limited in the same way as the performance of conventional information retrieval without term frequency information, i.e. where the system knows which terms occur in which documents, but not how often (Buckley, 1993).

Fully automatic high-quality machine translation is the prototypical application where word order is crucial. In such an application, a word-to-word translation model can serve as an independent module in a more complex string-to-string translation model. The independence of such a module is desirable for two reasons, one practical and one philosophical. The practical reason is illustrated in this article: Order-independent translation models can be accurately estimated more efficiently in isolation. The philosophical reason is that words are an important epistemological category in our naive mental representations of language. We have many intuitions (and even some testable theories) about what words are and how they behave. We can bring these intuitions to bear on our translation models without being distracted by other facets of language, such as phrase structure. For example, Chapter 9 of my dissertation is based on the intuition that words can have multiple senses (Melamed, 1998b); Brown et al. (1993)'s Model 3 and my work on non-compositional compounds (Melamed, 1997b) are based on the intuition that spaces in text do not necessarily delimit words.

The independence of a word-to-word translation module in a string-to-string translation model can be effected by a two-stage decomposition. The first stage is based on the observation that every string $S$ is just an ordered bag, and that the bag $B$ can be modeled independently of its order $O$. For example, the string $(abc)$ consists of the bag $\{c, a, b\}$ and the ordering relation $\{(b, 2), (a, 1), (c, 3)\}$.
If we represent each string \( S \) as a pair \((B, O)\), then

\[
\Pr(S) \equiv \Pr(B, O) \equiv \Pr(B) \cdot \Pr(O|B) \tag{1}
\]

Now, let \( S_1 \) and \( S_2 \) be two strings and let \( A \) be a one-to-one mapping between the elements of \( S_1 \) and the elements of \( S_2 \). Borrowing a term from the operations research literature, I shall refer to such mappings as assignments. Let \( \mathcal{A} \) be the set of all possible assignments between \( S_1 \) and \( S_2 \). Using assignments, we can decompose conditional and joint probabilities over strings:

\[
\Pr(S_1|S_2) = \sum_{A \in \mathcal{A}} \Pr(S_1, A|S_2) \tag{3}
\]

\[
\Pr(S_1, S_2) = \sum_{A \in \mathcal{A}} \Pr(S_1, A, S_2) \tag{4}
\]

where

\[
\Pr(S_1, A|S_2) \equiv \Pr(B_1, O_1, A|S_2) \equiv \Pr(B_1, A|S_2) \cdot \Pr(O_1|B_1, A, S_2) \tag{5}
\]

\[
\Pr(S_1, A, S_2) \equiv \Pr(B_1, O_1, A, B_2, O_2) \equiv \Pr(B_1, A, B_2) \cdot \Pr(O_1, O_2|B_1, A, B_2) \tag{7}
\]

The second stage of decomposition takes us from bags of words to the words that they contain. The following bag-pair generation process illustrates how a word-to-word translation model can be embedded in a bag-to-bag translation model for languages \( L_1 \) and \( L_2 \):

1. Generate a bag size \( b \) with probability \( Z(b) \) (mnemonic: \( Z \) is the size distribution). \( b \) is also the assignment size.

2. Generate \( b \) language-independent concepts \( C_1, \ldots, C_b \).

3. From each concept \( C_i \), \( 1 \leq i \leq b \), generate a pair of word strings \((\vec{u}_i, \vec{v}_i)\) from \( L_1^* \times L_2^* \), according to the distribution \( \text{trans}(\vec{u}, \vec{v}) \), to lexicalize the concept in the two languages. Some concepts are not lexicalized in some languages, so one of \( \vec{u}_i \) and \( \vec{v}_i \) may be empty.

A pair of bags containing \( m \) and \( n \) non-empty word strings can be generated by a process where \( b \) is anywhere between 1 and \( m + n \).

Without loss of generality, we can assume that each different pair of word string types \((\vec{u}, \vec{v})\) is deterministically generated from a different concept. Thus, a bag-to-bag translation model can be fully specified by the distributions \( Z \) and

---

2 Assignments are different from Brown et al. (1993)’s alignments in that assignments can range over pairs of arbitrary labels, not necessarily string position indexes. Also, unlike alignments, assignments must be one-to-one.
For notational convenience, the elements of the two bags can be labeled so that \( B_1 \equiv \{ \vec{u}_1, \ldots, \vec{u}_b \} \) and \( B_2 \equiv \{ \vec{v}_1, \ldots, \vec{v}_b \} \), where some of the \( \vec{u} \)'s and \( \vec{v} \)'s may be empty. The elements of an assignment, then, are pairs of bag element labels: \( A \equiv \{ (i_1, j_1), \ldots, (i_b, j_b) \} \), where each \( i \) ranges over \( \{ \vec{u}_1, \ldots, \vec{u}_b \} \), each \( j \) ranges over \( \{ \vec{v}_1, \ldots, \vec{v}_b \} \), each \( i \) is distinct and each \( j \) is distinct. The label pairs in a given assignment can be generated in any order, so there are \( b! \) ways to generate an assignment of size \( b \).

It follows that the probability of generating a pair of bags \((B_1, B_2)\) with a particular assignment \( A \) of size \( b \) is

\[
\Pr(B_1, A, B_2 | Z, \text{trans}) = Z(b) \cdot b! \prod_{(i,j) \in A} \text{trans}(\vec{u}_i, \vec{v}_j) \quad (9)
\]

The joint probability distribution \( \text{trans}(\vec{u}, \vec{v}) \) is a word-to-word translation model.

### 3 The One-to-One Assumption

The most general word-to-word translation model \( \text{trans}(\vec{u}, \vec{v}) \), where \( \vec{u} \) and \( \vec{v} \) range over the strings of \( L_1 \) and \( L_2 \), has an infinite number of parameters. This model can be constrained in various ways to make it more practical. The models presented in this article are based on the one-to-one assumption: Each word is translated to at most one other word. In these models, \( \vec{u} \) and \( \vec{v} \) may consist of at most one word each. As before, one of the two strings (but not both) may be empty. I shall describe empty strings as consisting of a special null word, so that each word string will contain exactly one word and can be treated as a scalar. Henceforth, I shall write \( u \) and \( v \) instead of \( \vec{u} \) and \( \vec{v} \). Under the one-to-one assumption, a pair of bags containing \( m \) and \( n \) non-empty words can be generated by a process where the bag size \( b \) is anywhere between \( \max(m, n) \) and \( m + n \).

The one-to-one assumption is not as restrictive as it may appear: The explanatory power of a model based on this assumption may be raised to an arbitrary level by redefining what words are. For example, I have shown elsewhere how to efficiently estimate word-to-word translation models where a word can be a non-compositional compound consisting of several space-delimited tokens (Melamed, 1997a). For the purposes of this article, however, words are the tokens generated by my tokenizers and stemmers for the languages in question. Therefore, the models in this article are only a first approximation to the vast complexities of translational equivalence. They are intended mainly as stepping stones towards better models.

### 4 Previous Work

Most methods for estimating translation models from bitexts start with the following intuition: Words that are translations of each other are more likely to
appear in corresponding bitext regions than other pairs of words. Following this intuition, most authors begin by counting the number of times that word types in one half of the bitext co-occur with word types in the other half. Different co-occurrence counting methods stem from different models of co-occurrence.

A model of co-occurrence is a boolean predicate, which indicates whether a given pair of word tokens co-occur in corresponding regions of the bitext space. Different models of co-occurrence are possible, depending on the kind of bitext map that is available, the language-specific information that is available, and the assumptions made about the nature of translational equivalence. All the translation models reviewed and introduced in this article can be based on any of the co-occurrence models described by Melamed (1998a). For expository purposes, however, I shall assume a boundary-based model of co-occurrence throughout this article. A boundary-based model of co-occurrence assumes that both halves of the bitext have been segmented into s segments, so that segment \( U_i \) in one half of the bitext and segment \( V_i \) in the other half are mutual translations, \( 1 \leq i \leq s \). Under this model of co-occurrence, the co-occurrence count \( \text{cooc}(u, v) \) for word types \( u \) and \( v \) is the number of times that \( u \in U_i \) and \( v \in V_i \) in some aligned segment pair \( i \).

### 4.1 Non-Probabilistic Translation Lexicons

Many researchers have proposed greedy algorithms for estimating non-probabilistic word-to-word translation models, also known as translation lexicons (e.g. Cattelzone et al., 1993; Gale & Church, 1991; Fung, 1995; Kumano & Hirakawa, 1994; Melamed, 1995; Wu & Xia, 1995). Most of these algorithms can be summarized as follows:

1. Choose a similarity function \( S \) between word types in \( L_1 \) and word types in \( L_2 \).
2. Compute association scores \( S(u, v) \) for a set of word type pairs \( (u, v) \in (L_1 \times L_2) \) that occur in training data.
3. Sort the word pairs in descending order of their association scores.
4. Discard all word pairs for which \( S(u, v) \) is less than a chosen threshold \( t \). The remaining word pairs become the entries in the translation lexicon.

The various proposals differ mainly in their choice of similarity function. Almost all the similarity functions in the literature are based on a model of co-occurrence with some linguistically-motivated filtering (see Fung, 1995 for a notable exception).

Given a reasonable similarity function, the greedy algorithm works remarkably well, considering how simple it is. However, the association scores in Step 2 are typically computed independently of each other. The problem with this independence assumption is illustrated in Figure 1. The two strings represent corresponding regions of a bitext. If \( q \) and \( v \) co-occur much more often than expected
by chance, then any reasonable similarity metric will deem them likely to be mutual translations. If \(q\) and \(v\) are indeed mutual translations, then their tendency to co-occur is called a \textit{direct association}. Now, suppose that \(q\) and \(r\) often co-occur within their language. Then \(v\) and \(r\) will also co-occur more often than expected by chance. The arrow between \(v\) and \(r\) in Figure 1 represents an \textit{indirect association}, since the association between \(v\) and \(r\) arises only by virtue of the association between each of them and \(q\). Models of translational equivalence that are ignorant of indirect associations have “a tendency . . . to be confused by collocates” (Dagan et al., 1993).

Paradoxically, the irregularities (noise) in text and in translation mitigate the problem. If noise in the data reduces the strength of a direct association, then the same noise will reduce the strengths of any indirect associations that are based on this direct association. On the other hand, noise can reduce the strength of an indirect association without affecting any direct associations. Therefore, direct associations are usually stronger than indirect associations. If all the entries in a translation lexicon are sorted by their association scores, the direct associations will be very dense near the top of the list, and sparser towards the bottom.

\textbf{Gale & Church (1991)} have shown that entries at the very top of the list can be over 98% correct. Their algorithm gleaned lexicon entries for about 61% of the word tokens in a sample of 800 English sentences. To obtain 98% precision, their algorithm selected only entries for which it had high confidence that the association score was high. These would be the word pairs that co-occur most frequently. A random sample of 800 sentences from the same corpus showed that 61% of the word tokens, where the tokens are of the most frequent types, represent 4.5% of all the word types. A similar strategy was employed by \textbf{Wu & Xia (1995)} and by \textbf{Fung (1995)}.

Fung skimmed off the top 23.8% of the noun-noun entries in her lexicon to achieve a precision of 71.6%. Wu & Xia have reported automatic acquisition of 6517 lexicon entries from a 3.3-million-word corpus, with a precision of 86%. The first 3.3 million word tokens in an English corpus from a similar genre contained 33490 different word types, suggesting a recall of roughly 19%.

\footnote{These two results should not be judged on the same scale, because it is arguably more difficult to construct translation lexicons between English and Chinese than between English and French.}
Note, however, that Wu & Xia chose to weight their precision estimates by the probabilities attached to each entry:

For example, if the translation set for English word *detect* has the two correct Chinese candidates with 0.533 probability and with 0.277 probability, and the incorrect translation with 0.190 probability, then we count this as 0.810 correct translations and 0.190 incorrect translations. (Wu & Xia, 1995, p. 211)

This is a reasonable evaluation method, but it is not comparable to methods that simply count each lexicon entry as either right or wrong (e.g. Daille et al. 1994; Melamed, 1996b). A weighted precision estimate pays more attention to entries that are more frequent and hence easier to estimate. Therefore, weighted precision estimates are generally higher than unweighted ones.

### 4.2 Re-estimated String-to-String Translation Models

Most translation model re-estimation algorithms published to date are variations on the theme proposed by Brown et al. (1993). These models involve conditional probabilities, but they can be compared to symmetric models based on joint probabilities if the latter are normalized by the appropriate marginal distribution. I shall review these models using the notation in Table 1.

| \((U, V)\) | the two halves of the bitext |
| --- | --- |
| \((U, V)\) | a pair of aligned text segments in \((U, V)\) |
| \(e(u)\) | the frequency of \(u\) in \(U\) |
| \(f(v)\) | the frequency of \(v\) in \(V\) |
| \(\text{cooc}(u, v)\) | the number of times that \(u\) and \(v\) co-occur |
| \(\text{links}(u, v)\) | the number of times that \(u\) and \(v\) are hypothesized to co-occur as mutual translations |
| \(\text{trans}(v|u)\) | the probability that a token of \(u\) will be translated as a token of \(v\) |

Table 1

Variables used to describe translation models.

Methods for estimating translation parameters from co-occurrence counts invariably involve **link counts** \(\text{links}(u, v)\), which represent hypotheses about the number of times that \(u\) and \(v\) were generated together from the same language-independent concept, for each \(u\) and \(v\) in the bitext. A **link token** is an ordered pair of word tokens, one from each half of the bitext. A **link type** is an ordered pair of word types. The link counts \(\text{links}(u, v)\) range over link types.

#### 4.2.1 Models Using Only Co-occurrence Information

Brown et al.’s Model 1 is estimated from co-occurrence information only, using the Expectation-Maximization (EM) algorithm (Dempster et al., 1977).

E step:

\[
\text{links}(u, v) = \frac{\text{trans}(v|u)}{\sum_{u' \in U} \text{trans}(v|u')} e(u) \cdot f(v) 
\]  (10)
M step:

\[ trans(v|u) = \frac{\text{links}(u, v)}{\sum_{u'} \text{links}(u', v)} \]  

(11)

It is instructive to consider the form of Equation 10 when all the translation probabilities \( trans(v|u) \) for a particular \( u \) are initialized to the same constant \( p \), as Brown et al. (1993, p. 273) actually do:

\[ \text{links}(u, v) = \sum_{(U,V) \in (U,V)} p \cdot e(u) \cdot f(v) \cdot \frac{1}{\text{length}(U)} \]  

(12)

\[ = \sum_{(U,V) \in (U,V)} e(u) \cdot f(v) \cdot \frac{1}{\text{length}(U)} \]  

(13)

The initial link count for each \((u, v)\) pair is set proportional to the co-occurrence count of \( u \) and \( v \) and inversely proportional to the length of each segment \( U \) in which \( u \) occurs. The intuition behind the numerator is central to most bitext-based translation models: The more often two words co-occur, the more likely they are to be mutual translations. The intuition behind the denominator is that the co-occurrence count of \( u \) and \( v \) should be discounted to the degree that \( v \) also co-occurs with other words in the same segment pair.

Now consider how Equation 13 would behave under a distance-based model of co-occurrence (Melamed, 1998a), where each token of \( v \) co-occurs with exactly \( c \) words (where \( c \) is constant):

\[ \text{links}(u, v) = \sum_{(U,V) \in (U,V)} \frac{e(u) \cdot f(v)}{c} \]  

(14)

\[ = \frac{1}{c} \sum_{(U,V) \in (U,V)} e(u) \cdot f(v) \]  

(15)

The discount factor \( \frac{1}{c} \) disappears in the M step. The only difference between Equations 13 and 14 is that the former discounts co-occurrences proportionally to the segment lengths. When information about segment lengths is not available, Model 1’s initial parameters boil down to co-occurrence counts.

4.2.2 Word Order Correlation Biases In any bitext, the positions of words with respect to the true bitext map correlate with the positions of their translations. The correlation is stronger for language pairs with more similar word order. Brown et al. (1988) introduced the idea that this correlation can be encoded in translation model parameters. Dagan et al. (1993) expanded on this idea by replacing Brown et al.’s word alignment parameters, which were based on absolute word positions in aligned segments, with a much smaller set of relative offset parameters. The much smaller number of parameters allowed Dagan et al.’s model to be effectively trained on much smaller bitexts. Vogel et al. (1996) have shown how some additional independence assumptions can turn this model into a Hidden Markov Model, enabling even more efficient parameter estimation.
It cannot be overemphasized that the word order correlation bias is just knowledge about the problem domain, which can be used to guide the search for the optimum model parameters. Translational equivalence can be empirically modeled for any pair of languages, but some models and model biases work better for some language pairs than for others. The word order correlation bias is most useful when it has high predictive power, i.e. when the distribution of alignments or offsets has low entropy. The entropy of this distribution is indeed relatively low for the language pair that both Brown et al. and Dagan et al. were working with — French and English have very similar word order. A word order correlation bias would be of less benefit with noisier training bitexts or for language pairs with less similar word order. The same is true of the phrase structure biases in Brown et al. (1993)’s Models 4 and 5.

4.3 Re-estimated Bag-to-Bag Translation Models

At about the same time that I developed the models in this article, Hiemstra (1996) independently developed his own bag-to-bag model of translational equivalence. His model is also based on a one-to-one assumption, but it differs from my models in that it does not allow empty words to be generated. i.e., it assumes that the two bags in each pair contain the same number of words. His estimation method is also different in that it does not impose any structure on the hidden parameters: Whereas my estimation methods revolve around assignments (see Equation 4), Hiemstra has modeled pairs of word bags as a multinomial over the crossproduct of two vocabularies. Maximum likelihood parameter estimation is computationally too expensive for Hiemstra’s model, so he proposed the Iterative Proportional Fitting Procedure (IPFP) (Demming & Stephan, 1940) as a cheaper approximation method.

The IPFP is quite sensitive to initial conditions, so Hiemstra investigated a number of initialization options. Choosing the most advantageous, Hiemstra has published parts of the translational distributions of certain words, induced using both his method and Brown et al. (1993)’s Model 1 from the same training bitext. Subjective comparison of these examples suggests that Hiemstra’s method is more accurate. Hiemstra (1998) has also evaluated the recall and precision of his method and of Model 1 on a small hand-constructed set of link tokens in a particular bitext. Model 1 fared worse, on average.

5 Parameter Estimation

This section describes my methods for estimating the translation parameters of a symmetric word-to-word translation model from a bitext. For most applications, we are interested in estimating the probability \(\text{trans}(u, v)\) of generating the pair of words \((u, v)\). For estimation purposes, however, it is more convenient to deal with likelihoods \(\text{like}(u, v)\), the likelihood that \(u\) and \(v\) can ever be mutual translations, i.e. that there exists some context where tokens \(u\) and \(v\) are generated from the same concept. There are various possible definitions for \(\text{like}(u, v)\) and the relationship between \(\text{like}(u, v)\) and \(\text{trans}(u, v)\) can be more or less direct,
depending on the model. The maximum likelihood estimate of $\text{trans}(\mathbf{u}, \mathbf{v})$ can always be derived by normalizing the link counts so that $\sum_{\mathbf{u}, \mathbf{v}} \text{trans}(\mathbf{u}, \mathbf{v}) = 1$:

$$\text{trans}(\mathbf{u}, \mathbf{v}) = \frac{\text{links}(\mathbf{u}, \mathbf{v})}{\sum_{\mathbf{u}', \mathbf{v}'} \text{links}(\mathbf{u}', \mathbf{v}')}$$ (16)

Link counts, and therefore also the translation parameters $\text{trans}(\mathbf{u}, \mathbf{v})$, cannot be directly observed in a training bitext, because we don’t know which words in one half of the bitext were generated together with which words in the other half. The observable features of the bitext are only the co-occurrence counts $\text{cooc}(\mathbf{u}, \mathbf{v})$ (see Section 4). All my methods for estimating the translation parameters $\text{trans}(\mathbf{u}, \mathbf{v})$ from the co-occurrence counts $\text{cooc}(\mathbf{u}, \mathbf{v})$ share the following general outline:

1. Initialize the model parameters to a first approximation.
2. Estimate the link counts $\text{links}(\mathbf{u}, \mathbf{v})$, as a function of the model parameters and the co-occurrence counts.
3. Estimate the model parameters $\text{like}(\mathbf{u}, \mathbf{v})$, as a function of the link counts and the co-occurrence counts.
4. Repeat from Step 2, until the model converges to the desired degree. I have adopted the simple heuristic that the model has converged when less than .0001 of the $\text{trans}(\mathbf{u}, \mathbf{v})$ distribution changes from one iteration to the next.
5. Compute the maximum likelihood estimate (MLE) of $\text{trans}(\mathbf{u}, \mathbf{v})$, by normalizing the converged link counts as in Equation [16].

Under certain conditions, a parameter estimation process of this sort is an instance of the Expectation-Maximization (EM) algorithm (Dempster et al., 1977). As explained below, meeting these conditions is computationally too expensive for my models. Therefore, I employ some approximations, which lack the EM algorithm’s convergence guarantee.

The maximum likelihood approach to estimating the unknown parameters is to find the set of parameters $\hat{\Theta}$ that maximize the probability of the training bitext $(\mathbf{U}, \mathbf{V})$.

$$\hat{\Theta} = \arg \max_{\Theta} \Pr(\mathbf{U}, \mathbf{V}|\Theta)$$ (17)

where the probability of the bitext is a weighted sum over the distribution $\mathcal{A}$ of possible assignments:

$$\Pr(\mathbf{U}, \mathbf{V}|\Theta) = \sum_{\mathcal{A} \in \mathcal{A}} \Pr(\mathbf{U}, \mathcal{A}, \mathbf{V}|\Theta).$$ (18)

The MLE method is infeasible, because the number of possible assignments grows exponentially with the size of the bitext. Due to the parameter interdependencies introduced by the one-to-one assumption, we cannot decompose the assignments into parameters that can be estimated independently of each other (as in
Melamed
Models of Translational Equivalence

Brown et al., 1993, Equation 26). This is why we must make do with approximations to the EM algorithm.

In this situation, Brown et al. (1993, p. 293) recommend “evaluating the expectations using only a single, probable alignment.” The single most probable assignment \( A_{\text{max}} \) is called the Viterbi assignment:

\[
A_{\text{max}} = \arg \max_{A \in A} \Pr(U, A, V | \Theta)
\]  
(19)

\[
= \arg \max_{A \in A} Z(b) \cdot b! \prod_{(x,y) \in A} \text{trans}(u_x, v_y)
\]  
(20)

\[
= \arg \max_{A \in A} \log \left( Z(b) \cdot b! \prod_{(x,y) \in A} \text{trans}(u_x, v_y) \right)
\]  
(21)

\[
= \arg \max_{A \in A} \left\{ \log[Z(b) \cdot b!] + \sum_{(x,y) \in A} \log \text{trans}(u_x, v_y) \right\}
\]  
(22)

To simplify things further, let us assume that \( Z(b) \cdot b! \) is constant, so that

\[
A_{\text{max}} = \arg \max_{A \in A} \sum_{(x,y) \in A} \log \text{trans}(u_x, v_y)
\]  
(23)

If we represent the bitext as a bipartite graph and weight the edges by \( \log \text{trans}(u, v) \), then the right-hand side of Equation 23 is an instance of the weighted maximum matching problem and \( A_{\text{max}} \) is its solution. For a bipartite graph \( G = (V_1 \cup V_2, E) \), with \( v = |V_1 \cup V_2| \) and \( e = |E| \), the lowest currently known upper bound on the computational complexity of this problem is \( O(ve + v^2 \log v) \) (Ahuja et al., 1993, p. 500). Although this upper bound is polynomial, it is still too expensive for typical bitexts. The next subsection describes a greedy approximation to the Viterbi approximation.

5.1 Method A: The Competitive Linking Algorithm

5.1.1 Step 1: Initialization

Almost every published translation model estimation algorithm exploits the well-known correlation between the link likelihoods \( \text{like}(u, v) \) and the co-occurrence counts \( \text{cooc}(u, v) \). As discussed in Section 3, many algorithms also normalize the correlation by the marginal frequencies of \( u \) and \( v \). However, these quantities account for only three of the cells in the following contingency table:

|          | u     | ¬u    | Total       |
|----------|-------|-------|-------------|
| v        | \( \text{cooc}(u, v) \) | \( \text{cooc}(¬u, v) \) | \( \text{cooc}(\cdot, v) \) |
| ¬v       | \( \text{cooc}(u, ¬v) \) | \( \text{cooc}(¬u, ¬v) \) | \( \text{cooc}(\cdot, ¬v) \) |
| Total    | \( \text{cooc}(u, \cdot) \) | \( \text{cooc}(¬u, \cdot) \) | \( \text{cooc}(\cdot, \cdot) \) |

The statistical interdependence between two word types can be estimated more robustly by considering the whole table. For example, Gale & Church (1991)
suggest that “φ^2, a χ^2-like statistic, seems to be a particularly good choice because it makes good use of the off-diagonal cells” of the contingency table. In informal experiments reported elsewhere (Melamed, 1995), I found that the G^2 statistic suggested by Dunning (1993) slightly outperforms φ^2. Let the cells of the contingency table be named as follows:

|   | u | ¬u |
|---|---|----|
| v | a | b  |
| ¬v| c | d  |

Now, \[ G^2(u, v) = -2 \log \frac{B(a|a+b, p_1)B(c|c+d, p_2)}{B(a|a+b, p)B(c|c+d, p)} \] (24)

where \( B(k|n, p) = \binom{n}{k} p^k (1-p)^{n-k} \) are binomial probabilities. The statistic uses maximum likelihood estimates for the probability parameters: \( p_1 = \frac{a}{a+b} \), \( p_2 = \frac{c}{c+d} \), \( p = \frac{a+b}{a+b+c+d} \). G^2 is easy to compute because the binomial coefficients cancel out. All my methods initialize the model parameters like \((u, v)\) to \(G^2(u, v)\), except that the likelihood of any word being linked to NULL is initialized to an infinitesimal value. I have also found it useful to smooth the co-occurrence counts using the Simple Good-Turing smoothing method (Gale & Sampson, 1995) before computing \(G^2\).

### 5.1.2 Step 2: Estimation of Link Counts
To further reduce the complexity of estimating the model parameters, I employ the competitive linking algorithm, which is a greedy approximation to the Viterbi approximation:

1. Sort all the translation likelihood estimates like \((u, v)\) from highest to lowest.

2. For each likelihood estimate like \((u, v)\), in order:

   (a) If \(u\) (resp., \(v\)) is NULL, consider all tokens of \(v\) (resp., \(u\)) in the bitext linked to NULL. Otherwise, link all co-occurring token pairs \((u, v)\) in the bitext.

   (b) The one-to-one assumption implies that linked words cannot be linked again. Therefore, remove all linked word tokens from their respective halves of the bitext.

The competitive linking algorithm can be viewed as a heuristic search for the most likely assignment in the space of all possible assignments. The search heuristic is that the most likely assignments contain links that are individually the most likely. The search proceeds by a process of elimination. In the first search iteration, all the assignments that do not contain the most likely link are discarded. In the second iteration, all the assignments that do not contain the second most likely
link are discarded, and so on until only one assignment remains. The algorithm greedily selects the most likely links first, and then selects less likely links only if they don’t conflict with previous selections. The probability of a link being rejected increases with the number of links that are selected before it, and thus decreases with the link’s likelihood. In this problem domain, the competitive linking algorithm usually finds one of the most likely assignments, as I will show in Section 5. Under an appropriate hashing scheme, the expected running time of the competitive linking algorithm is linear in the size of the input bitext.

5.1.3 Step 3: Re-estimation of the Model Parameters Method A re-estimates the model parameters simply by normalizing the link counts to sum to 1 as in Equation 16. The competitive linking algorithm only cares about the relative magnitudes of the various $\text{like}(u,v)$. However, Equation 14 is a sum rather than a product, so I scale the parameters logarithmically, to be consistent with its probabilistic interpretation:

$$\text{like}(u,v) = \log \text{trans}(u,v)$$ (25)

5.2 Method B: Improved Estimation Using an Explicit Error Model

Yarowsky (1993) has shown that “for several definitions of sense and collocation, an ambiguous word has only one sense in a given collocation with a probability of 90-99%.” In other words, a single contextual clue can be a highly reliable indicator of a word’s sense. One of the definitions of “sense” studied by Yarowsky was a word token’s translation in the other half of a bitext. For example, the English word sentence may be considered to have two senses, corresponding to its French translations peine (judicial sentence) and phrase (grammatical sentence). If a token of sentence occurs in the vicinity of a word like jury or prison, then it is far more likely to be translated as peine than as phrase. “In the vicinity of” is one kind of collocation. Co-occurrence in bitext space is another kind of collocation. If each word’s translation is treated as a sense tag (Resnik & Yarowsky, 1997), then “translational” collocations have the unique property that the collocate and the word sense are one and the same!

Method B exploits this property under the hypothesis that “one sense per collocation” holds for translational collocations. This hypothesis implies that if $u$ and $v$ are possible mutual translations, and a token $u$ co-occurs with a token $v$ in the bitext, then with very high probability the pair $(u, v)$ was generated from the same concept and should be linked. To test this hypothesis, I ran one iteration of Method A on 300000 aligned sentence pairs from the Canadian Hansards bitext. I then plotted the ratio $\frac{\text{links}(u,v)}{\text{cooc}(u,v)}$ for several values of $\text{cooc}(u,v)$ in Figure 2. The bimodality of the surface shows that the ratio $\frac{\text{links}(u,v)}{\text{cooc}(u,v)}$ tends to be either very

---

5 Given a method of assigning probabilities to assignments, the competitive linking algorithm can be generalized to stop searching before the number of possible assignments is reduced to one, at which point the link counts can be computed as weighted averages over the remaining assignments using Equation 18.
high or very low. Note that the frequencies are plotted on a log scale — the bimodality is quite sharp.

Information about how often words co-occur without being linked can be used to bias the estimation of translation model parameters. The smaller the ratio \( \frac{\text{links}(u,v)}{\text{cooc}(u,v)} \), the more likely it is that \( u \) and \( v \) are not mutual translations, and that links posited between tokens of \( u \) and \( v \) are noise. The bias can be implemented via auxiliary parameters that model the curve illustrated in Figure 2. The competitive linking algorithm creates all the links of a given type independently. So, the distribution of the number \( \text{links}(u,v) \) of links connecting word types \( u \) and \( v \) can be modeled by a binomial distribution with parameters \( \text{cooc}(u,v) \) and \( p(u,v) \). \( p(u,v) \) is the probability that \( u \) and \( v \) will be linked when they co-occur. There is never enough data to robustly estimate each \( p \) parameter separately. Instead, I shall model the \( p \)'s via only two distinct parameters. If \( u \) and \( v \) are mutual translations, then \( p(u,v) \) will average to a relatively high probability, which I will call \( \lambda^+ \). If \( u \) and \( v \) are not mutual translations, then \( p(u,v) \) will average to a relatively low probability, which I will call \( \lambda^- \). \( \lambda^+ \) and \( \lambda^- \) correspond to the two peaks of the distribution of \( \frac{\text{links}(u,v)}{\text{cooc}(u,v)} \), a fragment of which is illustrated in Figure 2. The two parameters can also be interpreted as the rates of true and false positives. If the translation in the bitext is consistent and the translation model is accurate, then \( \lambda^+ \) will be close to 1 and \( \lambda^- \) will be close to 0.

---

6 Except for the case when multiple tokens of the same word type occur near each other, which I hereby sweep under the carpet.
To find the most likely values of the auxiliary parameters $\lambda^+$ and $\lambda^-$, I adopt the standard method of maximum likelihood estimation, and find the values that maximize the probability of the link frequency distributions, under the usual independence assumptions, where

$$
\Pr(\text{links}|\text{model}) = \prod_{u,v} \Pr(\text{links}(u,v)|\text{cooc}(u,v), \lambda^+, \lambda^-).
$$

(26)

The factors on the right-hand side of Equation 26 can be written explicitly with the help of a mixture coefficient. Let $\tau$ be the probability that an arbitrary co-occurring pair of word types are mutual translations. Let $B(k|n,p)$ denote the probability that $k$ links are observed out of $n$ co-occurrences, where $k$ has a binomial distribution with parameters $n$ and $p$. Then the probability that two arbitrary word types $u$ and $v$ are linked $\text{links}(u,v)$ times out of $\text{cooc}(u,v)$ co-occurrences is a mixture of two binomials:

$$
\Pr(\text{links}(u,v)|\text{cooc}(u,v), \lambda^+, \lambda^-) = \tau B(\text{links}(u,v)|\text{cooc}(u,v), \lambda^+)
+ (1-\tau) B(\text{links}(u,v)|\text{cooc}(u,v), \lambda^-).
$$

(27)

One more variable allows us to express $\tau$ in terms of $\lambda^+$ and $\lambda^-$. Let $\lambda$ be the probability that an arbitrary co-occuring pair of word tokens will be linked, regardless of whether they are mutual translations. Since $\tau$ is constant over all word types, it also represents the probability that an arbitrary co-occurring pair of word tokens are mutual translations. Therefore,

$$
\lambda = \tau \lambda^+ + (1-\tau) \lambda^-.
$$

(28)

$\lambda$ can also be estimated empirically. Let $K$ be the total number of links in the bitext and let $N$ be the total number of co-occurring word token pairs:

$$
K = \sum_{u,v} \text{links}(u,v),
$$

(29)

$$
N = \sum_{u,v} \text{cooc}(u,v).
$$

(30)

By definition,

$$
\lambda = K/N.
$$

(31)

Equating the right-hand sides of Equations 28 and 31 and rearranging the terms, we get:

$$
\tau = \frac{K/N - \lambda^-}{\lambda^+ - \lambda^-}.
$$

(32)

Since $\tau$ is now a function of $\lambda^+$ and $\lambda^-$, only the latter two variables represent degrees of freedom in the model.

The probability function expressed by Equations 26 and 27 may have many local maxima. In practice, these local maxima are like pebbles on a mountain, invisible at low resolution. I computed Equation 26 over various combinations
of $\lambda^+$ and $\lambda^-$ after one iteration over 300000 aligned sentence pairs from the Canadian Hansard bitext. Figure 3 illustrates that the region of interest in the parameter space, where $1 > \lambda^+ > \lambda > \lambda^- > 0$, has only one dominant global maximum. This global maximum can be found by standard hill-climbing methods, as long as the step size is large enough to avoid getting stuck on the pebbles.

Given estimates for $\lambda^+$ and $\lambda^-$, we can compute $B(\text{links}(u, v)|\text{cooc}(u, v), \lambda^+)$ and $B(\text{links}(u, v)|\text{cooc}(u, v), \lambda^-)$ for each occurring combination of $\text{links}$ and $\text{cooc}$ values. These are the probabilities that $\text{links}(u, v)$ links were generated out of $\text{cooc}(u, v)$ possible links by a process that generates correct links and by a process that generates incorrect links, respectively. The ratio of these probabilities is the likelihood ratio in favor of the types $u$ and $v$ being possible mutual translations, for all $u$ and $v$:

$$\text{like}(u, v) = \log \frac{B(\text{links}(u, v)|\text{cooc}(u, v), \lambda^+)}{B(\text{links}(u, v)|\text{cooc}(u, v), \lambda^-)}. \quad (33)$$

In the preceding equations, either $u$ or $v$ can be NULL. However, the number of times that a word co-occurs with NULL is not an observable feature of bitexts. To make sense of co-occurrences with NULL, we can view co-occurrences as potential links and $\text{cooc}(u, v)$ as the maximum number of times that tokens of $u$ and $v$ might be linked. From this point of view, $\text{cooc}(u, \text{NULL})$ should be set to the marginal frequency of $u$, since each token of $u$ represents one potential link to NULL. These co-occurrence counts should be summed together with all the others in Equation 30.

Method B differs from Method A only in its use of the auxiliary parameters in Equation 33 to re-estimate the model parameters. These parameters and the error model that they represent can be employed the same way in translation models that are not based on the one-to-one assumption. An interesting property of Equation 33 is that it is possible, for a given word type $u$, that $\text{like}(u, v) < 0$.
for all $v$ including NULL. These are the words about which the model is uncertain, and they represent fertile ground for future work.

**5.3 Method C: Improved Estimation Using Pre-Existing Word Classes**

In Method B, the estimation of the auxiliary parameters $\lambda^+$ and $\lambda^-$ depends only on the co-occurrence counts and on the distributions of link frequencies generated by the competitive linking algorithm. All word pairs that co-occur the same number of times and are linked the same number of times are assigned the same like value. More accurate models can be induced by taking into account various features of the linked tokens. For example, frequent words are translated less consistently than rare words (Melamed, 1997a). To account for these differences, we can estimate separate values of $\lambda^+$ and $\lambda^-$ for different ranges of $\text{cooc}(u,v)$. Similarly, the auxiliary parameters can be conditioned on the linked parts of speech. A kind of word order correlation bias can be effected by conditioning the auxiliary parameters on the relative positions of linked word tokens in their respective texts. Just as easily, we can model link types that coincide with entries in an on-line bilingual dictionary separately from those that do not (cf. Brown et al., 1994). When the auxiliary parameters are conditioned on different link classes, Step 3 of Method B is repeated for each link class.

**6 Effects of Sparse Data**

The one-to-one assumption is a potent weapon against the ever-present sparse data problem. The assumption enables accurate estimation of translational distributions even for words that occur only once, as long as the surrounding words are more frequent. In most translation models, link likelihood is correlated with co-occurrence frequency. So, links between tokens $u$ and $v$ for which $\text{like}(u,v)$ is highest are the ones for which there is the most evidence, and thus also the ones that are easiest to predict correctly. Winner-take-all link assignment methods, such as the competitive linking algorithm, can prevent links based on indirect associations (see Section 1.1), thereby leveraging their accuracy on the more confident links to raise the accuracy of the less confident links. For example, suppose that $u_1$ and $u_2$ co-occur with $v_1$ and $v_2$ in the training data, and the model estimates $\text{like}(u_1,v_1) = .05, \text{like}(u_1,v_2) = .02,$ and $\text{like}(u_2,v_2) = .01$. According to the one-to-one assumption, $(u_1,v_2)$ is an indirect association and the correct translation of $v_2$ is $u_2$. To the extent that the one-to-one assumption is valid, it reduces the probability of spurious links for the rarer words. The more the incorrect candidate translations can be eliminated for a given rare word, the more likely the correct translation is to be found. So, the probability of a correct match for a rare word is proportional to the fraction of words around it that can be linked with higher confidence. This fraction is largely determined by two bitext properties: the distribution of word frequencies, and the distribution of co-occurrence counts. I shall explore each of these properties in turn.

The distribution of word frequencies is a function of corpus size. The words in any text corpus are drawn from a large but finite vocabulary. As the corpus
gets larger, fewer new words appear, and the average frequency of words already in the corpus rises. I took random samples of varying sizes from large text corpora in French and in English. The corpora comprised news text (Le Monde and Wall Street Journal), parliamentary debate transcripts (Hansards) and Sun Microsystems software documentation (AnswerBooks). Figure 4 shows the log-log relationship between corpus size and the proportion of singletons.

**Figure 4**
The log-log relationship between corpus size and the proportion of singletons.

The log-log relationship between sample size and the fraction of words (by token) that appear in the sample only once. For example, suppose we draw a random sample of one million words from Le Monde, and then select a random word type \( w \) from this random sample. According to Figure 4, the chances are roughly 0.017 that \( w \) appears only once in that one million words. If the sample were only one thousand words, however, our chances of drawing a singleton rise to 0.317. The nearly linear shape of the log-log curve seems largely invariant across languages and text genres, as predicted by Zipf (1936). Some curves in the graph are higher than others, because the language genres from which the corpora were drawn have richer vocabularies. For example, the fraction of singleton words is consistently smaller in the stemmed English Hansards than in the same text when it is not stemmed, which is the whole motivation for stemming. Figure 5, based on Le Monde text, shows that the log-log relationship holds for higher frequencies too. In a larger corpus, a larger fraction of the word types appear more frequently.

Corpus size determines the probability that a randomly chosen word will have a particular frequency. The likelihood of a correct link for a rare word token \( w \) also depends on one other variable. If \( w \) co-occurs with only one other rare word
Figure 5
The log-log relationship for higher frequencies. The bottom curve in this graph is the same as the top curve in Figure 4.

(in the opposite half of the bitext), then the competitive linking algorithm is likely to eliminate all of w’s indirect associations before it attempts to link w. Problems arise only when more than one candidate remains for linking to w. What is the probability that w co-occurs with more than one rare word? The analysis is easiest under the distance-based model of co-occurrence, where the threshold δ on the distance from the bitext map is specified in words rather than in characters (Melamed, 1998a). Suppose that w co-occurs with γ words in the opposite half of the bitext, where γ is either the vertical or horizontal component of δ. Let p be the probability that a word co-occurring with w is rare. Then the probability of exactly k rare words co-occurring with w can be approximated by a binomial distribution with parameters γ and p. It follows that the probability of more than one rare word co-occurring with w is

\[ \Pr(>1 \text{ rare word co-occurring}) = 1 - B(0|\gamma, p) - B(1|\gamma, p). \]  

(34)

Figure 6 plots Equation 34 over different values of γ and p. The range of p corresponds roughly to the range of the y-axis in Figures 4 and 5. The figure illustrates how the power of the one-to-one assumption varies with corpus size.

\footnote{\textit{I.e.} γ is the same as Dagan \textit{et al.} (1993)’s window width.}
7 Evaluation

7.1 Evaluation By Token
This section compares translation model estimation methods A, B and C to each other and to Brown et al. (1993)’s Model 1. Until now, translation models have been evaluated either subjectively (e.g. White & O’Connell, 1993) or using relative metrics, such as perplexity with respect to other models (Brown et al., 1993). More objective and more accurate tests can be carried out using a “gold standard.” I hired bilingual annotators to link roughly sixteen thousand corresponding words between on-line versions of the Bible in French and English. This bitext was selected to facilitate widespread use and standardization (see Melamed, 1998d, for details). The entire Bible bitext comprised 29614 verse pairs, of which 250 verse pairs were hand-linked using a specially developed annotation tool. The annotation style guide (Melamed, 1998c) was based on the intuitions of the annotators, so it was not biased towards any particular translation model. The annotation was carried out 5 times by different annotators.

A straightforward metric for evaluating a translation model with respect to a gold standard can be derived from the recall and precision measures widely used in the information retrieval literature. When comparing a set of “test” elements $X$ to a set of “correct” elements $Y$,

$$\text{precision}(X|Y) = \frac{|X \cap Y|}{|X|},$$

$$\text{recall}(X|Y) = \frac{|X \cap Y|}{|Y|}.$$
X and Y can be fuzzy sets, such as probability distributions, in which case \(|X|\) is defined as the sum of the weights of the elements in X and \(|X \cap Y|\) is the sum of the weights of the elements shared by X and Y.

Equations 35 and 36 differ only in the set whose size is used as the denominator. If neither X nor Y is privileged, or if precision and recall are equally important, we can compute a symmetric measure of agreement \(D\) as the harmonic mean of precision and recall:

\[
D(X, Y) = \frac{2 \cdot |X \cap Y|}{|X| + |Y|},
\]

Equation 37

\(D\) is the set-theoretic equivalent of the Dice coefficient (Dice, 1945) and conveniently ranges from zero to one.

To reiterate, Model 1 is based on co-occurrence information only; Method A is based on the one-to-one assumption; Method B adds the “one sense per collocation” hypothesis to Method A; Method C conditions the auxiliary parameters of Method B on various word classes. Whereas Methods A and B and Model 1 were fully specified in Section 4.2.1 and Section 5, the latter section described a variety of features on which Method C might classify words. For the purposes of the experiments reported in this article, Method C employed the simple classification in Table 2 for both languages in the bitext. All classification was performed by table lookup; no context-aware part-of-speech tagger was used. In particular, words that were ambiguous between open classes and closed classes were always deemed to be in the closed class. The only language-specific knowledge involved in this classification method is the list of function words in class F. Certainly, more sophisticated word classification methods could produce better models, but even the simple classification in Table 2 should suffice to demonstrate the method’s potential.

Each of the four methods was used to estimate a word-to-word translation model from the 29614 verse pairs in the Bible bitext. All methods were deemed to have converged when less than .0001 of the translational probability distribution changed from one iteration to the next. The links assigned by each of methods A, B and C in the last iteration were normalized into joint probability distributions using Equation 16. I shall refer to these joint distributions as Model A, Model B and Model C, respectively. Each of the joint probability distributions was further

| Class Code | Description                  |
|------------|------------------------------|
| EOS        | End-Of-Sentence punctuation |
| EOP        | End-Of-Phrase punctuation, such as commas and colons |
| SCM        | Subordinate Clause Markers, such as ” and ( |
| SYM        | Symbols, such as ” and * |
| NU         | the NULL word, in a class by itself |
| C          | Content words: nouns, adjectives, adverbs, non-auxiliary verbs |
| F          | all other words, i.e. function words |

Table 2

Word classes used by Method C for the experiments reported in this article.
normalized into two conditional probability distributions, one in each direction. Since Model 1 is inherently directional, its conditional probability distributions were estimated separately in each direction, instead of being derived from a joint distribution.

The four models' predictions were compared to the gold standard annotations. Although the models were evaluated on part of the same bitext on which they were trained, the evaluations were with respect to the translational equivalence relation hidden in this bitext, not with respect to any of the bitext's visible features. Such testing on training data is acceptable for unsupervised learning algorithms.

Before comparing the accuracies of the different models, it is interesting to consider their convergence rates. Figure 7 shows that, although the EM algorithm guarantees monotonic convergence for Model 1, it requires more iterations to converge on these training data than models A, B and C. To be fair, we must remember that Method B and Method C take time to estimate their auxiliary parameters on each iteration. So, Figure 7 does not say which method is fastest in real time. Such a comparison is very dependent on the details of each method’s implementation. In the current (very inefficient) implementations, Model A converged in about 6 hours, Model B in about 20 hours, Model C in about 24 hours and Model 1 converged in about 27 hours.

The first evaluation was on “single-best” translation of the kind that somebody might use to get the gist of a foreign-language document. The input to the
experiment was one side of the gold standard bitext. The output was the model’s single best guess about the translation of each word in the input, together with the input word. In other words, each model produced link tokens consisting of input words and their translations. I computed the models’ precision and recall by comparing the link tokens produced by each model to the link tokens in the gold standard. The accuracy of each model was averaged over the two directions of translation: English to French and French to English. Figure 8(a) shows that each of the innovations introduced in Section 5 improves both precision and recall on this task on these data. The gold standard bitext was actually annotated five times by seven different annotators. This replication helped to establish statistical significance among the differences in model accuracy. The performance differences reported in this section are statistically significant at the $\alpha = .05$ level, according to the Wilcoxon signed ranks test.

Some applications don’t care about function words. To get a sense of the relative effectiveness of the different translation model estimation methods when function words are taken out of the equation, I removed all closed-class words (including non-alphabetic symbols) from the models and renormalized the conditional probabilities. Then, I removed from the gold standard all link tokens where one or both of the linked words were closed-class words. Finally, I recomputed precision and recall. The results are shown in Figure 8(b). When closed-class words were ignored, Model 1 performed better than Method A, because open-class words are more likely to violate the one-to-one assumption. However, the explicit error model in Methods B and C boosted their recall and precision significantly higher than Model 1 and Method A. As expected, there was no significant difference in accuracy between Method B and Method C on this task, because it left only two classes for Method C to distinguish: content words and NULLs.

For some applications, it is insufficient to guess only the most likely translation of each word in the input. The model is expected to output the entire distribution of possible translations for each input word. This distribution is then convolved with other distributions that are relevant to the application. For example, in cross-language information retrieval, the translational distribution is convolved with the distribution of term frequencies. In statistical machine translation, the translational distribution can be convolved with a target language model [Brown et al., 1988]. To see how the different models might perform on this “whole distribution” task, I performed a second set of experiments. This time, the models generated a whole set of links from each input word, weighted according to the probability assigned to each of the input word’s translations. I computed the precision and recall of the fuzzy sets of links generated by the models to the five gold standard annotations as before. I repeated the experiment once with closed-class words and once without, and again averaged the results over the two directions of translation. The results are in Figure 9, which is plotted on the same scale as Figure 8 to facilitate comparison. The only change in the relative accuracy of the models was that Methods B and C no longer had significantly higher precision than Model 1 when closed-class words were ignored. However, all the scores were lower than their counterparts on the “single-best” translation
task, because it is more difficult for any statistical method to correctly model the less common translations. The “best” translations are usually the most common.

Figure 8
Comparison of model performance on “single-best” translation task. (a) All links; (b) open-class links only.
Figure 9
Comparison of model performance on “whole distribution” task. (a) All links; (b) open-class links only.
To study how the benefits of the various biases vary with training corpus size, I evaluated Models A, B, C and 1 on the “whole distribution” translation task, after training them on three different-size subsets of the Bible bitext. The first subset consisted of only the 250 verse pairs in the gold standard. The second subset included these 250 plus another random sample of 2250 for a total of 2500, an order of magnitude larger than the first subset. The third subset contained all 29614 verse pairs in the Bible bitext, roughly an order of magnitude larger than the second subset. All models were compared to the five gold standard annotations. The correlation between recall and precision was very high on this task ($\rho = .99$), as illustrated in Figure 9(a). So, the results can be well represented by the set-theoretic Dice coefficient in Equation 37, as applied to probabilistic (fuzzy) sets. The mean Dice scores over the five gold standard annotations are graphed in Figure 10. The figure suggests that, at least for French/English translation models, each of the biases presented in this article improves the efficiency of modeling the available training data. The one-to-one assumption is useful, even though it is tractable only under a greedy estimation method. In relative terms, the advantage of the one-to-one assumption is much more pronounced on smaller training sets. For example, Model A is 29% more accurate than Model 1 when trained on only 250 verse pairs. The explicit error model buys a considerable gain in accuracy across all sizes of training data, as do the link classes of Model C. In concert, on the gold standard test set, the three biases outperformed Model 1 by up to 55%. This difference is even more significant given the absolute performance ceiling of 82% established by the inter-annotator agreement rates on the gold standard (Melamed, 1998d).
7.2 Evaluation By Type
An important application of statistical translation models is to help lexicographers compile bilingual dictionaries. Dictionaries are written to answer the question, “What are the possible translations of X?” This is a question about link types, rather than about link tokens.

Evaluation by link type is a thorny issue. Human judges often disagree about the degree to which context should play a role in judgements of translational equivalence. For example, the Harper-Collins French Dictionary (Cousin et al., 1990) gives the following French translations for English appoint: nommer, engager, fixer, désigner. Likewise, most lay judges would not consider instituer a correct French translation of appoint. In actual translations, however, when the object of the verb is commission, task force, panel, etc., English appoint is usually translated into French as instituer. To account for this kind of context-dependent translational equivalence, link types must be evaluated with respect to the bitext whence they were induced.

I performed a post-hoc evaluation of the link types produced by an earlier version of Method B. The bitext used for this evaluation was the same aligned Hansards bitext used by Gale & Church (1991), except that I used only 300,000 aligned segment pairs to save time. The bitext was automatically pre-tokenized to delimit punctuation, English possessive pronouns and French elisions. Morphological variants in both halves of the bitext were stemmed to a canonical form.

The link types assigned by the converged model were sorted by the log-likelihood scores in Equation 33. Figure 11 shows the distribution of these scores on a log scale. The log scale helps to illustrate the plateaus in the curve. The longest plateau represents the set of word pairs that were linked once out of one co-occurrence (1/1) in the bitext. All these word pairs were equally likely to be correct. The second-longest plateau resulted from word pairs that were linked twice out of two co-occurrences (2/2) and the third longest plateau is from word pairs that were linked three times out of three co-occurrences (3/3). As usual, the entries with higher likelihood scores were more likely to be correct. By discarding entries with lower likelihood scores, recall could be traded off for precision. This trade-off was measured at three points, representing cutoffs at the end of each of the three longest plateaus.

The traditional method of measuring recall requires knowledge of the correct link types, which is impossible to determine without a gold standard. An approximate recall measure can be based on the number of different words in the corpus. For lexicons extracted from corpora, perfect recall implies at least one entry containing each word in the corpus. One-sided variants, which consider only source words, have also been used (Gale & Church, 1991). Table 3 reports both the marginal (one-sided) and the combined recall at each of the three cut-off points. It also reports the absolute number of (non-NULL) entries in each of the three lexicons. Of course, the size of automatically induced lexicons depends on the size of the training bitext. Table 3 shows that, given a sufficiently large bitext,
the method can automatically construct translation lexicons with as many entries as published bilingual dictionaries.

The next task was to measure precision. It would have taken too long to evaluate every lexicon entry manually. Instead, I took 5 random samples (with replacement) of 100 entries each from each of the three lexicons. Each of the samples was first compared to a translation lexicon extracted from a machine readable bilingual dictionary (Cousin et al., 1991). All the entries in the sample that appeared in the dictionary were assumed to be correct. I checked the remaining entries in all the samples by hand. To account for context-dependent translational equivalence, I evaluated the precision of the translation lexicons in the context of the bitext whence they were extracted, using a simple bilingual concordancer. A lexicon entry \((u,v)\) was considered correct if \(u\) and \(v\) ever appeared as direct translations of each other in an aligned segment pair.
Direct translations come in different flavors. Most entries that I checked by hand were of the plain vanilla variety that you might find in a bilingual dictionary (entry type V). However, a significant number of words translated into a different part of speech (entry type P). For instance, in the entry (protection, protégé), the English word is a noun but the French word is an adjective. This entry appeared because “to have protection” is often translated as “être protégé” in the bitext. The entry will never occur in a bilingual dictionary, but users of translation lexicons, be they human or machine, will want to know that translations often happen this way. Incomplete entries, described above, were counted in a third category (entry type I).

Table 4
Distribution of different types of correct lexicon entries at varying levels of recall (mean ± standard deviation).

| cutoff | recall | % type V   | % type P   | % type I   | total % precision |
|--------|--------|------------|------------|------------|--------------------|
| 3/3    | 36%    | 89 ± 2.2   | 3.4 ± 0.5  | 7.6 ± 3.2  | 99.2 ± 0.8         |
| 2/2    | 46%    | 81 ± 3.0   | 8.0 ± 2.1  | 9.8 ± 1.8  | 99.0 ± 1.4         |
| 1/1    | 90%    | 82 ± 2.5   | 4.4 ± 0.5  | 6.0 ± 1.9  | 92.8 ± 1.1         |

Table 4 reports the distribution of correct lexicon entries among the types V, P and I. Figure 12 graphs the precision of the method against recall, with 95% confidence intervals. The upper curve represents precision when incomplete links are considered correct, and the lower when they are considered incorrect. On the former metric, the method can generate translation lexicons with precision and recall both exceeding 90%, as well as dictionary-sized translation lexicons that are over 99% correct.

Translation lexicon precision with 95% confidence intervals at varying levels of recall.
8 Conclusion

There are many ways to model translational equivalence and many ways to estimate translation models. “The mathematics of statistical machine translation” proposed by Brown et al. (1993) are just one kind of mathematics for one kind of statistical translation. In this article, I have proposed and evaluated new kinds of translation model biases, alternative parameter estimation strategies, and general techniques for exploiting pre-existing knowledge that may be available about particular languages and language pairs. On a variety of evaluation metrics, each infusion of knowledge about the problem domain resulted in better translation models.

Each innovation presented here opens the way for more research. Model biases can be mixed and matched with each other, with previously published biases like the word order correlation bias, and with other biases yet to be invented. The competitive linking algorithm can be generalized in various ways. New kinds of pre-existing knowledge can be exploited to effect significant accuracy improvements for particular language pairs or even just for particular bitexts. It is difficult to say where the greatest advances will come from. Yet, one thing is clear from our current vantage point: Research on empirical methods for modeling translational equivalence has not run out of steam, as some have claimed, but has only just begun.
