ABSTRACT: The tau neutrino is the least well measured particle in the Standard Model. Most notably, the tau neutrino row of the lepton mixing matrix is quite poorly constrained when unitarity is not assumed. In this paper we identify several new and overlooked data sets involving tau neutrinos that improve our understanding of the tau neutrino part of the mixing matrix. We present new results on the unitarity of the tau row leveraging existing constraints on the electron and muon rows for the cases of unitarity violation, with and without kinematically accessible steriles. We also show the expected sensitivity due to upcoming experiments and demonstrate that the tau neutrino row precision is expected to be comparable to the muon neutrino row in a careful combined fit.
1 Introduction

The tau neutrino is the second to last discovered particle of the Standard Model (SM) in 2000 [1], only followed by the Higgs boson discovery in 2012 [2, 3] to complete the known particle content of the SM. Nevertheless, the tau neutrino remains one of the least studied particle of the SM even more than two decades after its discovery.

In particular, the tau row of the leptonic mixing matrix, the PMNS matrix [4, 5], presents large uncertainties [6–9] such that the PMNS matrix is significantly less constrained than the CKM matrix [10, 11] for the quark sector [12]. One of the most important methods of robustly constraining the mixing matrix is a thorough test of its unitarity. Non-unitary mixing matrices arise in many extensions of the SM like models with neutrinos propagating in extra dimensions [13–15] and most notably in extensions of the SM introducing new, heavy neutrinos potentially connected to neutrino mass generation [16–18]. These scenarios lead to apparent low energy unitarity violation (UV) as the mixing matrix of the full theory, including the often kinematically inaccessible sterile neutrinos, is unitary. We will not consider the case where the mixing matrix of the full theory is not unitary,
rather we focus on the following on two scenarios: UV coming from kinematically accessible sterile neutrinos whose mass is large such that their oscillations are averaged out at the detector of neutrino oscillation experiments, and the case of kinematically inaccessible sterile neutrinos whose mass is too large to be produced in the neutrino source. While in the first case UV constraints provide complementary (and more general) bounds on the sterile neutrino parameters which can be compared to constraints from direct searches for steriles, kinematically inaccessible sterile neutrinos at oscillation experiments can only be directly constrained by high energy collider searches for sterile neutrinos with masses up to $\sim 100$ GeV (for a recent review of sterile neutrino bounds across many energy scales see [19]). In fact, UV is the only detectable signature of heavy sterile neutrinos with mass $m_4 \gtrsim 1$ TeV, beyond which direct searches lose sensitivity. Since these experiments rely on the detection of the decay products of sterile neutrinos, these experiments are generally insensitive to light steriles with mass $m_4 \lesssim 10$ MeV which corresponds to decay length outside of the detector\(^1\). Therefore UV constraints from oscillations can also be converted into bounds in unexplored regions of sterile neutrino parameter space. Hence probing UV constrains a vast parameter space and is a robust way of testing sterile neutrinos across many energy scales.

While the constraints on UV in the electron row are already rather tight and will continue to improve [7–9, 20] due to the very precise measurements of reactor experiments, the muon and tau rows currently allow for sizable deviations from unitarity. The muon row is mostly informed from muon disappearance and electron appearance at long baseline experiments like NOvA and T2K as well as atmospheric neutrinos measured by Super-KamiokaNDE and IceCube. On the other hand so far only tau appearance data in the long baseline experiment OPERA and from atmospheric muon disappearance has been considered to constrain the tau row. Together with the conditions from the unitarity of the full matrix constraints on the tau row has been derived in the literature for the two scenarios we will consider in the following. However due to the small size of the tau neutrino data set the constraints are rather poor.

In the following we will identify new tau neutrino data sets\(^2\) and demonstrate that up to now not all available tau data has been used optimally. In fact, the tau data sets are richer than previously assumed which already leads to a noticeable improvement of the constraints with current data but even more so in the near future. Specifically we take so far overlooked results from atmospheric tau neutrino appearance, astrophysical tau neutrino appearance, and charged current scattering experiments into account. Additionally, we investigate the impact of neutral current measurements to constrain UV subject to theoretical predictions. Even though in these experiments the flavor of the neutrino is not identified, compelling bounds arise from a reduction of the total neutrino flux and non-trivial cross section modifications due to UV which can be compared to theoretical predictions.

\(^1\)This is true for the coupling of steriles to $\nu_\mu$ and $\nu_\tau$. The sterile coupling to $\nu_e$ can be constrained by peak searches in nuclear decays which allow to probe smaller sterile masses down to the eV scale [19].

\(^2\)We will focus on oscillation and scattering experiments here but it is also possible to constrain UV using electroweak precision data [21–23].
After introducing the UV framework in section 2, we will present UV results on the tau row for two benchmark cases, with and without kinematically accessible steriles, as well as forecast future sensitivities in section 3 and show that with the advent of new experiments and more data improvements are anticipated such that the tau row can be potentially constrained as well as the other rows. As we want to focus on the tau row only and establish the use of these new data sets we will not conduct a full global fit including the electron and muon row but use priors on these rows from the literature. We discuss our results and conclude in sections 4 and 5. Appendix A contains more information about the experiments considered in the analysis and their implementation.

2 Unitary violation framework

A UV framework is a relatively model independent framework to quantify how much the $3 \times 3$ lepton mixing matrix deviates from unitary. Apparent unitary violation can manifest itself out of a number of complete models, often related to neutrino mass generation. In fact, any new sterile neutrino state, whether connected to neutrino mass generation [16–18] or otherwise leads to apparent UV. Another potential source of UV comes from models with neutrinos propagating in extra dimensions [13–15]. For concreteness, we focus on models that are parameterized as additional singlet fermions that may or may not be kinematically accessible in the typical decays that produce neutrinos, but do not lead to new frequencies ($\Delta m^2$'s) that are directly accessible through oscillations.

In this section we first present our framework and define and justify our focus on two particular UV schemes. We then move on to calculating the physical observables in each scheme, in particular the oscillation probabilities including the matter effect, as well as cross sections.

2.1 Unitary violation schemes

We parameterize UV in terms of a larger $n \times n$ unitary matrix for which $m$ states are kinematically accessible in a given production channel, see table 1 for a summary of the kinematics of different relevant neutrino sources. We then describe a given scenario by the pair of numbers: $(n, m)$, that is: (total number of neutrinos, number of accessible neutrinos). So the standard oscillation picture is (3,3). The case with one extra light ($m_4 \sim 10$ eV) sterile neutrino that is oscillation averaged in all relevant experiments is (4,4). The case with three additional heavy ($m_4 \gtrsim 50$ MeV) states would be (6,3). We focus on two cases of phenomenological interest: (4,4) and (5,3), although there are numerous others that are distinct from these.

The (4,4) case is the one with one new mass eigenstate that is accessible. This is well motivated phenomenologically due to a large number of searches for this scenario in the averaged out limit along with some very slight hints for this case [24–26]. The (4,4) case

---

3This case should not be confused with the “light sterile” scenario which features kinematically accessible sterile neutrinos ($\Delta m^2 \sim 1$ eV) whose oscillations can be resolved at experiments, also in this case some slight hints exist [27–29].
corresponds to a 4 × 4 unitary matrix which, after rephasing, can be parameterized with 9 free parameters: 6 angles and 3 phases.

The (5,3) case is the one with two new heavy mass eigenstates that are kinematically inaccessible. This case is top-down motivated when heavy sterile neutrinos (also known as heavy neutral leptons) are involved in the light neutrino mass generation which requires at least two generations of steriles to be in agreement with the experimental data on light neutrino masses. This case is further motivated in leptogenesis models which, in the simplest realization of a high-scale leptogenesis mechanism [30], require at least two generations of sterile neutrinos with masses above the weak scale. We focus on (5,3) as opposed to (4,3) or (6,3) since the extra degrees of freedom in (6,3) are not accessible in standard oscillation experiments compared to the (5,3) case which has enough degrees of freedom such that all elements of the directly probably 3 × 3 matrix can vary freely, unlike in the (4,3) case. Hence the (5,3) case corresponds to a non-unitary (3,3) matrix which is a submatrix of the complete, unitary mixing matrix. This case can be parameterized with 13 real parameters corresponding to 9 angles and 4 phases.

While for the $n \geq m$ scenarios, the heavy neutrinos cannot be directly produced, in principle, with a large number of extremely precise measurements of $\nu_e$, $\nu_\mu$, and $\nu_\tau$ oscillations with the known $\Delta m^2$’s, it is possible to differentiate between (3,3), (4,3), and (5,3), but (5,3) cannot be differentiated from (6,3) or scenarios with more heavy sterile neutrinos. To see this, we note that there are 9 SM oscillation channels: 6 appearance channels and 3 disappearance channels. Of the 6 appearance channels 3 channels are related via T or CP such that they constrain only the complex phases. This means there are 6 channels to constrain the absolute values of the matrix elements. That’s enough to constrain the (3,3) and (4,4) cases. However in the (5,3) case we have more free parameters. This means that we cannot directly measure all matrix elements however we can make consistency check to see if the data fits the (5,3) case or the (4,4) case (or (4,3)) hence providing a distinction between these cases and motivates our study of them as benchmark cases.

Table 1 shows the approximate kinematic range for the new mass states considered for each scenario: (4,4) and (5,3) in all relevant experiments. For the lower limit in the (4,4) scenario we require averaged out oscillations with $\Delta m^2_{31} L/E \gg 1$. For the upper limit we require that the width of a decaying particle into a sterile neutrino is not more than $\sim 10\%$ smaller than the decay rate into an active neutrino. This assures that the neutrino production spectrum is not significantly affected by the presence of a sterile neutrino and we can use the same approach in calculating the expected number of events in all scenarios under consideration. If the neutrinos are produced via pion decays this bound is 15 MeV, if they are produced via $D_s$ meson decays this bound is 90 MeV. For solar neutrinos the upper bound is 5 MeV from the maximal energy of the $^8B$ flux which is 20 MeV. For astrophysical or solar neutrinos there is no lower bound as their baselines are so large that they are oscillation averaged.

For the (5,3) scenario we obtain only a lower bound on the

---

4 A general 4 × 4 unitary matrix has 16 real parameters, 7 of which are removed by rephasing of the charged and neutral leptons.

5 We assume that the new mass states are heavier than the known states. That is, that we are in the 3+1
Table 1. Overview of the experiments considered in the following and the relevant mass scales for the heavy states in the two UV scenarios considered. Notice that the atmospheric $\nu_\mu$ disappearance bounds only apply to the (4,4) case while the NOMAD/CHORUS constraints only apply to the (5,3) case.

| experiment                        | (4,4) $(m_4)$ | (5,3) $(m_4)$ |
|-----------------------------------|---------------|---------------|
| atmospheric $\nu_\mu$ disappearance | ∈ $[10 \text{ eV}, 15 \text{ MeV}]$ | $\gtrsim 40 \text{ MeV}$ |
| atmospheric $\nu_\tau$ appearance | $\lesssim 15 \text{ MeV}$ | $\gtrsim 40 \text{ MeV}$ |
| astrophysical $\nu_\tau$ appearance | $\lesssim 5 \text{ MeV}$ | $\gtrsim 20 \text{ MeV}$ |
| solar data                        |               |               |
| DONuT/FASERnu                     | ∈ $[100 \text{ eV}, 90 \text{ MeV}]$ | $\gtrsim 200 \text{ MeV}$ |
| LBL $\nu_\tau$ appearance (OPERA) | ∈ $[1 \text{ eV}, 15 \text{ MeV}]$ | $\gtrsim 40 \text{ MeV}$ |
| LBL $\nu_\mu$ disappearance (DUNE) | ∈ $[0.1 \text{ eV}, 15 \text{ MeV}]$ | $\gtrsim 40 \text{ MeV}$ |
| LBL $\nu_\mu$ appearance (DUNE)   | ∈ $[0.1 \text{ eV}, 15 \text{ MeV}]$ | $\gtrsim 40 \text{ MeV}$ |
| CEvNS                             | ∈ $[10 \text{ eV}, 15 \text{ MeV}]$ | $\gtrsim 40 \text{ MeV}$ |
| NOMAD/CHORUS                      |               | $\gtrsim 40 \text{ MeV}$ |

sterile mass above which the steriles are kinematically inaccessible. This means they cannot be produced in decays of pions or $D_s$ mesons. For pions this mass is $m_4 \gtrsim m_\pi - m_\mu \approx 40 \text{ MeV}$, for $D_s$ mesons $m_4 \gtrsim m_{D_s} - m_\tau \approx 200 \text{ MeV}$. Additional sources of tau neutrinos include those directly from $\tau$ lepton decays which leads to a higher available phase space $\sim 1.5 - 1.8 \text{ GeV}$ [32], but isn’t a dominant channel for the experiments we are considering.

2.2 Unitary violation observables

Turning now to the vacuum oscillation probability in the absence of unitarity which we will utilize in the following section for our numerical results. The oscillation probability from flavor $\alpha$ to flavor $\beta$ with a non-unitary mixing matrix $U$ is [21]

$$P_{\alpha\beta}(E, L) = \frac{\left| \sum_{i=1}^{N_{\text{acc}}} U^*_{\alpha i} e^{i P_i L U_{\beta i}} \right|^2}{\left( U U^\dagger \right)_{\alpha\alpha} \left( U U^\dagger \right)_{\beta\beta}},$$

(2.1)

where the sum in the numerator is over all kinematically accessible mass eigenstates $i$ with momentum eigenvalues $P_i = \sqrt{E_{i}^2 - m_{i}^2}$. The terms in the denominator $(UU^\dagger)_{\alpha\alpha}$ should be understood as $(UU^\dagger)_{\alpha\alpha} = \sum_{i=1}^{N_{\text{acc}}} U_{\alpha i} U_{i\alpha}^*$ where the sum is over kinematically accessible states. If all mass states are kinematically accessible this term sums to 1 and thus this term does not play a role in the (4,4) case, however it is crucial in the (5,3) case and drives the constraints.

The charged current (CC) cross sections and fluxes also get modified due to the non-unitary mixing matrix such that the measured cross section and flux are functions of the expected cross section in the SM $(\sigma^{CC,\text{SM}}, \phi^{CC,\text{SM}})$,

$$\sigma_{\alpha}^{CC} = \sigma_{\alpha}^{CC,\text{SM}}(UU^\dagger)_{\alpha\alpha}, \quad \frac{d\phi_{\alpha}^{CC}}{dE} = \frac{d\phi_{\alpha}^{CC,\text{SM}}}{dE} (UU^\dagger)_{\alpha\alpha}.$$

(2.2)

or 3+2 hierarchies and not a 1+3 type hierarchy which is disfavored from the cosmological sum of neutrino masses [31].
The neutral current (NC) cross sections get modified as

\[ \sigma_{NC}^i = \sigma_{NC,SM}^{acc} \sum_{j=1}^{\text{acc}} |(U^\dagger U)_{ij}|^2, \tag{2.3} \]

where \((U^\dagger U)_{ij} = \sum_{\alpha=e}^7 U^*_{\alpha i} U_{\alpha j}\) summed over all active flavors, in the flavor basis

\[ \sigma_{\beta}^NC = \sigma_{NC,SM}^{|(UU^\dagger)_{\beta\beta}|^2}, \tag{2.4} \]

summed over all accessible mass states as before. All together the number of measured events of flavor \(\beta\) coming from a beam of neutrinos with flavor \(\alpha\) is

\[ n_{\beta}^{\text{meas}} \sim \int dE \frac{d\phi_\alpha(E)}{dE} P_{\alpha\beta}(E, L) \sigma_{\beta}(E) \epsilon(E), \tag{2.5} \]

with the detection efficiency \(\epsilon\). In many experiments the production and detection are both CC processes so the number of events is

\[ n_{\beta}^{CC} \sim \int dE \frac{d\phi_{\alpha}^{CC,SM}(E)}{dE} \tilde{P}_{\alpha\beta}(E, L) \sigma_{\beta}^{CC,SM}(E) \epsilon(E), \tag{2.6} \]

where we define \(\tilde{P}_{\alpha\beta}\)

\[ \tilde{P}_{\alpha\beta} = \sum_{i=1}^{\text{acc}} U^*_{\alpha i} e^{iP_{\alpha i} L U_{\beta i}} |^2, \tag{2.7} \]

such that the extra terms from eq. (2.2) cancel the denominator in the probability from eq. (2.1). In this case the only impact of the UV matrix elements is in \(\tilde{P}_{\alpha\beta}\). On the other hand for NC detection processes the denominators don’t cancel. Then the number of detected events of any flavor assuming the probability is to be written in the form \(\tilde{P}_{\alpha i}\) as for solar neutrinos due to the adiabatic flavor changing MSW effect [33], is

\[ n_{\text{solar}}^{NC} \sim \int dE \sigma_{NC,SM}^{\tau} \sum_{\alpha=e}^7 \frac{d\phi_{\alpha}^{CC,SM}(E)}{dE} \sum_{i=1}^{\text{acc}} \tilde{P}_{\alpha i}(E, L) \sum_{j=1}^{\text{acc}} |(U^\dagger U)_{ij}|^2 \epsilon(E), \tag{2.8} \]

while for coherent elastic neutrino nucleus scattering (CEvNS) it is

\[ n_{\text{CEvNS}}^{NC} \sim \int dE \sigma_{NC,SM}^{\tau} \sum_{\alpha=e}^7 \frac{d\phi_{\alpha}^{CC,SM}(E)}{dE} \sum_{\beta=e}^7 \tilde{P}_{\alpha\beta}(UU^\dagger)_{\beta\beta} \epsilon(E), \tag{2.9} \]

where we note the presence of one extra factor of \((UU^\dagger)_{\beta\beta}\) due to the fact that this is a NC detection.

Hence in NC processes the UV matrix elements appear in several places, making these experiments an essential part of the data sets used to probe UV. We present in appendix A.6 a summary of the experiments and determine if there is a cancellation of the terms in the denominator or not.
Additionally, in the presence of UV in the (5,3) case the Fermi constant obtains corrections as not all mass states can get produced, the relation between $G^\mu_F$, extracted from muon decay, and $G^{\text{UV}}_F$ is

$$G^{\text{UV}}_F = \frac{G^\mu_F}{\sqrt{(UU^\dagger)_{\mu\mu}(UU^\dagger)_{\mu\mu}}}.$$  \hfill (2.10)

Even though the change in the Fermi constant depends only on elements in the electron and muon row when deriving constraints on the tau row the muon row elements are involved such that we often predict a deviation from $G^\mu_F$ for our constraints on the tau row. The matter effect must also be carefully included in the oscillations, see [34–36]. In fact, as we will show in the following the matter effect plays an important role in constraining the tau row, in particular for channels involving atmospheric neutrinos like atmospheric muon disappearance and atmospheric tau appearance.

3 Results

Here we will present the results for the (4,4) and (5,3) case. We introduce new tau data sets which can be grouped in different categories, for more details see appendix A.

- Atmospheric muon disappearance experiments: These experiments are sensitive to the mixing of heavy sterile neutrinos with tau neutrinos due to the presence of the SM matter effect [37]. This effect relies on the sterile neutrino being kinematically accessible hence these constraints are only applicable to the (4,4) case, but not to the (5,3) case. We use current constraints from DeepCore [38] and SuperKamiokaNDE [39] on the mixing between tau neutrinos and a sterile neutrino. This constraint will improve in the future by successors of these experiments as well as KM3NeT/ORCA [40].

- Atmospheric tau appearance experiments: The sensitivity to atmospheric tau appearance comes primarily from a combination of the matter effect, the lower tau neutrino reconstructed energy, and the rising cross section due to the tau lepton’s threshold [34]. IceCube [41] and SuperKamiokaNDE [42] have constrained the tau normalization $N_{\tau}$ defined as the ratio of the measured $\nu_{\tau}$ flux to the expected one assuming standard oscillations. This constraint will improve in the future with IceCube-Gen2 [43], KM3NeT/ORCA [44, 45] and HyperKamiokaNDE [46] data.

- Astrophysical tau appearance experiments: Astrophysical neutrino sources only produce electron or muon neutrinos\(^6\), hence the observation of astrophysical tau neutrinos indicates a flavor change [48]. From the ratio of currently observed astrophysical tau neutrinos to astrophysical muon neutrinos at IceCube [49, 50] we obtain constraints on the tau row. IceCube-Gen2 will measure this ratio even more precisely [51].

\(^6\)The matter effect in the source could induce oscillations, but only for energies $\lesssim 100$ GeV [47], well below the region of interest for IceCube. In addition, a subleading component of intrinsic $\nu_{\tau}$ could be present depending on the source, but will not contribute a considerable fraction of the total flux.
• Tau neutrino appearance at long baseline experiments: OPERA [52] as well as DUNE in the future are sensitive to tau appearance in a muon neutrino beam [53] which provides insights on the tau matrix elements.

• Charged current and neutral current scattering experiments: Charged current scattering experiments such as NOMAD/CHORUS [54, 55] as well as DONuT [56] and, in the future, FASERnu [57] and other future forward physics facilities [58] identify tau neutrinos at very short baselines where no SM oscillations have developed yet. On the other hand, neutral current scattering experiments like coherent elastic neutrino nucleus scattering (CEvNS) experiments or SNO don’t identify the tau neutrinos but they are sensitive to all neutrino flavors. As demonstrated in the previous section and in eqs. (2.8) and (2.9) these observations still provide constraints on the tau row.

As we are focused on the tau row and demonstrate that several new data sets lead to an improved knowledge of the tau matrix elements and the tau row normalization, we use priors on the matrix elements of the electron and muon row instead of conducting a full global fit. For the (4,4) case we use the current constraints on the electron and muon row from the recent global fit in [9], for the (5,3) case we use the constraints from the recent global fit in [7, 8]. These publications also included tau data from OPERA, NOMAD, and atmospheric muon disappearance in their global fit. These data sets also affect the muon row\(^7\), so the worry of double counting might arise. However, the strongest constraints on the muon row come from muon neutrino disappearance experiments like the long-baseline experiments NOvA and T2K as it can be seen from the small level of improvement of the muon row between older publications in the literature before appearance data existed such as [6], to the more recent publications [7–9]. Furthermore, the currently used tau data sets have lower statistics than the muon data sets such that they present larger uncertainties. Nevertheless, we caution the reader that a direct comparison to global analyses is potentially subject to small corrections due to double counting. We present our results in the context of the constraints derived from information in the \(\nu_e\) and \(\nu_\mu\) rows only, the addition of each class of experiments, and finally the sum of all constraints to highlight the impact on the tau neutrino row for each class of experiment.

For the forecasted results we use the same priors on the electron and muon rows. This can be understood as a conservative approach and will showcase the improvements from the new tau data sets alone. It should be noted though that the electron and muon rows will improve as well with future data from the JUNO, DUNE, T2HK, and IceCube-Gen2 experiments [7, 8, 20].

Our parameterization of the mixing matrix in both scenarios involves phases in the mixing matrix. However the sensitivity of the new tau data sets to CP violation is rather low and as in general there is no strong preference for any value of the phase in the

---

\(^7\)The electron row is also affected by these tau data however mostly in an indirect way via the unitarity triangles. Additionally the constraints on the electron row are mainly driven by reactor experiments which are not sensitive to tau neutrinos.
Figure 1. Constraint on the individual matrix elements in the tau row in the (4,4) case using the currently available data as well as priors on the electron and muon row elements from [9]. The different colors represent different data sets which have been included in addition to the constraints from unitarity using priors from the electron and muon row. The black lines represents the constraints using all data sets.

Figure 2. Constraint on the individual matrix elements in the tau row in the (4,4) case using forecasted data as well as priors on the electron and muon row elements from the current constraints in [9]. The different colors represent different data sets which have been included in addition to the constraints from unitarity using priors from the electron and muon row. The black lines represents the constraints using all data sets.

(3,3) scenario [59] we will constrain all phases to be CP conserving in our analysis. This assumption is also consistent with the findings of [7,8] which prefer CP conserving phases for the (5,3) case. This also allows us to treat neutrinos and anti-neutrinos in the same way in our analysis. Future analyses will need to account for all possible complex phases as NOvA and T2K data improve and DUNE and T2HK come online.

Finally, we use a simple $\chi^2$ test statistic depending on the expected number of events $n_{\text{theo}}^\text{events}$ under the UV hypothesis and the measured number of events $n_{\text{meas}}^\text{events}$ with uncer-

\footnote{In fact, there is currently a slight disagreement for the preferred value of the CP violating phase in the (3,3) scenario between NOvA [60] and T2K [61] which can be resolved with the introduction of new non-standard matter effects [62,63].}
Figure 3. Constraint on the individual matrix elements in the tau row in the (5,3) case using the currently available data as well as priors on the electron and muon row elements from [7, 8]. The different colors represent different data sets which have been included in addition to the constraints from unitarity using priors from the electron and muon row. The black lines represents the constraints using all data sets.

Figure 4. Constraint on the individual matrix elements in the tau row in the (5,3) case using forecasted data as well as priors on the electron and muon row elements from the current constraints in [7, 8]. The black lines represents the constraints using all data sets.

tainty \( \sigma_{\text{meas}} \)

\[
\chi^2 = \frac{(n_{\text{theo}}^{\text{events}} - n_{\text{meas}}^{\text{events}})^2}{\sigma_{\text{meas}}^2}.
\]  

(3.1)

For some experiments we also include nuisance parameters which we then minimize the test statistic over, see appendix A for more experiment specific details. We do not take any correlations between different experiments or theory predictions into account.

We present our results for the tau row matrix elements in the (4,4) case with current and forecasted in figs. 1, 2, and for the (5,3) case in figs. 3, 4. In each figure we show the constraints using unitarity constraints from the electron and muon row only (i.e. no dedicated tau data has been introduced), for unitarity plus one tau data set, and for all tau data sets together. Notice that not all data sets apply for both benchmark cases; atmospheric muon disappearance only constrains the (4,4) case while NOMAD only constrains
Figure 5. Constraints on the deviation from a unitary tau row $1 - (|U_{\tau 1}|^2 + |U_{\tau 2}|^2 + |U_{\tau 3}|^2)$ in the (4,4) case in blue and the (5,3) case in orange. The current constraints are the solid curves and the estimated future sensitivities are shown in the dashed curves.

In the (5,3) case (see appendix A for more details). Fig. 5 shows the deviation from apparent unitarity for the tau row for both benchmark cases with all current and all future data. No preference for deviation from unitarity has been found\(^9\). In the (4,4) case the constraints at $2\sigma$ are

\[
1 - (|U_{\tau 1}|^2 + |U_{\tau 2}|^2 + |U_{\tau 3}|^2) < 0.097(0.029) \text{ for current (future) data,} \tag{3.2}
\]

and for the (5,3) case

\[
1 - (|U_{\tau 1}|^2 + |U_{\tau 2}|^2 + |U_{\tau 3}|^2) < 0.259(0.088) \text{ for current (future) data.} \tag{3.3}
\]

### 4 Discussion

From figs. 1, 3 we see that currently with only the information from the electron and muon row all values of $|U_{\tau i}|$ are allowed at $\Delta\chi^2 < 1$ in both scenarios up to large values of the matrix elements where strong constraints from the normalization of the tau row apply. Even in the presence of a larger matrix the (3,3) matrix elements have a maximal value in order to satisfy the row normalization constraint. These maximal values of the matrix elements correspond to the case where all matrix elements involving the heavy mass states are zero (i.e. $|U_{\tau 4}| = |U_{\tau 5}| = 0$). As we add additional tau neutrino data sets, the constraints for large values of the matrix elements remain strong such that the upper limit on $|U_{\tau i}|$ remains similar, nearly independent of the data set added. However not all data sets have a big impact. From fig. 1 we see that solar NC data does not add much constraining power to

---

\(^9\)The slight bump in current (4,4) data is due to the slight disagreement between IceCube and SK data for atmospheric tau neutrino appearance.
the information from the electron and muon row alone in both benchmark case considered. The sensitivity in both benchmark cases is similar, for clarity of the presentation we omit this line in fig. 3. The reason for this can be understood from the fact that the measurement of the total neutrino flux is more precise than the theoretical prediction (see appendix A for more details) such that this data set does not add much information. Hence any future measurements of the solar neutrino flux will therefore need to be accompanied by equal improvements on the theoretical predictions to further constrain the tau row. Similarly, experiments DONuT and FASERnu don’t provide strong constraints in the (4,4) scenario. In fact they provide only mild constraints \( \Delta \chi^2 \lesssim 1 \) for intermediate values of the matrix elements around \( |U_{\tau i}| \sim 0.3 - 0.4 \). The reason for this is that in the (4,4) scenario the analytical oscillation probability is 
\[
P^{(4,4)}_{\text{CC scat}} = 1 - 2|U_{\tau 4}|^2(|U_{\tau 1}|^2 + |U_{\tau 2}|^2 + |U_{\tau 3}|^2) \]
which is then compared to the expected probability in the (3,3) case \( P^{(3,3)}_{\text{CC scat}} = 1 \) (see appendix A for more details). Since large values of \( |U_{\tau i}|, i = 1, 2, 3 \) imply a small \( |U_{\tau 4}| \), as the tau row normalization needs to be fulfilled, the second part of the expression is small and \( P^{(4,4)}_{\text{CC scat}} \sim 1 \). On the other hand if the \( |U_{\tau i}|, i = 1, 2, 3 \) are small \( |U_{\tau 4}| \) needs to be big to fulfill the row normalization but again \( P^{(4,4)}_{\text{CC scat}} \sim 1 \). Only in the case of medium large matrix elements \( |U_{\tau i}| \sim 0.3 - 0.4 \) where all matrix elements are of similar order the second term of the oscillation probability is not anymore small but around 0.6. This leads to medium large values of all matrix elements to be slightly disfavored. This cancellation is however not present in the (5,3) case due to the different expression of the oscillation probability (see appendix A). In this case the CC scattering experiments constrain small values of the matrix elements and will in the future lead to competitive constraints.

The measurements from NOMAD alone, which only apply to the (5,3) case, don’t provide strong constraints either and have \( \Delta \chi^2 \lesssim 1 \) up to very large values of the matrix elements. OPERA on the other hand is rather insensitive to medium values of the matrix elements in the (4,4) case and only strongly rules out small and large \( |U_{\tau i}| \) whereas the exclusion power for small values is weaker in the (5,3) case. DUNE in the future will provide strong constraints. As DUNE will be sensitive not only to tau appearance in the beam but also inform the tau row from muon disappearance data it will improve the long baseline constraints from OPERA. Astrophysical tau appearance is currently not very constraining due to the small data set of tau neutrino appearance \( \sim 2 \) events so far), however upcoming experiments will improve this data set and our forecasted results show that in both benchmark cases this channel is competitive with other data sets. Atmospheric tau appearance currently excludes small matrix elements at \( \Delta \chi^2 \gtrsim 9 \) level in the (4,4) case and \( \Delta \chi^2 \gtrsim 2 \) in the (5,3) case. In the future this data set will provide very strong constraints demonstrating that this channel is very useful to constrain unitarity. CEvNS is currently not very constraining in both benchmark cases and only provides constraints around \( \Delta \chi^2 \sim 1 \) level in the (4,4) case and below this level in the (5,3) such that we do not include this curve in our plot. In the future this data set will be one of the most constraining ones in the (4,4) case due to its high statistics and rule out small \( |U_{\tau i}| \) at \( \Delta \chi^2 \gtrsim 4 \) whereas it basically provides no constraints in the (5,3) case. Even though we need to rely on theory predictions for this NC channel, the uncertainties are rather small
due to well understood fluxes and cross sections. Atmospheric muon disappearance which only applies in the (4,4) case provides very strong constraints because of its high statistics. As this channel only constrains the $|U_{\tau 4}|$ matrix element no cancellations between different matrix elements are possible and we obtain a clean constraint on the deviation from the tau row normalization.

In comparison to previous constraints on the tau row matrix elements which only included data from OPERA, atmospheric muon disappearance, and NOMAD data we demonstrate that more tau data is currently available which improves the information on the tau row. It appeared that accelerator neutrinos DUNE might drive the tau row constraints in the future; we point, however, out that previously unaccounted for data from atmospheric tau appearance\footnote{Including, in principle, atmospheric tau neutrino appearance at DUNE \cite{64} which is not discussed in this article.} will be essential to obtain strong and complete constraints on the tau row together with more data from atmospheric muon disappearance. Also astrophysical tau appearance, CEvNS, as well as CC scattering experiments will further strengthen the constraints. In fact, we expect that in the future the tau row could be measured with comparable precision as the other rows with the inclusion of these data sets therefore improving the status of the tau row faster than previously anticipated.

As the combination of all current constraints on the tau row elements is comparable to future constraints from long baseline experiments, atmospheric muon disappearance or atmospheric tau appearance alone we see that adding current knowledge to future data basically returns the same constraints as from future data only. Finally, we also point out that at some point no improvement on the tau row can be achieved anymore without improving the other rows as well. This can be done with future experiments like JUNO, HK, and DUNE which will in turn lead to progress on the unitarity constraints on the electron and muon row.

Our constraints can, in principle, be compared to other results from direct searches and from electroweak UV fits, although most of these focus on just a single sterile neutrino at a time, while our constraints look at the unitary violating picture more generally. The strongest constraints for direct searches come from CHARM \cite{65}, DELPHI \cite{66}, and ArgoNeuT \cite{67} with anticipated improvement from DUNE’s near detector in the future \cite{68}. These constraints, along with our results, are summarized in fig. 6. Note that the constraints from the (4,4) analysis apply in the $10 \text{ eV} \lesssim m_4 \lesssim 15 \text{ MeV}$ range while the (5,3) analysis applies in the $m_4 \gtrsim 40 \text{ MeV}$ range$^{11}$. We can see that future UV studies focused on the tau neutrino are already starting to probe the parameter space expected from typical seesaw models. Additional constraints exist from electroweak precision data, big bang nucleosynthesis, the cosmic microwave background, and supernova data; for an overview of the constraints, see \cite{19}.

Our results demonstrate that the tau matrix elements are non-zero at a high level of confidence.

$^{11}$In between significant care is needed as the spectrum from pion decays would be modified; this can be leveraged in a careful measurement at e.g. DUNE \cite{68}. 

---
Figure 6. The current (solid curves and shaded regions) and future (dashed curves) constraints on heavy sterile neutrinos from oscillations and direct searches. The dominant existing constraints are from CHARM (blue) [65], DELPHI (purple) [66], and ArgoNeuT (tan) [67] with significant improvement anticipated from DUNE (green) [68]. Our oscillations constraints (orange) are divided into (4,4) (kinematically accessible) and (5,3) (kinematically inaccessible). The (5,3) constraints continue to the right. Note that the other constraints all assume no mixing with $\nu_e$ or $\nu_\mu$ while we do allow for this. The region that is likely interesting for seesaws is shown in pink.

5 Conclusions

The tau neutrino is the least well known particle of the SM. In fact, given the existing understanding of the data, large deviations from the SM expectation could be realized, making the tau sector an appealing window to new physics. In this manuscript we present new constraints on the unitarity of the tau row of the leptonic mixing matrix therefore probing a broad class of SM extensions which introduce unitarity violation.

Phenomenologically motivated models of additional steriles neutrinos lead to apparent UV as the complete leptonic mixing matrix is unitary but the directly testable $3 \times 3$ submatrix is not. We studied two benchmark cases for UV parameterized by a $4 \times 4$ unitary matrix with a sterile neutrino that is kinematically accessible but its oscillations are too fast to be resolved at detectors (i.e. $m_4 \in [10 \text{ eV}, 15 \text{ MeV}]$), and a scenario where the sterile neutrino is not kinematically accessible ($m_4 \gtrsim 40 \text{ MeV}$). For both benchmark scenarios we introduced new tau data sets available in the literature which have been previously neglected including atmospheric tau appearance, astrophysical tau appearance, as well as CC and NC scattering experiments like CEvNS or with solar neutrinos. Combined with the data sets also explored by other unitarity studies like long baseline tau appearance data...
from OPERA and DUNE in the future, CC scattering data from NOMAD, and atmospheric muon disappearance data we derive constraints on the individual tau matrix elements and the unitarity of the tau row. Therefore our results use all currently available tau data to derive novel constraints.

We find that the introduction of the new data sets improved the constraints on the tau row and will continue to do so in the future. To provide strong constraints in the future the introduction of neutral current measurements is crucial which we have demonstrated for the first time. Even though these measurements cannot directly identify tau neutrinos, they are sensitive to tau matrix elements when comparing measurements to theory predictions. We show that the tau row can be potentially measured as comparably well as the other rows.

Our results show no evidence for unitary violation which constrains the parameter space of new physics models. In addition to constraints on unitarity we also presented constraints on the individual matrix elements of the tau row. A precise measurement of the matrix elements can provide insights if the leptonic mixing matrix behaves similarly to the quark mixing matrix and if the $\mu - \tau$ symmetry is exactly realized in the mixing matrix which can guide flavor model building and constrain existing models [69, 70].

In summary, in this manuscript we have establish the use of new tau neutrino data sets and have shown that the tau row is in a better shape than previously assumed in the literature. We have also laid out the picture of tau neutrino unitarity constraints as they currently exist and will evolve over the coming decades. Hence our results provide novel, strong constraints new physics models, solidifying the 3 flavor oscillation picture.

A Experiments

In this appendix we describe the experimental data used in the analysis presented in the main text as well as the combinations of parameter constrained in the (4,4) and (5,3) cases.

When the experimental results are provided for both mass orderings we will assume for definiteness the normal ordering as current experiments provide a mild hint for the normal mass ordering in the three flavor scenario [59].

A.1 Atmospheric muon neutrino disappearance data

Atmospheric muon neutrino disappearance data is sensitive to the mixing of heavy sterile neutrinos with tau neutrinos due to the presence of the SM matter effect [37]. This effect exists hints for sterile neutrinos or UV don’t directly impact the tau neutrino row and aren’t included in this analysis.
relies on the sterile neutrino being kinematically accessible hence these constraints are only applicable to the (4, 4) case, but not to the (5, 3) case.

The best current constraints come from DeepCore [38] and SuperKamiokaNDE [39] which constrain

$$|U_{\tau 4}|^2 < 0.15 \text{ at } 90\% \text{ C.L.} \ (A.1)$$

The constraint will be improved in the future with more data from these experiments as well as by KM3NeT/ORCA [40] and HyperKamiokaNDE [46]. We assume these experiments find no evidence for unitary violation and use as future constraint

$$|U_{\tau 4}|^2 < 0.048 \text{ at } 90\% \text{ C.L.}, \ (A.2)$$

which is achievable with, for example, with 5.6 Mton year exposure of HyperKamiokaNDE.

### A.2 Atmospheric tau appearance

IceCube [41] and SuperKamiokaNDE [42] have constrained the tau normalization $N_\tau$ defined as the ratio of the measured $\nu_\tau$ flux to the expected one assuming standard oscillations. The results are

$$N_\tau = 1.47 \pm 0.32 \text{ from SuperKamiokaNDE}, \ (A.3)$$

$$N_\tau = 0.57^{+0.36}_{-0.34} \text{ from IceCube.} \ (A.4)$$

As the signal events are rather centered in one energy and zenith angle bin we use a 1 bin analysis for true energies\textsuperscript{13}. We simulate the decrease of events in the energy-zenith angle space as two Gaussians for energy and zenith angle centered at 20 GeV (15 GeV), with $\sigma = 20 \ (10)$ GeV for IC (SK), and zenith angle centered at $\cos(\theta_z) = -1$ with $\sigma = 0.3(0.2)$ for IC (SK). We integrate over the full zenith angle range between -1 and 0 and between 5.6-56 GeV for IC and 3.50-70 GeV for SK which are the ranges these experiments are sensitive to tau appearance. For these measurements the tau neutrinos are detected in CC processes coming from muon neutrinos produced in the atmosphere. The number of $\nu_\tau$ events in a bin is parameterized as

$$n_{\nu_\tau}^{\text{theo}} = \sigma_{2}^{CC,SM} (UU^\dagger)_{\tau\tau} \phi_{\mu}^{SM} (UU^\dagger)_{\mu\mu} \hat{P}_{\mu\tau} (UU^\dagger)_{\mu\mu} (UU^\dagger)_{\tau\tau} \ (A.5)$$

where $\hat{P}_{\mu\tau}$ is defined in eq. 2.7. The tau normalization can be written as the ratio of the measured tau neutrino flux to the theoretical expectation in a 3U framework,

$$N_\tau = \frac{\phi_{\mu\tau}^{\text{meas}}}{\phi_{\mu\tau}^{\text{theo}}} = \frac{\hat{P}^{UV}_{\mu\tau}}{\hat{P}^{3U}_{\mu\tau}} \ (A.6)$$

where we use the best fit values from [59] in the calculation of $\hat{P}^{3U}_{\mu\tau}$. As it has been shown in [34] the sensitivity to the tau normalization comes from SM matter effects which we

\textsuperscript{13}We take the translation between reconstructed and true energy into account.
parameterize with a constant density of $\rho = 7 \text{ g/cm}^3$. We then integrate over the energy and zenith angle to obtain $\tilde{P}^\mu\bar{\nu}^\tau$.

These constraints are going to be improved in the future by IceCube-Gen2, KM3NeT/ORCA [43–45] and by Hyper-KamiokaNDE [46]. For future measurements by IceCube-Gen2 and KM3NeT/ORCA we assume that the tau normalization will be

$$N_r = 1 \pm 0.15 \text{ from KM3NeT/ORCA or IceCube-Gen2} \quad (A.7)$$

which can be achieved for example with 1 year of KM3NeT/ORCA data [44]. To simulate the improvement we use a 1-bin analysis with a Gaussian centered at 20 GeV, $\sigma = 10$ GeV and $\cos \theta_z = -1 \sigma = 0.3$ integrated over 6-70 GeV. For the improvement by Hyper-KamiokaNDE we assume [46]

$$N_r = 1 \pm 0.07 \text{ from HyperKamiokaNDE} \quad (A.8)$$

and use the same Gaussians as for SuperKamiokaNDE.

### A.3 Astrophysical tau appearance

Astrophysical neutrinos are produced in sources via the decays of pions, muons, or neutrons. These particles only produce electron and muon neutrinos such that the detection of astrophysical tau neutrinos indicates flavor change.

IceCube has detected 2 high-energy astrophysical tau neutrinos which leads to a flux (sum of neutrinos and anti-neutrinos) of [49]

$$\frac{d\phi_{\nu_\tau}}{dE} = 3.0^{+2.2}_{-1.8} \left( \frac{E}{100 \text{ TeV}} \right)^{-2.87^{+0.21}_{-0.20}} \cdot 10^{-18} \text{ GeV}^{-1} \text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \quad (A.9)$$

as well as a flux of astrophysical muon neutrinos which lead to tracks in the IceCube detector (for the sum of neutrinos and anti-neutrinos) [50]

$$\frac{d\phi_{\text{track}}}{dE} = 1.44^{+0.25}_{-0.24} \left( \frac{E}{100 \text{ TeV}} \right)^{-2.28^{+0.08}_{-0.09}} \cdot 10^{-18} \text{ GeV}^{-1} \text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1}. \quad (A.10)$$

The number of events of flavor $\alpha$ at IceCube is given by

$$n_{\nu_\alpha}^{\text{theo}} = \sigma_{\alpha}^{CC,SM}(UU^\dagger)_{\alpha\alpha} \times \phi_p(\xi(UU^\dagger)_{ee}P_{e\alpha} + (1 - \xi)(UU^\dagger)_{\mu\mu}P_{\mu\alpha}) \quad (A.11)$$

with the flux of the decaying particle $\phi_p$ ($p = \text{pion, muon, or neutron}$). The factor $\xi$ parameterizes the fraction of produced electron neutrinos per decaying particle from $\xi = 0$ (pion) to $\xi = 1$ (neutron). Hence the product of $\phi_p\xi$ corresponds to the initial electron flux produced in the source (and $\phi_p(1 - \xi)$ for the produced muon flux). As the origin of astrophysical neutrinos is unclear we will scan over $\xi$ between 0 and 1 in our analysis and not assume any prior on $\xi$. Furthermore, we assume that no sterile neutrinos are produced at the source.
As neutrino oscillation lengths are much smaller than astrophysical scales oscillations are quickly averaged out and neutrinos have decohered when they arrive at the detector. Therefore the oscillation probability doesn’t contain a kinematic factor and is

\[ P_{\alpha\beta} = \frac{1}{(U U^\dagger)_{\alpha\alpha}(U U^\dagger)_{\beta\beta}} \sum_{i=1}^{acc} |U_{\alpha i}|^2 |U_{\beta i}|^2. \]  

(A.12)

Furthermore, IceCube cannot easily distinguish between neutrinos and anti-neutrinos. As we don’t know \( \phi_p \) we analyze the ratio of tau events to track event which is independent on \( \phi_p \)

\[ \left( \frac{\phi_{\nu_\tau}}{\phi_{\text{track}}} \right)_{\text{meas}} = \frac{\xi \sum_{i=1}^{acc} |U_{\alpha i}|^2 |U_{\tau i}|^2 + (1 - \xi) \sum_{i=1}^{acc} |U_{\mu i}|^2 |U_{\tau i}|^2}{(1 - \xi) \sum_{i=1}^{acc} |U_{\mu i}|^4 + \xi \sum_{i=1}^{acc} |U_{\alpha i}|^2 |U_{\mu i}|^2}. \]  

(A.13)

This ratio is also independent of the CC cross section as for high energies this quantity is flavor independent [73]. Finally, we focus on the \( E = 100 \) TeV bin of the measurement as it has the smallest uncertainty for all channels [50], this means that we don’t take the uncertainty on the spectral index into account.

In the future also other neutrino telescopes can measure astrophysical \( \nu_\tau \) appearance like IceCube-Gen2, P-ONE, Baikal-GVD, ANITA/PUEO, GRAND, and POEMMA [51, 74–78]. We assume that with future observation of \( \nu_\tau \) appearance the ratio will measured as

\[ \left( \frac{\phi_{\nu_\tau}}{\phi_{\text{track}}} \right)_{\text{meas}} = 1 \pm 0.14. \]  

(A.14)

### A.4 Long baseline accelerator tau appearance

Also human-made experiments with high energy neutrino beams like long baseline experiments are sensitive to tau neutrinos. The OPERA experiment directly detected the first tau neutrinos from oscillations in 2010 [79] and DUNE will continue to contribute to the tau neutrino appearance data set in the future.

The OPERA experiment was located 730 km from the neutrino beam source which had an average neutrino energy of 17 GeV [52]. We parameterize the number of observed events as

\[ n_{\nu_\tau}^{\text{meas}} = A P(\nu_\mu \to \nu_\tau) + B, \]  

(A.15)

where the constant factor \( A \) includes the neutrino (anti-neutrino) flux times cross-section and \( B \) is the background rate. The collaboration provided the background events and the expected number of events for fiducial values of the oscillation parameters [52] which allows to determine \( A \).

The number of events depend on the matrix elements as

\[ n_{\nu_\tau}^{\text{theo}} = \phi_\mu^{SM}(U U^\dagger)_{\mu\mu} \times \frac{1}{(U U^\dagger)_{\mu\mu}(U U^\dagger)_{\tau\tau}} \times \sigma_{\nu_\tau}^{CC,SM}(U U^\dagger)_{\tau\tau} \]  

(A.16)

For these baselines and energies matter effects are important which we parameterize with a matter density of \( \rho = 3 \) g/cm\(^3\). In the (5,3) case we consider also the change of the Fermi
constant as defined in eq. (2.10). We numerically calculate the oscillation probability. Due to the low number of events we conduct a Poisson analysis of the number of events. To validate our OPERA simulation we calculate the mass splitting in the (3,3) case \( \Delta m_{32}^2 = (2.7^{+0.9}_{-0.6}) \times 10^{-3} \text{ eV}^2 \) which is in good agreement with the experimental result from [52]

\[
\Delta m_{32}^2 = (2.7^{+0.7}_{-0.6}) \times 10^{-3} \text{ eV}^2
\]

In the future, DUNE will also provide valuable insights into the tau row. This experiment will also improve the other rows which by itself will advance the knowledge of the tau row using the unitarity conditions. We use literature results for the constraints in the (4,4) and (5,3) case from [53] (see also [80]) which assume 3.5 years \( \nu \) data + 3.5 years \( \bar{\nu} \) data. For the (4,4) case using \( \nu_e \)-appearance, \( \nu_\mu \)-disappearance data, and \( \nu_\tau \)-appearance [53] the constraint is

\[
\sin^2 \theta_{34} \leq 0.31 \text{ at 95\% C.L. . (A.17)}
\]

The constraint in the (5,3) case is [53]

\[
|U_{e3}|^2 + |U_{\mu 3}|^2 + |U_{\tau 3}|^2 = 1^{+0.05}_{-0.06} . (A.18)
\]

To avoid double counting we assume no improvements on the other rows when presenting future constraints on the tau row (see also discussion in the main text).

Notice that DUNE will also have near detector from which the neutrino flux and cross section can be extracted. If these measured quantities are used in the analysis the cancellation of the prefactors in the number of expected events is not present. For example for tau neutrino appearance at the DUNE far detector the expected number of \( \nu_\tau \) events is

\[
n_{\nu_\tau}^{\text{theo}} = \phi_{\mu}^{\text{meas}} \times \tilde{P}_{\mu\tau} \frac{1}{(UU^\dagger)_{\mu\mu}(UU^\dagger)_{\tau\tau}} \times \sigma_{\tau}^{CC,\text{meas}} . (A.19)
\]

In this case the matrix elements appear in several places, potentially increasing the sensitivity to them.

### A.5 Scattering experiments

Scattering experiments which are not sensitive to oscillations still provide valuable constraints on the tau row as we demonstrate in the following.

#### A.5.1 Charged current scattering experiments

Tau neutrino scattering experiments with a short baseline are sensitive to tau neutrino disappearance. If the 3 × 3 active-light mixing matrix is unitary the tau neutrino survival probability is 1 as for these experiments no SM oscillations have developed.

**DONuT** The DONuT experiment discovered tau neutrinos for the first time in 2000 by using a high energy beam with mean energy \( E \sim 100 \text{ GeV} \) and a detector close to the source with a baseline \( L \approx 40 \text{ m} \) [56].
We compare the number of observed events which is 9 to the number of predicted events from a Monte Carlo simulation which is 10. The difference is \(-1 \pm 4\) [56]. The number of expected events is parameterized as
\[
 n_{\nu\tau}^{\text{theo}} = \phi_{\tau}^{\text{SM}} (U U^\dagger)_{\tau\tau} \times \frac{1}{\tilde{P}_{\tau\tau}} \times \sigma_{\tau\tau}^{\text{CC,SM}} (U U^\dagger)_{\tau\tau} .
\] (A.20)

In the (4,4) case the probability is
\[
 \tilde{P}_{\tau\tau} = 1 - 2 |U_{\tau4}|^2 (|U_{\tau1}|^2 + |U_{\tau2}|^2 + |U_{\tau3}|^2) .
\] (A.21)

For the (5,3) case the sensitivity to the matrix elements comes from the first term in oscillation probability
\[
 \tilde{P}_{\tau\tau} = |U_{\tau1}|^2 + |U_{\tau2}|^2 + |U_{\tau3}|^2 \neq 1 .
\] (A.22)

**FASERnu** In the future FASERnu will use tau neutrinos from the LHC to measure tau cross sections\(^{14}\). The baseline is \(L = 480\) m and like DONuT, FASERnu also has a broad neutrino energy spectrum but with a much larger mean energy \(E \approx 1\) TeV . For FASERnu the number of expected detected events is \(\sim 11\) [57] and we assume that the number of observed events equals the number of expected events. The quantity to be constrained is the same as for DONuT in the previous subsection.

**NOMAD** NOMAD and CHORUS were experiments searching for tau appearance in the CERN wide-band \(\nu_\mu\) beam with \(E_\nu \sim 20 - 30\) GeV at a distance of 800 m. At these values of \(L/E\) no SM oscillations have developed yet such that the results can be used to constrain sterile oscillations. The oscillation probabilities have been constrained by NOMAD to be\(^{15}\) [54]
\[
 P(\nu_\mu \to \nu_\tau) < 1.63 \times 10^{-4} \text{ at } 90\%\text{C.L.} ,
\] (A.23)
\[
 P(\nu_e \to \nu_\tau) < 0.74 \times 10^{-2} \text{ at } 90\%\text{C.L.} .
\] (A.24)

The analytical expression of the oscillation probability is
\[
 \tilde{P}(\nu_\mu \to \nu_\tau) = \left| \sum_{i=1}^{\text{acc}} U_{\mu i}^* U_{\tau i} \right|^2 - 2 \Re \left( \sum_{j=\text{heavy}} U_{\mu j}^* U_{\tau j} \sum_{i=1}^3 U_{\mu i} U_{\tau i}^* \right) ,
\] (A.25)

where the first sum goes over all kinematically accessible mass states, the second is over accessible mass states that are heavy compared to \(m_1, m_2,\) and \(m_3,\) and the third sum is over just the first three mass states. The pairing of the second two sums is to ensure that the relevant \(\Delta m_{ji}^2 L/4E\) is large enough to be oscillation averaged. In the (4,4) case the first term (the so-called “zero-distance term”) in eq. A.25 is just \(\delta_{\mu\tau}\) while in the (5,3) case the second term (due to oscillation averaged) in eq. A.25 is zero.

\(^{14}\)We focus on FASERnu but also other experiments at the LHC are sensitive to tau neutrinos like SBND@LHC [81] however they expect less \(\nu_\tau\) events; see [58] for an overview of future forward physics facilities.

\(^{15}\)CHORUS has similar but slightly weaker constraints [55].
In the (4,4) case these experiments provide a constraint on the second term in the oscillation probability which depends as $\tilde{P}_{\mu\tau} \propto U_{\mu4}U_{\tau4}$. With a prior on $U_{\mu4}$ from the normalization of the muon row from [9] which is compatible with 0 at $1\sigma$ this also means that the oscillation probability $P_{\mu\tau}$ is compatible with 0 at $1\sigma$, hence we don’t obtain a constraint on $U_{\tau4}$ from NOMAD alone (equal arguments apply to $P_{e\tau}$) in the (4,4) case. This statement can be easily understood as the effect of a sterile neutrino needs to be present in both the appearance and disappearance channels.

For the (5,3) case the second part of the probability is zero but the first part is $\leq 1$ as not all mass states are accessible. The constraint in this case is on

$$\tilde{P}_{\mu\tau} = |U_{\mu1}^* U_{\tau1} + U_{\mu2}^* U_{\tau2} + U_{\mu3}^* U_{\tau3}|^2$$

and similarly for $P_{e\tau}$.

A.5.2 Neutral current scattering experiments

Even though one does not identify tau neutrinos in neutral current measurements a non-unitary matrix still affects the measurement due to a reduction of the flux and detection cross section. In fact, these measurements have potentially large statistics such that they dominate the combined fits. A crucial point about constraints of NC measurements is that the experimental result needs to be compared to a theory prediction of the number of events. This means the experiments benefit from theory predictions with small uncertainties.

CEvNS Coherent elastic neutrino nucleus scattering (CEvNS) describes a NC process where a neutrino scatters of a nucleus coherently [82]. This process was first observed by the COHERENT collaboration in 2017 using low energy neutrinos from pion decays at rest at the SNS [83]. Although CEvNS detectors are not sensitive to SM oscillations and the initial flux does not contain $\nu_\tau$ their measurements still lead to constraints on the tau row as the detection process is NC.\footnote{See [84] where UV constraints from CEvNS have been derived.} This is an example of how flavor blind detection processes can constrain the tau row. As an illustrative case we use the CEvNS measurement with the COHERENT CsI and Ar detectors\footnote{Notice that our results are independent of detector material as long as the same number of events with a similar uncertainty are detected.}. The initial flux contains muon and electron neutrinos from pion and muon decays at a stopped pion source. Due to the finite lifetime and different energy distributions of the flux different initial flavors can be partially distinguished. We conduct a simplified analysis using two timing bins integrated over the energy, the first bin ($t < 1 \mu s$) contains events from the prompt pion decay which produces muon neutrinos, the second bin ($t \in (1, 5) \mu s$) contains events from electron and muon neutrinos from the delayed muon decay.

In our analysis we use the results from [85–87] for the COHERENT Ar detector and [88] for the newest results from the COHERENT CsI detector. These references provide the number of expected events, measured events and background events. Due to the short baselines of $\mathcal{O}(20 \text{ m})$ and low energies $E \sim 30 \text{ MeV}$ at these detectors no oscillations have
developed in the standard picture and the number of coming from flavor $\alpha$ ($\alpha = e, \mu$) are

$$n_{NC}^{CE_{eNS}} = \sigma^{NC, SM}_{\alpha e} \sum_{\alpha = e, \mu} \phi^{SM}_{\alpha} \sum_{\beta = e} \left[ \sum_{i=1}^{\text{acc}} U_{\alpha i}^* U_{\beta i} \right]^2 - 2 \Re \left( \sum_{j=\text{heavy}}^{\text{acc}} U_{\alpha j}^* U_{\beta j} \sum_{i=1}^{3} U_{\alpha i} U_{\beta i} \right) \left( U U^\dagger \right)_{\beta \beta},$$

(A.27)

where the square bracket term is the same as the probability for NOMAD in eq. A.25, but the event rate now has an additional factor of $\left( U U^\dagger \right)_{\beta \beta}$ since this is a NC interaction.

We conduct a simple $\chi^2$ analysis$^{18}$ comparing the observed number of events to the predicted number of events including constant nuisance parameters on the signal normalization, the steady state background normalization, and the normalization of the beam related neutrons with uncertainties provided in [85–88].

In the future we forecast that events corresponding to 5 time the exposure of the CsI detector are detected. We assume an improvement of the signal normalization from 13% to 7%, possible for example with better quenching factor and efficiency measurements, and steady state and neutron background normalizations of 1%. Currently the signal normalization uncertainty is driven by the uncertainty on the neutrino flux. In the future this uncertainty can be reduced with the $D_2O$ detector [90] installed at the SNS by measuring the $\nu_e + d$ CC interactions. This measurement will however be impacted by the presence of UV as well which leads to a change in the CC cross section. Hence to make use of this data in a UV framework with future data, this effect needs to be included as well.

**NC measurement of solar neutrinos** The NC measurement of solar neutrinos by SNO proved to be crucial for establishing neutrino oscillations. Even though this measurement was insensitive to the neutrino flavors some of the detected neutrinos are tau neutrinos as all mass eigenstates have a sizeable $\nu_\tau$ component. By comparing the measured NC flux to the theoretical prediction we can hence obtain constraints on tau neutrinos.$^{19}$

From [91] using the standard solar model the theoretical expectation for the $^8\text{Be}$ flux is

$$\phi^{\text{theo}}_{\nu} = (5.88 \pm 0.65) \times 10^6 \text{ cm}^{-2}\text{s}^{-1} \text{(BPS09(GS))},$$

(A.28)

$$\phi^{\text{theo}}_{\nu} = (4.85 \pm 0.58) \times 10^6 \text{ cm}^{-2}\text{s}^{-1} \text{(BPS09(AGSS09))}$$

(A.29)

which needs to be compared to the measurement by SNO [91]

$$\phi^{\exp}_{\nu} = (5.25 \pm 0.16 \text{ (stat.)}^{+0.11}_{-0.13} \text{ (syst.)}) \times 10^6 \text{ cm}^{-2}\text{s}^{-1}.$$  

(A.30)

$^{18}$It has been shown in [89] that a careful statistical treatment is necessary to obtain robust constraints on new physics parameters. This conclusion was derived for the example of non standard interactions. For UV one would need to conduct a detailed study to see if these conclusions hold. We leave this for future work.

$^{19}$Previous UV fits also took solar data into account however as a ratio of the CC flux over the NC flux. However, since we are focusing on the tau row, the only information that would come to $U_{\tau 2}$ is from a knowledge of $U_{e 2}$ and $U_{\mu 2}$, but $U_{\tau 2}$ cannot be separated from $U_{\tau 1}$ based on KamLand data; data from JUNO, however, will be able to break the $\nu_1 \leftrightarrow \nu_2$ degeneracy separate from solar data.
Table 2. Overview of the experiments considered in this analysis including the way we analyze their data, the processes related to production and detection of neutrinos and if there is a cancellation of the normalization terms in the number of events. For forecasted DUNE events which rely on theoretical input for the cross section and flux from simulations there are cancellations in the denominator however as soon as near detector data will be used in the analysis there won’t be a cancellation anymore as measured quantities will get compared (see main text for more details).

| experiment                              | measurement | production | detection | cancellation |
|-----------------------------------------|-------------|------------|-----------|--------------|
| atmospheric $\nu_\mu$ disappearance     | $n_{\nu_\mu}^\text{meas}$ vs $n_{\nu_\mu}^\text{theo}$ | CC         | CC         | yes          |
| atmospheric $\nu_\tau$ appearance      | $n_{\nu_\tau}^\text{meas}$ vs $n_{\nu_\tau}^\text{theo}$ | CC         | CC         | yes          |
| astrophysical $\nu_\tau$ appearance    | $n_{\nu_\tau}^\text{meas}$ vs $n_{\nu_\tau}^\text{meas}$ | CC         | CC         | yes          |
| solar data                              | $\phi_{\nu_\mu}^\text{meas}$ vs $\phi_{\nu_\mu}^\text{theo}$ | CC         | NC         | no           |
| DONuT/FASERnu                           | $n_{\nu_\tau}^\text{meas}$ vs $n_{\nu_\tau}^\text{theo}$ | CC         | CC         | yes          |
| LBL $\nu_\tau$ appearance (OPERA)      | $n_{\nu_\tau}^\text{meas}$ vs $n_{\nu_\tau}^\text{theo}$ | CC         | CC         | yes (→ no)   |
| LBL $\nu_\tau$ appearance (DUNE)       | $n_{\nu_\tau}^\text{meas}$ vs $n_{\nu_\tau}^\text{theo}$ | CC         | CC         | yes (→ no)   |
| LBL $\nu_\mu$ disappearance (DUNE)     | $n_{\nu_\mu}^\text{meas}$ vs $n_{\nu_\mu}^\text{theo}$ | CC         | CC         | yes          |
| CEvNS                                   | $n_{\nu_\tau}^\text{meas}$ vs $n_{\nu_\tau}^\text{theo}$ | CC         | CC         | yes          |
| NOMAD/CHORUS                            | $P_{e/\mu\tau}^\text{exp}$ vs $P_{e/\mu\tau}^\text{theo}$ | CC         | CC         | yes          |

As the two theoretical values slightly disagree we use their average value with an uncertainty which also includes the $1\sigma$ values of each of the individual predictions

$$\phi_{\nu_\mu}^{\text{pred}} = (5.365 \pm 1.1) \times 10^6 \text{ cm}^{-2}\text{s}^{-1}.$$  \hspace{1cm} (A.31)

The number of events is

$$n_{\nu_\mu}^{\text{theo}} = \phi^{SM}(UU^\dagger)_{ee} \times \sum_{j=1}^{\text{acc}} \sum_{i=1}^{\text{acc}} |(U^\dagger U)_{ij}|^2 \times \bar{P}_{ei} \times \frac{1}{(UU^\dagger)_{ee}}.$$  \hspace{1cm} (A.32)

Note that the sums in the $U^\dagger U$ go over $\alpha \in \{e, \mu, \tau\}$ in the term from the cross section in the numerator. Since the states are properly normalized $(U^\dagger U)_{ii} = 1$ if summed over $\alpha \in \{e, \mu, \tau\}$. At $E \gtrsim 10$ MeV, $\bar{P}_{e1} \simeq 0$, $\bar{P}_{e2} \simeq |U_{e1}|^2 + |U_{e2}|^2$, $\bar{P}_{e3} \simeq |U_{e3}|^2$. In the (4,4) case additionally $\bar{P}_{e4} = |U_{e4}|^2$. Notice that since the sterile mass splitting is large enough to not be relevant for the transitions the Sun this probability is the same as in vacuum. In our analysis we are comparing the measured flux to the theory prediction, hence

$$\phi_{\nu_\mu}^{\text{meas}} = \phi^{SM}_{\nu_\mu} \times \sum_{i=1}^{\text{acc}} \sum_{j=1}^{\text{acc}} |(U^\dagger U)_{ij}|^2 \times \bar{P}_{ei}.$$  \hspace{1cm} (A.33)

As the theoretical uncertainty on the flux is larger than the experimental one the constraints from solar data are rather weak, see sec. 3. This means in order to obtain strong constraints from future measurements of the solar neutrino flux, for example by JUNO [92], an improvement of the theoretical prediction of the flux is necessary.

It should be noted that elastic scattering processes are also sensitive to tau matrix elements however the flavor blind cross section is smaller than one involving electron neutrinos. For this reason we focus on the NC measurement in our analysis.
A.6 Summary of experiments

We provide in table 2 a summary of all (current and future) experiments considered in the main text.
