(Dated: February 17, 2022)

Consider a Brownian particle in three dimensions which is attracted by a plane with a strength proportional to some dimensionless parameter $\alpha$. We investigate the fractal spatial structure of the visited lattice sites in a cubic lattice by the particle around and on the attractive plane. We compute the fractal dimensions of the set of visited sites both in three dimensions and on the attractive plane, as a function of the strength of attraction $\alpha$. We also investigate the scaling properties of the size distribution of the clusters of nearest-neighbor visited sites on the attractive plane, and compute the corresponding scaling exponent $\tau$ as a function of $\alpha$. The fractal dimension of the curves surrounding the clusters is also computed for different values of $\alpha$, which, in the limit $\alpha \to \infty$, tends to that of the outer perimeter of planar Brownian motion i.e., the self-avoiding random walk (SAW). We find that all measured exponents depend significantly on the strength of attraction.

I. INTRODUCTION

The laws of Brownian motion, formulated first by Einstein more than a century ago [1], have now found so many applications and generalizations in all quantitative sciences [2]. Many fractal structures in the nature can be derived from the sample paths of Brownian motion characterized by some appropriate fractal dimensions [3].

A $d$-dimensional Brownian motion is known to be recurrent, i.e., the particle returns to the origin, for $d \leq 2$ and escapes to infinity for $d > 2$. It is also known that the fractal (Hausdorff) dimension of the graph of a Brownian motion is equal to $3/2$ for $d = 1$, and 2 for $d \geq 2$.

The scaling limit of interfaces in various critical $2d$ lattice models are proven or conjectured to be described by the family of conformally invariant random curves i.e., Schramm-Loewner evolution (or SLE) [4] which is driven by a $1d$ Brownian motion of diffusivity $\kappa$ [5].

One of the most important invariance properties of planar Brownian motion is conformal invariance. Although the scaling limit of $2d$ random walk, i.e., $2d$ Brownian motion, because of self-crossing itself does not fall in the SLE category, variations of Brownian motion are described by SLE. Loop erased random walk (LERW) where loops are removed along the way, is one of the examples which has been studied by Schramm and shown that can be described by SLE$_2$.

The external perimeter of $2d$ random walk is also a non-intersecting fractal curve which can be defined by SLE. Verifying an earlier conjecture by Mandelbrot [3], it has been proven using SLE techniques [6] that the fractal dimension of the Brownian perimeter is $d_f = 4/3$, i.e. the same as the fractal dimension of self-avoiding random walk (SAW) and the external perimeter of the percolation hull.

In this paper, we investigate the statistical and fractal properties of a $3d$ random walker which is attracted by a plane. We believe that this study can provide useful intuitive extensions for many related physical phenomena including the problems with a discrete time lattice walk [7, 8], relaxation phenomena [9], exciton trapping [10] and diffusion-limited reactions [8, 11].

II. THE MODEL

We consider a random walker moving along the bonds of a cubic lattice with the $xy$-plane as an attractive plane. The ‘walker’ source is considered to be the origin of the coordinate system. At each lattice point with $z \neq 0$, there are six possibilities for the random walker to select a link and move along. In our model, the random walker prefers walking on and near the attractive plane, and thus the probability that the random walker chooses the link which approximates it to the attractive plane is set to be $\alpha p$, and for remaining five links is considered to be $p$, such that $\alpha > 1$ (and will be called the strength of attraction) and $p = \frac{1}{\alpha + 5}$. For each lattice point on the attractive plane with $z = 0$, the probability that each of the four links on the plane to be chosen is set to be $\alpha'p'$ and for two other links perpendicular to the plane is considered to be $p'$, where $p' = \frac{1}{\alpha' + 2}$. The single parameter $\alpha$ in our model, controls the strength of attraction. Note that in the limiting case $\alpha \to \infty$ our model reduces to the pure $2d$ random walk on the plane, and for $\alpha = 1$ the pure $3d$ random walk would be recovered.

Thus there are four possible probabilities. $\alpha p'$ for links that are in the attractive plane, $p'$ for links from the attractive plane to either of the neighboring planes, $p$ for links in all of the neighboring planes or leading from them into the bulk, and $\alpha p$ for links from all the neighboring planes to the attractive plane.

By detailed balance, in equilibrium at inverse temperature $\beta$, the ratio $\alpha p/p'$ of the probabilities onto and

*Electronic address: a_saberi@ipm.ir; ab.saberi@gmail.com
off the attractive plane, defines an attraction energy
\( \beta \varepsilon = \ln[2\alpha(1+2\alpha)/(\alpha + 5)] \).

III. FRACTAL DIMENSION OF THE SET OF ALL VISITED SITES AND ITS LEVEL SET

In the cases of random walks, systems exhibit a generic scale invariance, meaning that the systems can exhibit self-similarity and power laws without special tuning of parameters. This is why we already expect that our model would exhibit rich fractal properties for all values of \( \alpha \).

Let us first look at the fractal spatial structure of the 3d attracted random walk (ARW) and its intersection with the attractive plane. In order to estimate the fractal dimension \( d_f \) of the set of points visited (at least) once by the random walker, we examine the scaling relation between the average number of such points \( M^{(3d)} \) and their corresponding radius of gyration \( R_g \), i.e., \( M^{(3d)} \sim R_g^{d_f} \).

Each ensemble averaging for \( M^{(3d)} \) (and also for \( M^{(2d)} \) in the following) and \( R_g \) was taken over 5 \( \times \) \( 10^4 \) independent samples for a fixed number of random walk steps \( N \). The measurements were done for \( 10^3 \leq N \leq 10^5 \) with the number interval \( \delta N = 2 \times 10^3 \). We have also computed the fractal dimension of the total number of sites on the attractive plane (i.e., \( M^{(2d)} \)) visited by the random walker (in this case the corresponding radius of gyration is computed for all set of distinct visited sites

\[
M^{(3d)} \sim R_g^{d_f} \sim R_g^{1.87},
\]

\[
M^{(2d)} \sim R_g^{d_f} \sim R_g^{1.955},
\]

\[
\alpha = 1.3, \quad \alpha = 10.
\]

FIG. 1: (Color online) The average number of total lattice sites \( M^{(3d)} \) visited (at least) once by the attracted random walker (ARW) (main panel), and those \( M^{(2d)} \) on the attractive plane (inset), as function of their average radius of gyration for two different values of the strength of attraction \( \alpha = 1.3 \) (□) and \( \alpha = 10 \) (▲). The solid lines show the best fit to our data. The error bars are almost the same size as the symbols.

We find that the fractal dimensions have a remarkable continuous dependence on the parameter \( \alpha \). The results of these fractal dimensions as function of the strength of attraction \( \alpha \) are illustrated in Fig. 2. As can be seen from figure 2, for large values of \( \alpha \), since the problem reduces to the 2d random walk on the attractive plane, these two fractal dimensions converge to the same value close to the value \( \sim 1.83 \) (this is comparable with the fractal dimension of the set of distinct sites visited by an 2d RW on a square lattice, deduced from the results reported in [12]).

All error bars in this paper are estimated by using the standard least-squares analysis, and are almost of the same size as the symbols used in the figures.

For an ideal linearly self-similar fractal of dimension \( d_f \), one expects that the fractal dimension of the intersection being \( d_f' = d_f - 1 \) [3]. But this is not apparently the case here for \( \alpha \neq 1 \), since in our model, the attractive plane has disturbed the homogeneity of the probability distribution in the z-direction. Only for \( \alpha = 1 \) where \( d_f = 2 \) [15], we find \( d_f' = 1 = d_f - 1 \).

IV. CLUSTER SIZE DISTRIBUTION ON THE ATTRACTIVE PLANE

Henceforth we investigate the fractal and scaling properties of the set of all distinct sites visited by the 3d ARW only on the attractive plane. Each of these sites is visited at least once by the 3d ARW and marked upon visiting
In this section, rather than analyzing the properties of the whole set, after marking all visited sites on the plane, we identify each cluster-site as a set of all nearest-neighbor visited-sites on the lattice with a specific color. Two typical examples of such clustering are shown in Fig. 3 for two different values of the strength of attraction, the number of isolated clusters decreases until \( \alpha \to \infty \) for which, there will be only one large cluster on the attractive plane.

![Cluster examples](image)

**FIG. 3:** (Color online) Typical samples of clusters of the visited sites on the attractive plane by a 3d ARW of \( N = 10^6 \) shown in different colors, for \( \alpha = 2 \) (left) and \( \alpha = 10 \) (right).

To examine possible scale invariance of cluster ensemble for rather small values of \( \alpha \), we compute the cluster size distribution and check whether it follows a power-law scaling. In the critical statistical physics, the scaling properties of fractal clusters can be described by the percolation theory \([13]\), where the asymptotic behavior of cluster distribution \( n_s(\lambda) \) near the critical point \( \lambda \to \lambda_c \) has the following general form

\[
n_s(\lambda) = s^{-\tau} F[(\lambda - \lambda_c)s^\sigma],
\]

where \( \sigma \) is an critical exponent, and the scaling function \( F(u) \) approaches to a constant value for \( |u| \ll 1 \) and decays rather fast for \( |u| \gg 1 \).

We undertook simulations for several values of \( \alpha \) to measure the distribution of the cluster sizes of the visited lattice sites by the 3d ARW on the attractive plane (this is the probability that a visited lattice site on the attractive plane belongs to a cluster of size \( s \)). We gathered ensembles of a number of \( 5 \times 10^4 \) (for smaller \( \alpha \)) and \( 1.5 \times 10^6 \) (for larger values of \( \alpha \)) independent samples of fractal patterns with marked visited-sites on the attractive plane. The number of the random walk steps was chosen to be \( N = 4 \times 10^6 \) in all simulations. The number density \( n_s \) of the clusters of size \( s \) has then been computed for each specific value of \( \alpha \) by counting the number of clusters of size \( s \) divided by the total number of all clusters.

We find that for rather small and intermediate size scale clusters, the distribution shows a power law behavior compatible with the scaling relation in Eq. (1). As can be seen in the inset of Fig. 4, the curves for different values of \( \alpha \) exhibit a sharp drop-off, indicating indeed that they contain only small clusters. By increasing \( \alpha \) the interval for scaling region decreases and a peak appears which signals the formation of large scale clusters.

Our estimation of the cluster size distribution exponent \( \tau \) in the scaling region as a function of \( \alpha \) is also shown in Fig. 4. One observes that the exponent \( \tau \) has a significant dependence on the strength of attraction \( \alpha \).

**V. FRAC TAL DIMENSION OF THE CLUSTER BOUNDARIES ON THE ATTRACTIVE PLANE**

The remainder of this paper is dedicated to investigate the fractal properties of the boundaries of the visited-sites clusters on the attractive plane.

Given a configuration of visited sites by the 3d ARW on the attractive plane, the first step is to identifying different clusters as outlined before. After that, the boundary curve of each isolated cluster has to be identified. However the definition of interfaces and cluster boundaries on a square lattice can contain some ambiguities, there has been introduced a well-defined *tie-breaking* rule in \([14]\) that generates non-intersecting cluster boundaries on a square lattice without any ambiguity. To define the hull for each identified cluster according to the algorithm defined in \([14]\), a walker (which, of course, has to be distinguished from the 3d ARW) moves clockwise along the edges of the dual lattice (which is also a square lattice) around the cluster starting from a given boundary edge on the cluster. The direction at each step...
is always chosen such that walking on the selected edge leaves a visited site on the right and an empty plaquette on the left of the walker. If there are two possible ways of proceeding, the preferred direction is that to the right of the walker. The directions right and left are defined locally according to the orientation of the walker.

According to this procedure, we have generated an ensemble of cluster boundary loops for several different strengths of attraction in the range $1 \leq \alpha \leq 16$. Using the scaling relation $l \sim r_g^{d_f}$, between the average length of the perimeter of the loops $l$ and their average radius of gyration $r_g$, we computed the fractal dimension $d_f$ of the cluster boundaries as a function of $\alpha$. The results are shown in Fig. 5.

The fractal dimension shows again a significant dependence on the strength of attraction $\alpha$. In the limit $\alpha \to \infty$ $d_f$ converges to the value $\frac{4}{3} = 1.33$ which is the fractal dimension of the SAW i.e., the outer perimeter of the planar Brownian motion.

VI. CONCLUSIONS

In this paper, we have studied the scaling properties and the fractal structure of the visited lattice-sites by a Brownian particle in 3d which is attracted by a plane with the strength $\alpha$. The fractal dimensions of the set of visited sites by the 3d random walker in both three dimensions and on the attractive plane are computed which both converge to the same value $\sim 1.83$ for large $\alpha$. We also found that size distribution of the cluster of visited sites by the particle on the attractive plane, has a scaling form characterized by an exponent that depends significantly on the strength of attraction.

The fractal dimension of the surrounding loops of the clusters on the plane has been computed as a function of $\alpha$. This also converges asymptotically to the expected value for SAW i.e., the external perimeter of a planar Brownian motion.

These results need however some theoretical framework and mathematical proof. The other interesting feature which can be investigated, is the possible conformal invariance of the cluster boundaries on the attractive plane, which can be treated using SLE techniques (such study is already done only for the limiting case $\alpha \to \infty$ where the problem reduces to a 2d random walk in the attractive plane whose boundary is described by SLE$_{8/3}$). The fractal dimension of an SLE$_{\kappa}$ curve is given by $d_f = 1 + \kappa / 8$. In case of conformal invariance of cluster boundaries on the attractive plane in our model, they would be defined by a diffusivity $\kappa$ which depends on the strength of attraction.
