We present a model of discrete quantum evolution based on quantum correlations between the evolving system and a reference quantum clock system. A quantum circuit for the model is provided, which in the case of a constant Hamiltonian is able to represent the evolution over $2^n$ time steps in terms of just $n$ time qubits and $n$ control gates. We then introduce the concept of system-time entanglement as a measure of distinguishable quantum evolution, based on the entanglement between the system and the reference clock. This quantity vanishes for stationary states and is maximum for systems jumping onto a new orthogonal state at each time step. In the case of a constant Hamiltonian leading to a cyclic evolution it is a measure of the spread over distinct energy eigenstates, and satisfies an entropic energy-time uncertainty relation. The evolution of mixed states is also examined. Analytical expressions for the basic case of a qubit clock, as well as for the continuous limit in the evolution between two states, are provided.

I. INTRODUCTION

Ever since the foundations of quantum mechanics, time has been mostly considered as an external classical parameter. Various attempts to incorporate time in a fully quantum framework have nonetheless been made, starting with the Page and Wootters mechanism [1] and other subsequent proposals [2, 3]. This subject has recently received increasing attention in both quantum mechanics [4-8] and general relativity [9,10], where this problem is considered a key issue in the connection between both theories. In the present work we introduce a simple discrete quantum model of evolution, which on one hand, constitutes a consistent discrete version of the formalism of [1, 8], while on the other hand, provides a practical means to simulate quantum evolutions. We show that a quantum circuit for the model can be constructed, which in the case of a constant Hamiltonian is able to simulate the evolution over $N = 2^n$ times in terms of just $n$ time-qubits and $O(n)$ gates, providing the basis for a parallel-in-time simulation.

We then introduce and discuss the concept of system-time entanglement, which arises naturally in the present scenario, as a quantifier of the actual distinguishable evolution undergone by the system. Such quantifier can be related to the minimum time necessarily elapsed by the system. For a constant Hamiltonian we show that this entanglement is bounded above by the entropy associated with the spread over energy eigenstates of the initial state, reaching this bound for a spectrum leading to a cyclic evolution, in which case it satisfies an entropic energy-time uncertainty relation. Illustrative analytical results for a qubit-clock, which constitutes the basic building block in the present setting, are provided. The continuous limit for the evolution between two arbitrary states is also analyzed.

II. FORMALISM

A. History states

We consider a bipartite system $S + T$, where $S$ represents a quantum system and $T$ a quantum clock system with finite Hilbert space dimension $N$. The whole system is assumed to be in a pure state of the form

$$|\Psi\rangle = \frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} |\psi_t\rangle |t\rangle,$$  \hspace{1cm} (1)

where $\{|t\rangle, \ t = 0, \ldots, N-1\}$ is an orthonormal basis of $T$ and $\{|\psi_t\rangle, \ t = 0, \ldots, N-1\}$ arbitrary pure states of $S$. Such state can describe, for instance, the whole evolution of an initial pure state $|\psi_0\rangle$ of $S$ at a discrete set of times $t$. The state $|\psi_t\rangle$ at time $t$ can be recovered as the conditional state of $S$ after a local measurement at $T$ in the previous basis with result $t$:

$$|\psi_t\rangle = |\psi_t\rangle |t\rangle,$$  \hspace{1cm} (2)

where $\Pi_t = 1 \otimes |t\rangle \langle t|$. In shorthand notation $|\psi_t\rangle \propto \langle t|\Psi\rangle$. If we write

$$|\psi_t\rangle = U_t |\psi_0\rangle, \ t = 0, \ldots, N-1,$$  \hspace{1cm} (3)

where $U_t$ are unitary operators at $S$ (with $U_0 = 1$), the state (1) can be generated with the schematic quantum circuit of Fig. 1. Starting from the product initial state $|\psi_0\rangle |0\rangle$, a Hadamard-like gate $|1\rangle$ at $T$ turns it into the superposition $\frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} |\psi_t\rangle |t\rangle$, after which a control-like gate $\sum_{t} U_t \otimes |t\rangle \langle t|$ will transform it in the state (1). A specific example will be provided in Fig. 2.

From a formal perspective, the state (1) is a “static” eigenstate of the $S + T$ translation “super-operator”

$$U = \sum_{t=1}^{N} U_{t,t-1} \otimes |t\rangle \langle t-1|,$$  \hspace{1cm} (4)
where $U_{t, t-1} = U_t U_{t-1}^\dagger$ evolves the state of $S$ from $t-1$ to $t$ ($|\psi_t\rangle = U_{t, t-1} |\psi_{t-1}\rangle$) and the cyclic condition $|N\rangle \equiv |0\rangle$, i.e. $U_{N, N-1} = U_N^\dagger$, is imposed. Then, 

$$U |\Psi\rangle = |\Psi\rangle$$

(5)

showing that the state has remained strictly invariant under such global translations in the $S + T$ space.

Eq. (5) holds for any choice of initial state $|\psi_0\rangle$ in $H$. The eigenvalue $1$ of $U$ then has a degeneracy equal to the Hilbert space dimension $M$ of $S$, for $M$ orthogonal initial states $|\psi_0\rangle, |\psi_0\rangle = d_{ij}$, the ensuing states $|\Psi\rangle$ are orthogonal due to Eq. (8):

$$\langle \Psi | \Psi \rangle = \frac{1}{N} \sum_{t=0}^{N-1} \langle \psi_t^i | \psi_t^j \rangle = \langle \psi_0^i | \psi_0^j \rangle = \delta_{ij}.$$  

(6)

The remaining eigenstates of $U$ are of the form $|\Psi_k\rangle = \frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} e^{i2\pi k t/N} |\psi_t\rangle |t\rangle$ with $k$ integer and represent the evolution associated with operators $U^k = e^{i2\pi k t/N} U_t$:

$$U |\Psi_k\rangle = e^{-i2\pi k/N} |\Psi_k\rangle, \quad k = 0, \ldots, N-1.$$  

(7)

All eigenvalues $\lambda_k = e^{-i2\pi k/N}$ are $M$-fold degenerate by the same previous arguments. The full set of $N$ eigenvalues and a choice of $M N$ orthogonal eigenvectors of $U$ are thus obtained. We may then write, for general $U$,

$$U = \exp[-iJ],$$

(8)

with $J$ hermitian and satisfying $J |\Psi_k\rangle = 2\pi k/N |\Psi_k\rangle$ for $k = 0, \ldots, N-1$. In particular, the states $|\Psi\rangle$ satisfy

$$J |\Psi\rangle = 0,$$

(9)

which represents a discrete counterpart of the Wheeler-DeWitt equation determining the state $|\Psi\rangle$ in continuous time theories. In the limit where $t$ becomes a continuous unrestricted variable, the state $|\Psi\rangle$ with condition becomes in fact that considered in [8]. Note, however, that here $J$ is actually defined just modulo $N$, as any $J$ satisfying $J |\Psi_k\rangle = 2\pi k/N |\Psi_k\rangle$ with $n_k$ integer will also fulfill Eq. (8).

All $|\Psi_k\rangle$ are also eigenstates of the hermitian operators $U_{\pm k} = iU^{-1} (U \pm U^\dagger)/2$, with eigenvalues $\cos \frac{2\pi k}{N}$ and $\sin \frac{2\pi k}{N}$ respectively, i.e. 1 and 0 for the states $|1\rangle$.

The latter can then be also obtained as ground states of $-U_t$. An hermitian operator $H$ similar to $-U_t$ but with no cyclic condition ($H = -\tilde{U}_t + I_S \otimes \tilde{T}_t$), with $\tilde{U} = U - U_{N-1}^\dagger \langle (N-1) | + i I_S \otimes (|0\rangle \langle 0| + |N-1\rangle \langle N-1|)$ was considered in [9] for deriving a variational approximation to the evolution.

### B. Constant evolution operator

If $U_{t, t-1} = U \forall t$, then

$$U_t = (U)^t = \exp[-iHt], \quad t = 0, \ldots, N-1,$$  

(10)

where $H$ represents a constant Hamiltonian for system $S$. In this case the state $|1\rangle$ can be generated with the first step of the circuit employed for phase estimation [11], depicted in Fig. 2. If $N = 2^n$, such circuit, consisting of just $n$ time qubits and $m = \log_2 M$ system qubits, requires only $n$ initial single qubit Hadamard gates on the time-qubits if initialized at $|0\rangle$ (such that $|0\rangle_T \equiv \otimes_{j=0}^{T-1} |0\rangle_j \rightarrow \otimes_{j=0}^{T-1} |0\rangle_j + |1\rangle_j \sqrt{2}^j = \frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} |t\rangle$ for $t = \sum_{j=1}^{n-1} t_j 2^{j-1}$), plus $n$ control $U_t^{2^j-1}$ gates acting on the system qubits, which perform the operation $U_t^j |\psi_0\rangle = \prod_{j=1}^{n} U_t^{2^j-1} |\psi_0\rangle$. A measurement of the time qubits with result $t$ makes $S$ collapse to the state $|\psi_t\rangle = e^{-iHt} |\psi_0\rangle$.

![Fig. 2](image_url)
for $k = 0, \ldots, N - 1$, such that $P$ is the “momentum” associated with the time operator $T$:

$$T|t\rangle = t|t\rangle, \quad P|\tilde{k}\rangle = 2\pi \frac{k}{N}|\tilde{k}\rangle. \quad (13)$$

Hence, $J = H \otimes 1_T + 1_S \otimes P$ adopts in this case the same form as that of continuous theories [9].

### C. System-Time entanglement

Suppose now that one wishes to quantify consistently the “amount” of distinguishable evolution of a pure quantum state. Such measure can be related to a minimum time $\tau_m$ (number or fraction of steps) necessarily elapsed by the system. If the state is stationary, $|\psi_t\rangle \propto |\psi_0\rangle \forall t$, the quantifier should vanish (and $\tau_m = 0$) whereas if all $N$ states $|\psi_0\rangle$ are orthogonal to each other, the quantifier should be maximum (with $\tau = N - 1$), indicating that the state has indeed evolved through $N$ distinguishable states. We now propose the entanglement of the pure state [1] (system-time entanglement) as such quantifier, with $\tau_m$ an increasing function of this entanglement. In Figs. 1–2 such entanglement is just that between the system and the time-qubits, generated by the control $U_t$.

We first note that Eq. (1) is not, in general, the quadratic entanglement. For instance, a periodic evolution of period $L < N$ with $N/L$ integer, such that $|\psi_{t+L}\rangle = e^{i\gamma}|\psi_t\rangle \forall t$, will lead to

$$|\Psi\rangle = \frac{1}{\sqrt{L}} \sum_{t=0}^{L-1} |\psi_t\rangle|t_L\rangle, \quad |t_L\rangle = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} e^{i\gamma k}|t + Lk\rangle, \quad (20)$$

which takes the values 0 and $N - 1$ for the previous extreme cases. The vast majority of evolutions will lie in between. For instance, a periodic evolution of period $L < N$ with $N/L$ integer, such that $|\psi_{t+L}\rangle = e^{i\gamma}|\psi_t\rangle \forall t$, will lead to

$$|\Psi\rangle = \frac{1}{\sqrt{L}} \sum_{t=0}^{L-1} |\psi_t\rangle|t_L\rangle, \quad |t_L\rangle = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} e^{i\gamma k}|t + Lk\rangle, \quad (20)$$

with $\langle t'_L|t_L\rangle = \delta_{t't}$. Hence, its entanglement $E(S,T)$ will be the same as that obtained with an $L$ dimensional effective clock, as it should. Its maximum value, obtained for $L$ orthogonal states, will then be $\log_2 L$, in which case $\tau_m = L - 1$.

The Schmidt decomposition [13] represents in this context the “actual” evolution between orthogonal states, with $p_k$ proportional to the “permanence time” in each of them. A measurement on $T$ in the Schmidt Basis would always identify orthogonal states of $S$ for different results (vice versa), with the probability distribution of results indicating the “permanence” in these states. In particular, the maximum value of $\tau_m$ is always obtained when the state $|t_L\rangle$ is maximum. If $S$ and $T$ are qubits, then $|t_L\rangle$ is just the squared concurrence [15] of $|\Psi\rangle$.

$$E(S,T) = S(p_S) = S(p_T) = -\sum_k p_k \log_2 p_k \quad (16)$$

where $S(\rho) = -\text{Tr} \rho \log_2 \rho$ is the von Neumann entropy.

Eq. (16) satisfies the basic requirements of an evolution quantifier. If the state of $S$ is stationary, $|\psi_t\rangle = e^{i\gamma t}|\psi_0\rangle \forall t$, the state [11] becomes separable,

$$|\Psi\rangle = |\psi_0\rangle \left(\frac{1}{\sqrt{N}} \sum_t e^{i\gamma t}|t\rangle\right), \quad (17)$$

implying $E(S,T) = 0$. In contrast, if $|\psi_t\rangle$ evolves through $N$ orthogonal states, then $|\Psi\rangle$ is maximally entangled, with Eq. (11) already its Schmidt decomposition and

$$E(S,T) = E_{\text{max}}(S,T) = \log_2 N. \quad (18)$$

It is then natural to define the minimum time $\tau_m$ as

$$\tau_m = 2^{E(S,T)} - 1, \quad (19)$$

which takes the values 0 and $N - 1$ for the previous extreme cases. The vast majority of evolutions will lie in between. For instance, a periodic evolution of period $L < N$ with $N/L$ integer, such that $|\psi_{t+L}\rangle = e^{i\gamma}|\psi_t\rangle \forall t$, will lead to

$$|\Psi\rangle = \frac{1}{\sqrt{L}} \sum_{t=0}^{L-1} |\psi_t\rangle|t_L\rangle, \quad |t_L\rangle = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} e^{i\gamma k}|t + Lk\rangle, \quad (20)$$

with $\langle t'_L|t_L\rangle = \delta_{t't}$. Hence, its entanglement $E(S,T)$ will be the same as that obtained with an $L$ dimensional effective clock, as it should. Its maximum value, obtained for $L$ orthogonal states, will then be $\log_2 L$, in which case $\tau_m = L - 1$.

The Schmidt decomposition [13] represents in this context the “actual” evolution between orthogonal states, with $p_k$ proportional to the “permanence time” in each of them. A measurement on $T$ in the Schmidt Basis would always identify orthogonal states of $S$ for different results (vice versa), with the probability distribution of results indicating the “permanence” in these states. In particular, the maximum value of $\tau_m$ is always obtained when the state $|t_L\rangle$ is maximum. If $S$ and $T$ are qubits, then $|t_L\rangle$ is just the squared concurrence [15] of $|\Psi\rangle$.

$$E(S,T) = S(p_S) = S(p_T) = -\sum_k p_k \log_2 p_k \quad (16)$$

where $S(\rho) = -\text{Tr} \rho \log_2 \rho$ is the von Neumann entropy.

Eq. (16) satisfies the basic requirements of an evolution quantifier. If the state of $S$ is stationary, $|\psi_t\rangle = e^{i\gamma t}|\psi_0\rangle \forall t$, the state [11] becomes separable,

$$|\Psi\rangle = |\psi_0\rangle \left(\frac{1}{\sqrt{N}} \sum_t e^{i\gamma t}|t\rangle\right), \quad (17)$$

implying $E(S,T) = 0$. In contrast, if $|\psi_t\rangle$ evolves through $N$ orthogonal states, then $|\Psi\rangle$ is maximally entangled, with Eq. (11) already its Schmidt decomposition and

$$E(S,T) = E_{\text{max}}(S,T) = \log_2 N. \quad (18)$$

It is then natural to define the minimum time $\tau_m$ as

$$\tau_m = 2^{E(S,T)} - 1, \quad (19)$$

D. Relation with energy spread

In the constant case (10), we may expand $|\psi_t\rangle$ in the eigenstates of $U$ or $H$, $|\psi_t\rangle = \sum_k c_k |k\rangle$ with $H|k\rangle = E_k |k\rangle$, such that $|\psi_t\rangle = \sum_k c_k e^{-iE_k t}|k\rangle$ and

$$|\Psi\rangle = \frac{1}{\sqrt{N}} \sum_k c_k e^{-iE_k t}|k\rangle|t\rangle = \sum_k c_k |k\rangle|\tilde{k}\rangle T, \quad (22)$$
with \(|\tilde{k}\rangle_T = \frac{1}{\sqrt{N}} \sum_j e^{-iE_k t} |j\rangle\). We can always assume all \(E_k\) distinct in (22) such that \(c_k |k\rangle\) is the projection of \(|\psi_0\rangle\) onto the eigenspace with energy \(E_k\). In the cyclic case \(U^N = 1\), with \(E_k = 2\pi k/N\), \(k = 0, \ldots, N-1\), the states \(|\tilde{k}\rangle_T\) become the orthogonal FT states (12) \(|k\rangle_T = |\tilde{k}\rangle\). Eq. (22) is then the Schmidt decomposition (14), with \(p_k = |c_k|^2\) and

\[
E(S,T) = -\sum_k |c_k|^2 \log_2 |c_k|^2.
\]

For this spectrum, entanglement becomes then a measure of the spread of the initial state \(|\psi_0\rangle\) over the eigenstates of \(H\) with distinct energies. The same holds in the quadratic case (21) where \(E_2(E,T) = 2 \sum_k |c_k|^2 (1-|c_k|^2)\). If there is no dispersion \(|\psi_0\rangle\) is stationary and entanglement vanishes while if \(|\psi_0\rangle\) is uniformly spread over \(N\) eigenstates it is maximum \((E(S,T) = \log_2 N)\).

While Eq. (23) also holds for a displaced spectrum \(E_k = E_0 + 2\pi k/N\), for an arbitrary spectrum \(\{E_k\}\) it will hold approximately if the overlaps \(\tau(|\tilde{k}\rangle_T |\tilde{k}'\rangle_T) = \frac{1}{N} \sum_j e^{-i(E_k-E_{k'}) t}\) are sufficiently small for \(k \neq k'\). In general we actually have the strict bound

\[
E(S,T) \leq -\sum_k |c_k|^2 \log_2 |c_k|^2,
\]

since \(|c_k|^2 = \sum_{k'} p_{k'} (|k\rangle_S |k\rangle_S)^\dagger\) with \(|k\rangle\) the eigenstates of \(H\) and \(|k\rangle_S\) the Schmidt states in (14), which implies that the \(|c_k|^2\)'s are majorized (19) by the \(p_k\)'s,

\[
\{ |c_k|^2 \} \preceq \{ p_k \},
\]

where \(\{ |c_k|^2 \} \) and \(\{ p_k \} \) denote the sets sorted in decreasing order. Eq. (23) (meaning \(\sum_{k=1}^{N} |c_k|^2 \leq \sum_{k=1}^{N} p_k \) for \(j = 1, \ldots, N-1\)) implies that the inequality (24) actually holds for any Schur-concave function of the probabilities (19), in particular for any entropic form \(S_f(\rho) = \text{Tr} f(\rho)\) with \(f(\rho)\) concave and satisfying \(f(0) = f(1) = 0\) (11,20), such as the von Neumann entropy \((f(\rho) = -\rho \log_2 \rho)\) and the previous \(S_2\) entropy \((f(\rho) = 2\rho(1-\rho))\):

\[
E_f(S,T) = \sum_k f(p_k) \leq \sum_k f(|c_k|^2),
\]

as can be easily verified. Eqs. (24)–(26) then indicate that the entropy of the spread over Hamiltonian eigenstates of the initial state provides an upper bound to the corresponding system-time entanglement entropy than can be generated by any Hamiltonian diagonal in the states \(|\tilde{k}\rangle\). The bound is always reached for an equally spaced spectrum \(E_k = 2\pi k/N \in [0, 2\pi]\) leading to a cyclic evolution, which therefore generates the highest possible system-time entanglement for a given initial spread \(\{|c_k|^2\}\).

E. Energy-time uncertainty relations

For the aforementioned equally spaced spectrum, we may also expand the state \(|\psi_0\rangle\) of \(S\) in an orthogonal set of uniformly spread states,

\[
|\psi_0\rangle = \sum_{l=0}^{N} \tilde{c}_l |\tilde{l}\rangle_S, \quad |\tilde{l}\rangle_S = \frac{1}{\sqrt{N}} \sum_k e^{-i2\pi kl/N} |k\rangle,
\]

with \(\tilde{c}_l = \frac{1}{\sqrt{N}} \sum_k e^{-i2\pi kl/N} c_k\) the FT of the \(c_k\)'s in (22).

Since \(U^T |\tilde{l}\rangle_S = |l - t\rangle_S\), it is verified that these maximally spread states \(|\tilde{l}\rangle_S\) (which according to Eq. (28) lead to maximum system-time entanglement \(E(S,T) = \log_2 N\)) indeed evolve through \(N\) orthogonal states \(|l - t\rangle_S\). Moreover, Eq. (22) becomes

\[
|\Psi\rangle = \sum_{l,t} \tilde{c}_l |l - t\rangle_S |t\rangle = \sum_l |\tilde{l}\rangle_S (\sum_t \tilde{c}_l |t - l\rangle),
\]

showing that \(\tilde{c}_l\) determines the distribution of time states \(|t\rangle\) assigned to each state \(|\tilde{l}\rangle_S\), i.e., the uncertainty in its time location. Being related through a finite FT, \(\{c_k\}\) and \(\{\tilde{c}_l\}\) satisfy various uncertainty relations, such as (21–23)

\[
E(S,T) + \tilde{E}(S,T) \geq \log_2 N,
\]

where \(\tilde{E}(S,T) = -\sum |\tilde{c}_l|^2 \log_2 |\tilde{c}_l|^2\) is the entropy characterizing the time uncertainty and \(E(S,T)\) the energy uncertainty (23). If localized in energy \((|c_k\rangle = \delta_{kk'}, E(S,T) = 0)\), Eq. (29) implies maximum time uncertainty \((|\tilde{c}_l\rangle = \frac{1}{\sqrt{N}}, \tilde{E}(S,T) = \log_2 N)\) and vice versa. We also have \(n(|c_k\rangle) n(|\tilde{c}_l\rangle) = \frac{N}{2} \) in (24), where \(n(|c_k\rangle)\) denotes the number of non-zero \(c_k\)’s. Bounds for the product of variances in the discrete FT are discussed in (23).

F. Mixed states

Let us now consider that \(S\) is a bipartite system \(A + B\). By taking the partial trace of (11),

\[
\rho_{BT} = \text{Tr}_A |\Psi\rangle \langle \Psi| = \sum_j A(j |\Psi\rangle \langle |\Psi| j) A, \quad (30)
\]

we see that the system-time state for a subsystem is a mixed state. Of course, the state of \(B\) at time \(t\), setting now \(\Pi_t = I_B \otimes |t\rangle \langle t|\), is given by the standard expression

\[
\rho_{Bt} = \frac{\text{Tr}_T \rho_{BT} \Pi_t}{\text{Tr}_T \rho_{BT} \Pi_T} = \text{Tr}_A |\psi_i\rangle \langle \psi_i|, \quad (31)
\]

If the initial state of \(S\) is \(|\psi_0\rangle = \sum_j \sqrt{q_j} |j\rangle \rangle_A B\) (Schmidt decomposition). Eqs. (30)–(31) determine the evolution of an initial mixed state \(\rho_{BB} = \sum_j q_j |j\rangle \rangle_B\) of \(B\), considered as a subsystem in a purified state undergoing unitary evolution. For instance, if just subsystem \(B\) evolves, such that \(U_t = I_A \otimes U_{Bt} \forall t\), Eq. (31) leads to

\[
\rho_{BT} = \sum_j q_j |\psi_j\rangle \rangle_B \langle \psi_j|, \quad (32)
\]

where \(|\psi_j\rangle \rangle_B = \frac{1}{\sqrt{N}} \sum_{t=0}^{N-1} U_{Bt} |j\rangle \rangle_B\). Eq. (31) is then the mixture of the pure \(B + T\) states associated with
each eigenstate of $\rho_{B0}$, and implies the unitary evolution $\rho_{BT} = U_{BT} \rho_{B0} U_{BT}^\dagger$.

Since the state (30) is in general mixed, the correlations between $T$ and a subsystem $B$ can be more complex than those with the whole system $S$. The state (30) can in principle exhibit distinct types of correlations, including entanglement [26–27], discord-like correlations [28–31] and classical-type correlations. The exact evaluation of the quantum correlations is also more difficult, being in general a hard problem [32,33]. We will here consider just the entanglement of formation [27] $E(B,T)$ of the state (30), which, if nonzero, indicates that (30) cannot be written as a convex mixture of pure product states [26] $\langle \Psi_\alpha \rangle_{B,T} = |\psi_\alpha \rangle_B \phi_\alpha \rangle_T$. In this context the latter represent essentially stationary states. Separability with time would then indicate that $\rho_{BT}$ can be written as a convex mixture of such states, requiring no quantum interaction with the clock system for its formation.

III. EXAMPLES

A. The qubit clock

As illustration we examine the basic case of a qubit clock ($N = 2$). Eq. (10) becomes

$$|\Psi\rangle = (|\psi_0\rangle|0\rangle + |\psi_1\rangle|1\rangle)/\sqrt{2} = \sqrt{p_\uparrow} |\uparrow\rangle + \sqrt{1 - p_\uparrow} |\downarrow\rangle,$$

where $|\psi_1\rangle = U|\psi_0\rangle$ and (33) is its Schmidt decomposition, with $|\pm\rangle_S = (|\psi_0\rangle \pm e^{-i\gamma}|\psi_1\rangle)/\sqrt{4p_\uparrow}$, $|\pm\rangle_T = (|0\rangle \pm e^{i\gamma}|1\rangle)/\sqrt{2}$ and $e^{i\gamma} = \langle \psi_0 |\psi_1 \rangle$. Hence, $E(S,T) = -\sum_{p=\pm} p \log p$ will be fully determined by the overlap or fidelity $|\langle \psi_0 |\psi_1 \rangle|$ between the initial and final states, decreasing as the fidelity increases and becoming maximum for orthogonal states. The quadratic entanglement entropy $E_2(S,T)$ becomes just

$$E_2(S,T) = 4p_\uparrow p_\downarrow = 1 - |\langle \psi_0 |\psi_1 \rangle|^2.$$

These results hold for arbitrary dimension $M$ of $S$.

The operator (11) becomes $U = U \otimes |1\rangle \langle 0| + U^\dagger \otimes |1\rangle \langle 0|$, and is directly hermitian, with eigenvalues $e^{i2\kappa \pi/2} = \pm 1$ for $k = 0$ or 1, $M$-fold degenerate. Hence, in this case

$$\mathcal{J} = \pi(U - 1)/2,$$

involving coupling between $S$ and $T$ unless $U^\dagger \propto U$.

For $|\psi_1\rangle$ close to $|\psi_0\rangle$, Eq. (33) becomes proportional to the Friedberg-Study metric [34]. If $U = \exp[-i\mathcal{J}]$, an expansion of $|\psi_0\rangle$ in the eigenstates of $h$, $|\psi_0\rangle = \sum_k c_k |k\rangle$ with $h|k\rangle = \varepsilon_k |k\rangle$, leads to

$$E_2(S,T) = 1 - \sum_k |c_k|^2 e^{-i\varepsilon_k} \approx e^2(|\langle h^2 \rangle - \langle h \rangle^2|),$$

where the last expression holds up to $O(\varepsilon^2)$. Hence, for a “small” evolution the system-time entanglement of a single step is determined by the energy fluctuation $\langle \hbar^2 \rangle - \langle \hbar \rangle^2$ in $|\psi_0\rangle$ ($\langle O \rangle \equiv \langle \psi_0 |O|\psi_0 \rangle$), with $E_2(S,T)$ directly proportional to it. For instance, if $S$ is a single qubit and $\varepsilon_1 - \varepsilon_0 = \varepsilon$, the exact expression becomes

$$E_2(S,T) = 4 \sin^2 \left(\frac{\varepsilon}{2}\right) |c_0|^2 |c_1|^2$$

$$= 4 \sin^2 \left(\frac{\varepsilon}{2}\right) \frac{(\langle h^2 \rangle - \langle h \rangle^2)}{\varepsilon^2},$$

which reduces to (30) for small $\varepsilon$. It is also verified that $E_2(S,T) \leq S_2(|c_0|^2,|c_1|^2) = 4 |c_0|^2 |c_1|^2$, i.e., it is upper bounded by the quadratic entropy of the energy spread (Eq. (29)), reaching the bound for $E = \varepsilon = \pi$, in agreement with the general result (23) [24]. Returning to the case of a general $S$, we also note that $E_2(S,T)$ determines the minimum time required for the evolution from $|\psi_0\rangle$ to $|\psi_1\rangle$ in standard continuous time theories [35], which depends on the fidelity $|\langle \psi_0 |\psi_1 \rangle|$ and can then be expressed in terms of $E_2$ as $h^{-1}(\sqrt{E_2(S,T)}) \sqrt{\langle h^2 \rangle - \langle h \rangle^2}$.

Let us now assume that $S = A + B$ is a two-qubit system, with $U = I_4 \otimes U_B$. As previously stated, starting from an initial entangled pure state of $A+B$ (purification of $\rho_{B0}$), the state (30) will determine the evolution of the reduced state of $B$, leading to

$$\rho_{BT} = p|\psi_0^0\rangle\langle\psi_0^1| + q|\psi_1^1\rangle\langle\psi_1^0|, \quad t = 0, 1$$

where $p + q = 1$, $\langle \psi_0^0 |\psi_0^1 \rangle = 0$ and $\langle \psi_1^1 |\psi_1^0 \rangle = 0$. The reduced state (32) of $B + T$ becomes

$$\rho_{BT} = p|\psi_0^0\rangle\langle\psi_0^1| + q|\psi_1^1\rangle\langle\psi_1^0|,$$

with $|\psi_j^j\rangle = \frac{1}{\sqrt{2}}(|\psi_0^0\rangle + |\psi_1^1\rangle)$. Since (40) is a two-qubit mixed state, its entanglement of formation can be obtained through the concurrence [18] $C(B,T)$, whose square is just the entanglement monotone associated with the quadratic entanglement entropy $E_2(2(B,T) = E_2(B,T)$ for a pure $B + T$ state). It adopts here the simple expression

$$C^2(B,T) = (p - q)^2(1 - |\langle \psi_0^0 |\psi_1^1 \rangle|^2),$$

where $|\langle \psi_0^0 |\psi_1^1 \rangle| = |\psi_0^1 |U_B|\psi_0^1 \rangle$ is the same for $j = 0$ or 1 in a qubit system if $|\psi_0^0 |\psi_0^1 \rangle = 0$. Eq. (41) is then the pure state result (34) for any of the eigenstates of $\rho_{B0}$ diminished by the factor $(p - q)^2$, vanishing if $\rho_{B0}$ is maximally mixed ($p = q$). Remarkably, Eq. (41) can be also written as

$$C^2(B,T) = 1 - F^2(\rho_{B0}, \rho_{B1}),$$

where $F(\rho_{B0}, \rho_{B1}) = \text{Tr} \sqrt{(1/2) \rho_{B0} \rho_{B1}}^{1/2}$ is again the fidelity between the initial and final reduced mixed states of $B$ ($F = |\langle \psi_0 |\psi_1 \rangle|$ if $\rho_{B0}, \rho_{B1}$ are pure states). Note also that the total quadratic entanglement entropy is here

$$E_2(S,T) = 1 - |p|\psi_0^1 |\psi_0^0 \rangle + q|\psi_1^1 |\psi_0^0 \rangle|^2,$$

satisfying $E_2(S,T) \geq C^2(B,T)$ in agreement with the monogamy inequalities [14,35], coinciding if $pq = 0$ (pure case).
B. The continuous limit

Let us now assume that system $S$ is a qubit, with $T$ of dimension $N$ ($t = 0, \ldots, N - 1$). This case can also represent the evolution from an initial state $|\psi_0\rangle$ to an arbitrary final state $|\psi_f\rangle$ in a general system $S$ of Hilbert space dimension $M$ if all intermediate states $|\psi_t\rangle$ belong to the subspace generated by $|\psi_0\rangle$ and $|\psi_f\rangle$, such that the whole evolution is contained in a two-dimensional subspace of $S$. Writing the system states as

$$|\psi_t\rangle = \alpha_t|0\rangle + \beta_t|1\rangle, \quad t = 0, \ldots, N - 1,$$

with $\langle 0 | 1 \rangle = 0$ and $|\alpha_t|^2 + |\beta_t|^2 = 1$, we may rewrite state (11) as

$$|\Psi\rangle = \frac{1}{\sqrt{N}} [|0\rangle (\sum_t \alpha_t|t\rangle) + |1\rangle (\sum_t \beta_t|t\rangle)]$$

$$= \alpha_0|\phi_0\rangle + \beta_1|\phi_1\rangle,$$

where $|\phi_0\rangle = \frac{1}{\sqrt{\sum_t |\alpha_t|^2}} \sum_t \alpha_t|t\rangle$, $|\phi_1\rangle = \frac{1}{\sqrt{\sum_t |\beta_t|^2}} \sum_t \beta_t|t\rangle$, are normalized (but not necessarily orthogonal) states of $T$ and all sums over $t$ are from 0 to $N - 1$, with

$$\alpha^2 = \frac{1}{N} \sum_t |\alpha_t|^2, \quad \beta^2 = \frac{1}{N} \sum_t |\beta_t|^2 = 1 - \alpha^2.$$  

(45)

The Schmidt coefficients of the state (14) are given by

$$p_{\pm} = \frac{1}{2} \left(1 \pm \sqrt{1 - 4\alpha^2\beta^2(1 - |\langle \phi_1 | \phi_0 \rangle|^2)}\right).$$

(46)

We then obtain

$$E_2(S, T) = 4p_+p_- = 4\alpha^2\beta^2(1 - |\langle \phi_1 | \phi_0 \rangle|^2)$$

$$= 4(\alpha^2\beta^2 - \gamma^2), \quad \gamma = \frac{1}{N} \sum_t \beta^*_t \alpha_t,$$

(47)

a result which also follows directly from Eq. (21).

Let us consider, for instance, the states

$$|\psi_t\rangle = \cos \left( \frac{\phi t}{N - 1} \right) |0\rangle + \sin \left( \frac{\phi t}{N - 1} \right) |1\rangle,$$

(48)

such that $S$ evolves from $|\psi_0\rangle = |0\rangle$ to

$$|\psi_T\rangle = \cos \phi |0\rangle + \sin \phi |1\rangle,$$

in $N - 1$ steps through intermediate equally spaced states contained within the same plane in the Bloch sphere of $S$. The $S - T$ entanglement of this $N$-time evolution can be evaluated exactly with Eqs. (15) - (17), which yield

$$E_2(S, T_N) = 1 - \frac{\sin^2 \left( \frac{N\phi}{N - 1} \right)}{N^2 \sin^2 \left( \frac{\phi}{N - 1} \right)}.$$  

(49)

For $N = 2$ (single step) we recover Eq. (21) $(E_2(S, T_2) = 1 - \cos^2 \phi = 1 - |\langle \psi_1 | \psi_f \rangle|^2)$. If $\phi \in [0, \pi/2]$, $E_2(S, T_N)$ is a decreasing function of $N$ (and an increasing function of $\phi$), but rapidly saturates, approaching a finite limit for $N \to \infty$, namely,

$$E_2(S, T_\infty) = 1 - \frac{\sin^2 \phi}{\phi^2}.$$  

(50)

Therefore, system-time entanglement decreases as the number of steps through intermediate states between $|\psi_0\rangle$ and $|\psi_f\rangle$ is increased, reflecting the lower average distinguishability between the evolved states, but remains finite for $N \to \infty$. In this limit it is still an increasing function of $\phi$ for $\phi \in [0, \pi/2]$, reaching $1 - 4/\pi^2 \approx 0.59$ for $\phi = \pi/2$, i.e., when the system evolves to an orthogonal state $|\langle \psi_f | = 1\rangle$, and reducing to $\approx \phi^2/3$ for $\phi \to 0$. Hence, as compared with a single step evolution $(N = 2)$, the ratio $E_2(S, T_\infty)/E_2(S, T_2)$ increases from 1/3 for $\phi \to 0$ to $\approx 0.59$ for $\phi \to \pi/2$.

If $\phi$ is increased beyond $\pi/2$, the coefficients $\alpha_t, \beta_t$ cease to be all positive and entanglement can increase beyond $\approx 0.59$ due to the decreased overlap $\gamma$, reflecting higher average distinguishability between evolved states. Entanglement $E_2(S, T_\infty)$ reaches in fact 1 at $\phi = \pi$ (and also $k\pi, k \geq 1$ integer), i.e., when the final state is proportional to the initial state after having covered the whole circle in the Bloch sphere, since for these values the time states $|\phi_0\rangle$ and $|\phi_1\rangle$ become orthogonal and with equal weights. Note also that for $\phi > \pi/2$, $E_2(S, T_N)$ is not necessarily a decreasing function of $N$, nor an increasing function of $\phi$, exhibiting oscillations: $E_2(S, T_N) = 1$ for $\phi = k\pi(N - 1)/N, k \neq lN$, and $E_2(S, T_N) \to 0$ for $\phi \to l\pi(N - 1), l$ integer.

IV. CONCLUSIONS

We proposed a parallel-in-time discrete model of quantum evolution based on a finite dimensional clock entangled with the system. The ensuing history state satisfies a discrete Wheeler-DeWitt-like equation and can be generated through a simple circuit, which for a constant evolution operator can be efficiently implemented with just $O(n)$ qubits and control gates for $2^n$ time intervals.

We then showed that the system-clock entanglement $E(S, T)$ is a measure of the actual distinguishable evolution undergone by one of the systems relative to the other. A natural interpretation of the Schmidt decomposition in terms of permanence in distinguishable evolved states is also obtained. For a constant Hamiltonian leading to a cyclic evolution, this entanglement is a measure of the energy spread of the initial state and satisfies an entropic uncertainty inequality with a conjugated entropy which measures the time spread. Such Hamiltonian was rigorously shown to provide the maximum entanglement $E(S, T)$ compatible with a given distribution over Hamiltonian eigenstates. For other Hamiltonians, $E(S, T)$ (and also general entanglement entropies $E_f(S, T)$) are strictly bounded by the corresponding entropy of this distribution. We have also considered the evolution of mixed
states. Although in this case the evaluation and interpretation of system-clock entanglement and correlations become more involved, in the simple yet fundamental case of a qubit clock coupled with a qubit subsystem, such entanglement was seen to be directly determined by the fidelity between the initial and final states of the qubit. A direct relation between this entanglement and energy fluctuation was also derived for the pure case. Finally, we have also shown that $E(S,T)$ does remain finite and non-zero in the continuous limit, i.e., when the system evolves from an initial to a final state through an arbitrarily large number of closely lying equally spaced intermediate states.

The present work opens the way to various further developments, starting from the definition of proper time basis according to the Schmidt decomposition. It could be also possible in principle to incorporate other effects such as interaction between clocks [7], explore possiblities of an emergent space-time or a qubit model for quantum time crystals [36]. At the very least, it provides a change of perspective, allowing to identify a qubit clock as a fundamental “building block” of a discrete-time based quantum evolution.
